
*Symptoms:* Fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis.

*Treatment:* Aspiration, drainage, irrigation, resection of ribs (Estlander's operation), or resection of chest wall (Schede's operation). Operation of some sort is the only treatment.

8. *Prostatic hypertrophy is characterized by:* Slowness in starting urination; difficult micturition; frequency of micturition, particularly at night; the presence of residual urine; dull, aching pain in the perineum and above the pubes; enlargement of the lateral lobes of the prostate; there may be cystitis and retention of urine. The *cause:* It is a senile change, and may be due to increase of the glandular substance or of the interstitial fibrous or muscular tissue.

"If the patient is intelligent and dextrous, if cystitis is not severe, if the amount of residual urine is not very large, if obstruction is not great, if the bladder retains considerable expulsive power, and if catheterization is easy and painless, we are justified in relying upon this simple plan of treatment."—(Alexander). Otherwise, operation is indicated.

9. Every case should be submitted to operation as soon as obstruction is proved or is even probable. The prospects of success depend largely upon the early period at which the operation is undertaken.

10. *Shock* is the name given to a sudden and general depression of the vital powers, due to some strong

stimulation (such as injury or emotion), acting on the vital centers in the medulla and producing vasomotor paralysis. Shock is *primary* when the symptoms appear promptly; it is *secondary* when the symptoms don't appear for several hours (often observed after railway accidents, intoxication, etc.)

"The explanation of shock usually accepted, largely on the authority of Crile and Mummery, is that the paralysis or exhaustion of the vasomotor center in the medulla results in a lessening of the vascular tone, particularly that of the arteries, and a marked fall in the blood pressure. Most of the blood leaves the arteries and collects in the large venous trunks, especially those of the abdomen, and there is thus produced an anemia of the brain and of the superficial parts of the body. At the same time the right side of the heart becomes overloaded and impeded in its action. According to J. D. Malcolm the disturbance of the vasomotor center results, not in dilatation, but in contraction of the arteries. At first the superficial vessels are constricted, and if the exciting cause is kept up this condition spreads back to the larger vessels, so that the blood is driven out into the tissues and back into the abdominal veins."

"*Prevention of Operation Shock.*—In the preparation of a patient for operation, drastic purgation and prolonged fasting must be avoided, and about half an hour before a prolonged and severe operation a pint of saline solution should be slowly introduced into the rectum; and this is repeated, if necessary, during the operation, and at its conclusion. The operating-room must be warm—not less than 70° F.—and the patient should be wrapped in cotton wool and blankets and surrounded by hot bottles. All lotions used must be warm (100° F.); and the operation should be completed as speedily and as bloodlessly as possible. With a view to preventing the passage of exciting afferent impulses, Crile advocates "blocking" of the nerves by the injection of a 1 per cent. solution of eucaine into their substance on the proximal side of the field of operation. In selecting an anesthetic it may be borne in mind that chloroform lowers the blood pressure more than ether does, and that with spinal anesthesia there is no lowering of the blood pressure." (Thomson and Miles' *Surgery.*)

OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

1. MARGINAL BLEPHARITIS. *Symptoms:* The margins of the lids are red and swollen, the lashes fall out readily but others grow, there may be yellowish crusts which glue the lashes together, and later on the lashes fall out and are not replaced by others; itching, soreness, photophobia and epiphora are present.

*Etiology:* Poor hygienic surroundings, a run-down condition of health, errors of refraction, exanthematous diseases, dust, smoke, wind, conjunctivitis.

2. IRITIS. *Causes:* Syphilis, rheumatism, gonorrhea, gout, diabetes, leprosy, scrofula, tuberculosis, injury, transmission from the eye. *Symptoms:* Pain, photophobia, small pupil, ciliary congestion, discoloration of iris, exudate in anterior chamber.

*Complications:* Involvement of conjunctiva, cornea, or some other part of the eye, inflammation of the ciliary body is common, diminution in vision, and varied ocular tension.

3.

| CONJUNCTIVITIS. | IRITIS. |
|---|---|
| 1. No change in iris. | 1. Discolored, swollen and dull iris. |
| 2. Pupil normal. | 2. Pupil small, gray, sluggish, irregular after use of atropine. |
| 3. Anterior chamber normal. | 3. Exudation in anterior chamber. |
| 4. Conjunctival injection, coarse meshes, most pronounced in fornix and fading toward the cornea. | 4. Ciliary (circumcorneal) injection; pink zone of fine vessels surrounding cornea and fading toward fornix. |
| 5. Mucous or mucopurulent secretion. | 5. Lacrymation, but no secretion. |
| 6. Discomfort, but no real pain. | 6. Pain, worse at night. |
| 7. Conjunctiva reddened and opaque. | 7. Conjunctiva usually transparent. |
| 8. No interference with vision. | 8. Vision diminished in acuteness. |

—(May's *Diseases of the Eye.*)

4. *Dacryocystis* is an inflammation of the mucous lining of the lacrymal sac; it is due to stricture of the nasal duct. The patient complains of epiphora, and conjunctivitis and blepharitis are commonly present. Pressure over the lacrymal sac causes fluid to appear through the puncta. The condition is treated by passing probes into the nasal duct, or by slitting the canaliculus and cutting the stricture in the nasal duct.

5. *Valsalva's method of inflating the middle ear:* "The patient closes both nostrils by grasping the nose with the thumb and forefinger of one hand, shuts the mouth firmly, and then makes a strong expiratory effort. In this way he compresses the air in the pharyngeal and nasal cavities to such an extent that it seeks an outlet through the Eustachian tubes. If the effort is successful, the physician, who has previously established a communication between his own ear and that of the patient, by means of a flexible auscultation tube, will hear a slight puff or thud, as the air enters the middle ear and distends the drum-membrane."

*Politzer's method of inflating the middle ear:* "The patient is told to take a little water into his mouth and to hold it there, with closed lips, until the physician says, Swallow. At this signal he should forthwith swallow the water. The physician, on his part, is to hold the Politzer bag in his right hand, and then, as soon as the patient has taken the water into his mouth, he is to introduce the nose-piece into the patient's left nostril, using, if necessary, the left hand to aid him in accomplishing this. When the nose-piece of the instrument is in its proper position on the floor of the nasal passage, the physician should at once compress the nostrils over the rubber nose-piece, and give the patient the signal to swallow. The act of compressing the bag and forcing air into the nasal cavities should follow the signal almost instantly—that is, at the precise moment when, in the act of swallowing, the thyroid cartilage makes an upward movement."—(Buck's *Otology.*)

6. In fracture of the base of the skull, blood, cerebrospinal fluid, or brain substance may escape from the ear.

7. Tonsillitis may be complicated with partial deafness, inflammation, or infection of the ear.

8. "The *causes of edma of the glottis* are: acute laryngitis; chronic diseases, such as tuberculosis, malignant disease, or syphilis; inflammatory disorders, such as diphtheria and erysipelas; acute infectious diseases; Bright's disease; aneurysm; whooping-cough; pneumonia; quinsy; wounds of the larynx; wounds of the neck; scalds and burns of the larynx, and the inhalation of irritating vapors, such as those of ammonia and sulphur. The *symptoms* are sudden and rapidly increasing dyspnea, respiratory stridor, huskiness of the voice, and finally aphonia. The swollen epiglottis may be felt with the finger and may be seen with the help of a mirror."—(Da Costa's *Modern Surgery.*)

9. *Tuberculosis of the larynx* is due to the tubercle bacillus; it is generally secondary to pulmonary tuberculosis, and chronic laryngitis is believed to be a predisposing factor.

*Differential diagnosis* is shown in the table on the following page (from the *Reference Handbook of the Medical Sciences*).

10. *Instruments used in intubation* are: An introducing instrument, an extracting instrument, a set of tubes of various sizes, a mouth-gag, and a finger stall. *Indications* are: Diphtheria, and any condition in which there is serious obstruction to respiration, such as stenosis, tumors, foreign bodies, and edema of the glottis.

HYGIENE, MEDICAL JURISPRUDENCE, MENTAL AND NERVOUS DISEASES.

1. *Incubation period* of *scarlet fever* is about one day to three weeks; of *mumps* is about two to three weeks; of *measles* is about ten to twelve days.

2. *Uncinariasis* is hookworm disease, due to ingestion of the eggs of the hookworm. Prophylaxis consists in the use of proper toilet facilities and the wearing of shoes; flies should be excluded.

3. An *occupation-disease* is a disease which is directly traceable to the effects of a particular trade in which a person is engaged. Caisson disease, writer's cramp, miner's nystagmus, and plumbism are occupational diseases. They can be prevented by a careful study of the etiological factors in each case, followed by removal or lessening of the harmful features.

4. *Herpes zoster* is characterized by the formation of groups of vesicles along the line of a cutaneous nerve (such as an intercostal nerve), and accompanied by

| TUBERCULOSIS. | SYPHILIS. | CARCINOMA. | LUPUS. |
|---|---|---|---|
| Pain severe on deglutition.... | Pain usually slight..... | Paint constant, lancinating... | No pain. |
| Favorite site in the interarytenoid space, and base of arytenoid cartilages. | Attacks any portion of the larynx ..... | Attacks any portion of the larynx ..... | Attacks epiglottis. |
| Ulcerates slowly ..... | Ulcerates rapidly ..... | Ulcerates more slowly than syphilis. | Ulcerates very slowly. |
| Usually first appears as small spots or nodules which are rapidly followed by great edema. | Is rarely seen in stage of induration, the first evidence being a clear-cut, deep ulcer. | First appearance is that of a new growth occupying laryngeal cavity; no clear-cut ulcer. | Nodular mass. |
| Great edema of arytenoids... | Some induration around ulcer, but usually very little edema. | The growth fills or encroaches upon the laryngeal cavity. | Little or no edema. |
| Ulcers extend laterally but not deeply. | Ulcers extend deeply, often involving cartilage. | Growth extends in all directions, involving all tissue in its course. | Very slow in progress. Ulcers rarely observed. |
| Surface of ulcer covered with thick mucopurulent secretion and agglutinated mucus. | Surface of ulcer covered with mucopurulent secretion and necrosed tissue. | Surface of growth covered with discharge. | Little or no discharge. |
| Mucous membrane usually pale | Mucous membrane hyperemic, injected. | Mucous membrane hyperemic. | Mucous membrane injected. |
| Laryngeal stenosis rarely occurs ..... | Laryngeal stenosis uncommon until cicatrization occurs. | Laryngeal stenosis common... | Slight stenosis. |
| Health impaired previous to laryngeal involvement. | General health unimpaired.... | Early in disease no impairment of general health. Later, marked cachexia. | Very little impairment of general health. |
| Previous or coincident pulmonary trouble common. | Frequently evidence of syphilitic disease in other tissues. | In primary laryngeal carcinoma no other evidences until later in the disease. | Frequently nasal, pharyngeal, and cutaneous manifestations. |
| Iodides have no influence.... | Readily improves under iodides | Iodides may at first have slight influence, later none, on the course of the disease. | Iodides have no influence. |

neuralgic pains. The disease is self-limited, is generally unilateral, and seldom recurs.

*Syphilitic eruptions of the skin* are generally roughly symmetrical, ham-colored, do not itch, may assume several different forms, and are more or less grouped.

5. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head.

6. A *poison* is a substance which being in solution in or acting chemically upon the blood is capable of causing death or serious bodily harm. Example: Carbon monoxide, opium, nux vomica, arsenic trioxide, hydrocyanic acid.

7. Impacted Stone in Ureter. *Symptoms:* Colic pain shooting along ureter, tenderness over ureter, hematuria, anuria (if opposite kidney is blocked or diseased), abdominal tumor (persistent or intermittent). Urine contains crystals, blood, or pus. Prolapse of ureter into bladder. Skiagram shows stone. In the majority of cases the symptoms are simply those of renal calculus, and diagnosis is only complete on lumbar exploration and passing ureteral sound.

In some cases the stone can be felt per rectum or per vaginam.

*From encysted vesical calculus:* impossible clinically.

*From cystitis.*—In this: Urine is alkaline; pus at beginning or end of micturition.

*From ureteritis.*—Difficult in absence of history of colic.

*From vesical tuberculosis.*—In this: Tubercle in urine; polyuria; frequent micturition; slight hematuria; symptoms not relieved by rest.

*From prolapsed inflamed ovary.*—Ovary lies behind broad ligament and at greater distance from vaginal wall. Stone is felt in anterolateral fornix. Hardness and outline are more definite.

*The skiagram* shows a shadow in the course of the ureter, but this has to be distinguished from that of calcareous iliac glands or that of an appendix concretion (the latter very rarely throws a shadow).

*Ureteral catheterization* through the cystoscope not only shows which side is affected, but the end of the catheter may touch the stone and a waxed tip receives a scratched impression.—(Graves' *Synopsis of Surgery.*)

8. *Acetone and diacetic acid* are found in the urine in diabetes mellitus.

*Acetone* may be found in the urine in typhoid, scarlet fever, pneumonia, high fevers generally, some digestive disturbances, carcinoma, autointoxication, and chloroform narcosis.

*Diacetic acid* may be found in the urine in the same conditions as acetone.

9. *Babinski's reflex:* If the skin of the sole of the foot is irritated, extension of the toes occurs instead of flexion; found in organic hemiplegia and lesions of the pyramidal tract.

*Stellwag's sign:* Absence or diminution in the frequency of the winking movements of the eyelids, and abnormal width of the palpebral fissure; seen in exophthalmic goiter.

*Kernig's sign:* If the patient lies on his back and his thigh is flexed to a right angle with his body, he is unable to extend the leg on the thigh; found in meningitis.

10.—

| SIMPLE MENINGITIS. | TUBERCULOUS MENINGITIS. |
|---|---|
| *Age.*—Any age. | *Age.*—Young children and young adults. |
| *Cause.*—Injury or local causes, fevers, etc. | *Cause.*—No local cause, but symptoms of tubercle elsewhere. |
| *Course.*—Short. | *Course.*—Longer than simple, especially the prodromal stage. |
| *Convulsions.* — May be present. | *Convulsions.* — Common, even during the compression stage; often precede death. |
| *Abdomen.* — Nothing marked. | *Abdomen.*—Markedly retracted. |
| *Morbid changes.*— | *Morbid changes.*— |
| 1. Those of simple or suppurative inflammation. | 1. Those associated with the presence of tubercle, and formation of peculiar greenish pus. |
| 2. Attacks convexity of brain. | 2. Attacks the base of brain. |
| 3. Ventricles not distended. | 3. Ventricles are distended, and hyprocephalus may follow. |
| *Lumbar puncture.* — Fluid turbid; polymorphonuclear leucocytosis. | *Lumbar puncture.*—Fluid much less turbid or almost clear; lymphocytosis. |

—(Wheeler and Jack's *Handbook of Medicine.*)

**Microorganisms Isolated from Non-Ulcerating Cancerous Growths.**—E. P. Minett concludes that the *Micrococcus neoformans* is identical with that type of *Staphylococcus albus* which can be isolated from deep tissues, both in human beings and in animals. The coccus isolated from deep tissues is merely the ordinary skin staphylococcus, modified by growing for considerable periods in the tissues where oxygen is absent or very scarce. The above statement is justified by the fact than an anaerobic growth of skin staphylococcus gradually assumes the characters of the *Micrococcus neoformans.* The serum of cancerous patients does not possess specific agglutinins for *Micrococcus neoformans* in a greater degree than does normal serum. Cancerous patients do not react in any marked degree to vaccine treatment with this organism. The temperature is not affected by large doses of the vaccine, nor can specific opsonins be detected.—*Proceedings of the Royal Society of Medicine.*

### THE PRACTICAL MANAGEMENT OF CHRONIC OSTEOARTHRITIS.

BY PERCY WILLARD ROBERTS, M.D.

NEW YORK.

ASSOCIATE ORTHOPEDIST, MT. SINAI HOSPITAL; ASSISTANT SURGEON, HOSPITAL FOR RUPTURED AND CRIPPLED; INSTRUCTOR IN ORTHOPEDICS, POST-GRADUATE HOSPITAL.

ONE of the striking features in the histories of patients suffering from chronic osteoarthritis is the variety of treatments to which they have submitted without permanent relief. The inference to be drawn from this is a lack of appreciation by the profession at large of the fundamentals underlying the causes of the malady and the possible remedies. That the published literature is somewhat responsible for such a state of affairs is quite probable, for much of it is confusing and not a little of it misleading.

It is not the purpose of this paper to question the value of the research work which is in progress, looking to the identification of the etiological factors of the chronic arthritides and the development of specific remedies, nor to comment upon the various classifications into which chronic osteoarthritis has been divided. That the latter are unnecessarily numerous goes without saying, but the nomenclature is in a state of evolution and in time order will no doubt come out of chaos. It is the intent, rather, to outline a method of treatment which in various forms of lesions has given favorable results, and to cite a sufficient number of cases to illustrate the fact that extreme refinement in diagnosis is not an essential to reasonable treatment. The explanation of this lies in the fact that, whatever the cause, the joint picture is always one of altered nutrition, and that by using what information we have of the influence of the ductless glands upon metabolism, much may be done to relieve pain and prevent deformity. As our knowledge of the etiological factors grows, improvement in therapy will follow, but under present mixed opinions it will not be amiss to adopt measures which, if lacking much in precision and true scientific application, still are in the majority of cases effective. Care should be taken, however, to differentiate between progressive conditions and rapidly developing deformities resulting from severe acute infections which are often erroneously classified among chronic joint diseases.

As a broad working basis, it is sufficient in the light of our meager knowledge of the etiology of chronic joint troubles, excluding those of tuberculous and syphilitic origin, to divide them into two classes, namely: those due to or following up a demonstrable infection, and those due to a vicious metabolism. That disturbed metabolism may be due to the remote effects of infection, that tissue changes may be hypertrophic or atrophic, that sometimes osseous lesions predominate over those of the soft tissues and vice versa, is of course apparent; but it adds nothing but confusion to the practical management of these conditions to separate them into distinct classes and regard them as of individual origin.

It is enough, until laboratory investigators have shed more light upon the matter, to know that the causes of chronic osteoarthritis are toxic and mechanical irritants and traumatism, and emphasis should be laid upon traumatism. In the clinics it is a very common experience to find a monarticular osteoarthritis of the hip following a fall or other injury. It is obvious, also, that the joints most used, notably those of the hands, are the subjects of greatest deformity. Conversely, affected joints, as, for instance, knees which are swollen and exquisitely sensitive, undergo recession in both pain and enlargement when immobilized in plaster-of-Paris, while those difficult of immobilization, as the cervical vertebræ and shoulders, are frequently the last in which pain subsides.

An effect of traumatism to which attention has not heretofore been called is the production by muscular pull of pain at the attachments of tendons and ligaments. These areas will be found in the early stages of osteoarthritis over the tuberosities of the condyles of the humeri and femora, the great trochanters, the heads of the fibulæ, the tips of the malleoli, and the spines of the vertebræ. Very constant points of tenderness, also, are the heads of the humeri where they are superficial. Patients are often unaware of the presence of these tender areas until subjected to examination, as this tenderness appears before the disease has progressed far enough to cause pain upon motion. Thus it is that people frequently come for advice complaining only of painful feet in whom a well established osteoarthritis can be demonstrated. Among other early symptoms a sense of insecurity in the knees in going up and down stairs is quite characteristic, and precedes actual pain. Search for these conditions will be of material aid in arriving at an early diagnosis.

The rôle played by toxic and mechanical irritants as the primary causes of osteoarthritis is obviously very great. Toxins of the various pathogenic organisms and those emanating from the intestinal tract are credited with power to induce tissue changes in the joints. Mechanical irritants have not usually been included among the etiological factors, but the writer has observed an abnormal number of arthritides in a district where an excess of lime is present in the drinking water and believes that the possible effects of this should not be overlooked.

As to the manner in which irritants operate to cause tissue change, there seem to be two reasonable theories. One recognizes a local action upon the affected parts and the other a central action upon nu-

trition, through alteration of the secretions of the ductless glands, either in quantity or character. The latter seems wholly tenable, if we stop to consider what recent research has revealed in regard to the influence of these bodies upon nutrition and bear in mind that the changes occurring in osteoarthritis are changes of nutrition. In any event, it is quite evident, from the cases outlined below, that the administration of glandular preparations has a distinct effect in reestablishing the equilibrium of joint metabolism.

In considering the treatment of osteoarthritis, the problem presented is plainly one of removing discernible foci of infection, improving local nutrition, correcting such deformities as tend to put undue strain upon weight-bearing joints, and to place the painful parts at rest, so far as that is possible. Before touching upon these points specifically, however, a word of caution should be spoken regarding the useless things which are commonly in vogue. It has long since been demonstrated that so-called antirheumatic remedies, such as the alkalis, salicylates, and iodides, have no effect upon the conditions under discussion and should be avoided because of the digestive disturbances which frequently follow their exhibition. The diet usually prescribed for "rheumatism" is harmful, because it denies certain elements of nutrition which the economy demands. Such treatment as is afforded at the various watering places is at best of merely temporary benefit and has at times been observed to be a source of real injury (Case II). Massage and manipulation of joints with the idea of keeping them pliable is an inexcusable error, for it serves only to perpetuate the irritation of the already sensitive tissues. It would seem, too, that the importance of correcting viceroptosis in these cases has been very much overestimated.

Approaching now the practical management of the chronic arthritides, it will be recalled that they were arbitrarily separated into those with demonstrable infective foci and those without. Naturally, where a focus of infection exists, it should be removed, and here is a fertile field of investigation in which the theorists have run riot. Not a single cavity of the body has been above suspicion as the possible source of toxins which have wrought joint impairment. The teeth, the tonsils, the throat, the nose, the sinuses, the ears, the stomach, the intestines, and the pelvic organs have been attacked with radical enthusiasm in the hope of clearing away the offending organisms, or, if these are found, of utilizing them in the preparation of vaccines to offset the injury they have done. The vaccine treatment offers much that is hopeful for the future, but it is still in the developmental stage, and while many cases subjected to vaccines have been observed, the writer has been content to clean up such avenues of toxic invasion as came to notice and to depend upon other means of combating tissue changes.

The essentials of treatment followed in the cases cited below have been the administration of glandular preparations, rest, a diet reducing the intake of calcium, and the use of the d'Arsenval or bipolar high frequency current. Of the glands which have direct influence upon nutrition, three stand out in clearly defined prominence; namely, the thymus, the thyroid, and the pituitary, each of which has its place in the treatment of osteoarthritis. It should be borne in mind that the subject of nutritional control is an extremely complex one—that these and other glands interact upon each other and that no single one of them meets all the requirements of a regulator of metabolism under all conditions.

The thyroid, which is most widely known, is least often indicated in osteoarthritis. It is seldom of value alone, but may be useful in conjunction with other glands where there has been recent marked increase in weight. When given it should be carefully carried to physiological limits and the dose then considerably reduced and continued at that point over a long period.

Thymus gland, for the knowledge of the efficacy of which we are indebted to the painstaking work of Nathan, has longer stood the test than any of the others. It is slow in action, but has an undoubtedly beneficial effect upon the course of osteoarthritis, whether of the metabolic type described by Nathan and in which it was first used, or of the chronic conditions following low grade infections. It should be given in doses of 10 or 15 grains, three times a day over a period of many months. It is contraindicated only in cases in which there has been a rapid increase in weight, as at times it stimulates general nutrition to an unusual extent. The gland deteriorates rapidly, therefore fresh preparations are essential. The powder, sealed in capsules at the laboratory, is perhaps the most reliable form for administration. The powder dispensed in bulk is of very uncertain strength. Disappointment in the use of thymus is frequently due to its slow action. It should not be abandoned before six months of continuous use.

Pituitary body has recently shown some very encouraging results. Wallace has used 1 per cent. and 2 per cent. solutions of the whole gland injected intramuscularly with the result, in many cases, of striking improvement in pain and joint swellings (Case V). The dose is 1 c.c., injected daily, using a 1 per cent. solution for two weeks and then a 2 per cent. solution. Uranalyses should occasionally be made for sugar and the blood pressure should be observed from time to time. Tablets of the whole gland will sometimes effect the same result as solutions (Case VI), but are apparently not quite so dependable. The posterior lobe alone does not seem to have any decided influence upon joints, but, promped by the illuminating work of Cushing, who, among other things, has demonstrated the effect of the anterior lobe on bone growth, the writer has used capsules of powdered anterior lobe, sealed at the laboratory, with beneficial effect. The anterior lobe used in conjunction with thymus appears to have a greater influence than thymus alone. The dose is 2 grains, three times a day, in capsules which have been sealed at the laboratory. The preparation is not yet on the market in this form.

In addition to these agents, there is undoubted value in the d'Arsonval current given for the local effect of the heat produced, and as a general application by means of autocondensation. The manner of its action would seem to be by dilatation of the vessels, plus the sedative effect of the rapid electrical vibrations. The improvement noted in the left hand of Case VII was undoubtedly due to this alone, as the thymus given had not time in the four weeks of treatment to become effective.

Not less important than the administration of remedies internally, is rest of the affected joints. In the same ratio that joint activity increases pain, immobolization reduces it. Too much stress can-

not be laid upon this point, and frequent failures in the treatment of clinic patients may reasonably be ascribed to their inability to obtain the needed amount of rest. Cases I, III, and XI illustrate its beneficial effect. Nothing is more fallacious than the idea that joints which are limited in motion should be exercised during the painful stage for the purpose of preventing ankylosis.

If plaster of Paris is used for immobilization, it is well—excepting in hip conditions—to remove the cast once in two weeks and leave it off for forty-eight hours for gentle, passive motion of the joints twice a day. Hands and wrists may preferably be put up in aluminum splints, shaped to meet the anatomical lines, and carried well up the arm. These may be removed once a day for gentle extension and flexion of the fingers (Case VII). Flexion deformities of the knee will often yield to repeated applications of plaster casts at intervals of a week or two without forcible stretching (Cases I and III). Such cases usually retain their arc of motion. Where the knees are stiff in the flexed position and painful, forcible stretching under an anesthetic is indicated, with tenotomy of the tendo Achilles to bring the foot to a right angle with the leg, if necessary. The leg should remain in plasted two weeks and the knee then be examined and plaster reapplied (Cases I and III). If tenotomy has been performed, the parts should not be disturbed for six weeks (Case X). Prognosis as to the restoration of motion should be guarded where forcible stretching has been undertaken. It does not return if the cartilage is destroyed.

In addition to tenotomies to relieve contractures of the hamstrings and tendo Achilles, operative measures may be advisable in severe monarticular osteoarthritis of the hip. Albee has devised an ankylosing procedure which locks up the hip, but relieves pain. Baer of Baltimore, has introduced an operation by which much of the joint motion may be conserved. It consists of trimming off the femoral head and removing the osteophytes which have accumulated about the rim of the acetabulum. Bone operations on the feet are also occasionally necessary for the relief of extreme hallux valgus or valgus of the entire foot. Both procedures are comparatively simple. Deformities of the hands are seldom subjected to operative treatment.

The following brief outlines of cases taken from private records will illustrate the effect of the measures which have been suggested in the foregoing paragraphs. It will be noted that nearly all of these patients had been growing progressively worse over a period of years despite a variety of different forms of treatment in which the cost was not considered. It will also be noted that the cases have a varied etiological history.

Case I.—Woman, aged 38 years, married. Multiple osteoarthritis. First symptoms appeared fourteen years ago with slight stiffness of two fingers of the right hand. Progress of the disease was very slow for five years, but by this time nearly all of the joints of the body were stiff and painful. During the next seven years pain and deformity increased notwithstanding various forms of treatment, including five visits of two months each to a well-known springs in the middle West. During this time patient was confined to her room, except when taken out in a wheeled chair. When she came under observation, two years ago, she considered herself a hopeless invalid. Had exaggerated palisade deformity of the fingers, stiff wrists, limitation of extension of elbows to about a right angle, little use of shoulders, practically stiff neck, limitation of motion at the temporomaxillary joints, limitation of extension of knees of about 40 degrees, valgus deformity of feet. Constant pain in all joints, and knees extremely sensitive and swollen. Treatment of this case consisted of administration of thymus gland fifteen grains three times a day, plaster of Paris for the knees and later the d'Arsonval current. Legs were encased in plaster from the bottom of feet to the groin and renewed three times during a period of four months. She was kept in bed five months altogether. During the past year has had d'Arsonval current half an hour three times a week. Improvement has been gradual and continuous, with occasional slight setbacks due to overexertion. Because of an increase in pain in the neck and shoulders, thymus was discontinued in November, 1913, and the anterior lobe of the pituitary body, in capsules sealed at the laboratory, was given in doses of 2 grains three times a day for five weeks with unmistakable benefit. Thymus treatment was then resumed. Patient is now practically free from pain, excepting some discomfort in the shoulders and neck. Extension of elbows has increased about 40 degrees, knees are nearly straight, much more freedom in neck and shoulders, deformity of the hands persists. Patient can walk a mile without discomfort; has climbed the long flights of steps in Morningside Park without ill effect and has long since discarded her cane.

Case II.—Woman, aged 50, married. Multiple osteoarthritis. First symptoms noticed five years ago, beginning with twinges in the shoulders and neck. Gradually practically all of the joints of the body were involved. Hands somewhat deformed, wrists enlarged and somewhat stiff, limitation of extension at the elbows, limitation of motion of the shoulders, both knees enlarged and tender, extremely painful on walking, spine slightly stiff, moves about the house with great difficulty. Has had many forms of treatment, including a long period in a sanatorium, where, because of the vigor of the measures used, she lost strength and weight rapidly, and had an increase of symptoms. Had thymus about a year before coming under observation. General condition much improved during that time, but there has been an increase in contraction at the elbows, in the swelling of the knees, and in her inability to get about. After two months of the use of thymus in capsules and of the d'Arsonval current through the knees condition much improved. Complains less of pain. Circumference of each knee decreased about one-half inch. In February, 1914, after nine months of treatment, patient's condition has improved remarkably in all respects. She has very little discomfort, is able to walk moderately long distances, knees nearly straight, extension of the elbows very much increased, has gained in weight, and general condition is excellent.

Case III.—Woman, age 50, unmarried. Multiple osteoarthritis. Symptoms first appeared twelve years ago with slight pains in left hand and elbow. No known history of infection. In a year's time nearly all the joints of the legs and arms were involved and patient walked with difficulty. Many forms of treatment were tried, including trips to the South and elsewhere. In June, 1913, her condition was one of apparently hopeless, painful invalidism. Extreme palisade deformities of the fingers, complete dislocation of the last phalanx of the right thumb, wrists stiff, elbows limited to about 40 degrees motion, shoulders to about 45 degrees of motion, knees flexed about 30 degrees, swollen and exquisitely tender, feet and toes deformed; walking or standing alone impossible; was taking aspirin and codeine in frequent doses to relieve pain; emaciation extreme. Fifteen grains of thymus gland three times a day ordered. Legs encased in plaster of Paris from bottom of feet to the groin. On removal from cast, seventeen days later, knees were found to be reduced in size, pain had disappeared, except over one or two spots on each knee, and there was a gain of about 10 degrees in extension. After gentle, passive motion once a day for a week casts were reapplied. On removing these, eighteen days later, all pain had disappeared, swelling had abated and extension was nearly normal. Casts were not reapplied. General condition showed improvement, with moderation of all joint pains; anodynes discontinued. Up to the present time, nine months after treatment was begun, improvement has been gradual and continuous. Patient is practically free from pain, except some of moderate degree in the upper extremities and neck. She can walk about the house; has gained in weight and has a very noticeable increase in motion at the wrists, elbows, shoulders, and knees; is still under treatment.

Case IV.—Woman, age 30, married; came under observation June 7, 1911. Multiple osteoarthritis of mod-

erate grade, involving practically all the joints of the body; tenderness of all on pressure. Moderate palisade deformities of the fingers with enlargement of the metacarpophalangeal joints; limited motion at the hip; 10 degrees limitation of extension at the knees; tenderness of the mediotarsal joints and valgus deformity of the feet. Condition has existed about five years. Dorsal and lumbar vertebral spines tender. Fifteen grains of thymus three times a day ordered. No other treatment. June 28, 1911—There was some improvement in the local symptoms; spine free from tenderness, less swelling in knees, less deviation of left hand and less tenderness of the left knee. General condition unsatisfactory. Weight, 92½ pounds. Tenderness has developed over both sacroiliac joints. Improvement began about this time and continued until October 6. Was unable to get thymus gland for about two weeks and noticed a general increase in the soreness. December 2, 1911—Patient has showed steady improvement; has gained 7½ pounds. Pains have materially abated. January 20, 1912—General condition excellent, weight 107 pounds. Pregnancy occurred some time before this examination and patient went through childbirth without difficulty. Under date of February 20, 1912, she writes: "My joints are all very free from soreness, save my ankles. Perhaps my extra weight is hard on them, for I have risen to the dignity of 118 pounds, the top notch in all my life." Her condition remained satisfactory until the duties of motherhood began to tell upon her, when she began to have an increase in symptoms. At this time she passed out of observation. A letter written in February, 1914, says that she is hardly able to walk across the floor and is generally incapacitated. Thymus was discontinued long ago. She has been under other treatment, growing steadily worse. This case illustrates the evil effect of activity. The patient was obliged to take care of her child and the necessary lifting, the use of her hands and her broken rest resulted in a relapse.

Case V.—Woman, age 64 years, married; multiple osteoarthritis. Was apparently perfectly well until five years ago, when the hands became somewhat stiffened and slightly painful. During the next three years all the joints of the extremities had become involved and the progress of the disease was continuous despite many forms of treatment. When first seen, about the middle of December, 1913, patient was suffering both day and night with constant pain throughout most of her joints. She had reached a degree of emaciation which might well be described as skin and bone; hands, wrists, and feet badly deformed; elbows and knees contracted. Was taking morphine for severe pain. She was given daily injections of one cubic centimeter of a 1 per cent. solution of whole pituitary body. In three weeks pain had receded very perceptibly; morphine discontinued. She then received 1 c.c. of a 2 per cent. solution of while pituitary body, but this was discontinued at the end of ten days because of continued drowsiness, and thymus was substituted. By the middle of February all pain had ceased, emaciation and deformity remained about the same, but the patient is more comfortable than she has been for several years.

Case VI.—Woman, age 35, unmarried; multiple osteoarthritis. Symptoms of infection nine years ago with stiffness and pain in left shoulder. During the succeeding five years symptoms occurred very gradually in the hands, feet, and knees. During the next four years the disease was progressive despite long periods of treatment in various New York hospitals. When the patient came under observation she was suffering from pain in her hands, elbows, shoulders, knees, and feet, which was constant. Joints of the fingers much enlarged and stiff. Knees somewhat swollen, very painful. Feet so painful that she walked with difficulty. She was put upon five-grain tablets of whole pituitary gland three times a day. In two weeks there was a slight recession of pain, in six weeks she was practically free from pain, swelling of the hands was very much reduced, the fingers sufficiently pliable for her to resume work. She states that she is more comfortable than she has been for more than five years. Stiffness of all the joints has been very much improved and the recession of both pain and deformity in the feet has been very striking. Still under treatment.

Case VII.—Woman, age 29, married; multiple osteoarthritis. When eighteen years old had an attack of pain in both shoulders, accompanied by temperature and other evidence of infection. This cleared up in a few days. Occasional stiffness in shoulders afterward. Has not been ill since, until seven years ago, six months after childbirth, fingers of right hand became stiff and swollen. Wrists and feet also involved. Two acute attacks of pain at the articulations of the jaws. Complains chiefly at present of pains in hands and feet. During the last five years has been under various forms of treatment in this country and spent a year and a half in Germany and England under the care of well-known men. She had six months of radium treatment in London. Hands have grown progressively worse. October 29, 1913—Flexion of fingers of right hand so limited that the tips of the fingers are about 2½ inches from the palm—of the left hand about 1 inch from the palm. Greatest angle of flexion of the index finger of the right hand at the metacarpophalangeal joints 55 degrees; on the left hand 65 degrees. Treatment consisted of fifteen grains of thymus, three times a day, the daily application of the bipolar high frequency current through the tips of the fingers and the immobilization of the right hand on an aluminum splint. The result of four weeks' treatment was marked reduction in the swelling of the joints, practical elimination of pain, which has been constant and severe for five years, and an increase of 25 degrees in the flexion of both index fingers; in other words, the tips of the fingers on the right hand approached the palm to within about three-quarters of an inch, and those of the left hand just touched the palm. Patient obliged at this time to leave for her home in the West, and is to return for further treatment. This case illustrates the benefit of the d'Arsonval current, as the recession of pain and swelling of the joints and the increase of flexibility of the fingers was far more rapid than would have occurred under thymus alone.

Case VIII.—Woman, age 33, unmarried; multiple osteoarthritis. In August, 1911, had an acute infection of one finger and two weeks later tonsillitis. A month later many joints were aching and were somewhat stiffened. Treated for rheumatism. When she came under observation in December, 1911, she had lost about thirty pounds, all large joints were stiff, tender, and somewhat swollen; walked with extreme difficulty and was unable to use her hands in her professional work, which was that of a sculptor. She was given fifteen grains of thymus three times a day and the d'Arsonval current daily. Slight improvement was noticed in a few weeks and progress from that time on was continuous but slow. After five months she began to use her hands and her general condition showed obvious gain in nutrition. The d'Arsonval current was discontinued about two months later and there followed increased stiffness of the joints, notably in the hands. These symptoms receded on resumption of the electricity. Patient has made a practically complete recovery, occasional twinges of pain at long intervals being the only reminder of her former disability.

Case IX.—Man, age about 40; multiple osteoarthritis. When this patient was first seen four years ago he was suffering from an osteoarthritis of gradual onset, which had been progressive for many years. Hardly a joint of his body permitted more than twenty degrees motion, and the knees and elbows were practically ankylosed. Pain all over his body was severe and constant. Having tried innumerable forms of treatment, he frankly avowed his skepticism regarding thymus. However, he took fifteen grains three times a day faithfully. In three months he reluctantly admitted an improvement in his pain, which continued to abate until its final disappearance, and it has not since returned. As the patient lives at a distance he has not been seen since the first examination, and whether there has been any increase in the mobility of the joints—as so often happens when pain ceases—is not known. The case is cited merely to show the effect of thymus. The man had no other treatment.

Case X.—Woman, age 52, married; multiple osteoarthritis. This case is briefly outlined to show what may be done in restoring to activity patients who have been disabled on account of deformities. Twenty-five years ago multiple osteoarthritis developed which gradually spread to all the joints of the body. When the patient was seen in June, 1913, the hands were badly deformed, one elbow was ankylosed at a right angle, the other had slight motion. Knees flexed at about 90 degrees, with 20 degrees of motion, feet in equinus, toes badly deformed. Shoulders and neck were also involved. Patient had not walked nor stood alone for twenty-three years. She was taken to the Postgraduate Hospital and the hamstring and tendon

Achillis on both sides cut. She was then put up in plaster of Paris for six weeks. On removing plaster knees were straight, with about 50 degrees of motion, tenderness had subsided and feet were at a right angle. She was gradually encouraged to use her legs, and at this writing, eight months later, has no pain and is able to walk about the room without crutches. She has been taking thymus gland since July, 1913.

Case XI.—Woman, about 45 years of age, married; multiple osteoarthritis. Joint symptoms have been present for about ten years, and when the patient was seen three years ago she was suffering from extremely painful multiple osteoarthritis, involving shoulders, elbows, wrists, hands, knees, hips, and feet; very marked deformities of the hands, contractures of the elbows, contracture of the knees to an agle of about 135 degrees, deformities of the feet and toes. Knees were extremley sensitive and swollen; left knee practically stiff, right knee had about 45 degrees of motion. Patient had for some time been unable to get about, and was carried up and downstairs. Had had many forms of treatment. She was put upon thymus, 15 grains three times a day, the knees encased in plaster from bottoms of feet to the groins. She remained in bed about four months, plaster casts being changed once a month. At the end of this time pain and swelling had receded; pains throughout the joints very much improved. Her progress was slow but continuous, and at the present time she is able to go up and downstairs several times a day and walk reasonable distances without discomfort and complains of no pain, excepting some discomfort in right shoulder and hand. Motion was not regained in the left knee, but that of the right knee is free. Motion at elbows increased. Her general health is better than it has been for many years and she has resumed her place in the social activities of her city.

The conclusions which a fairly broad experience with the chronic arthritides suggests are:

1. Regardless of their etiology, a majority of sufferers from progressive osteoarthritis may be relieved by the use of glandular preparations, rest, and such local measures as have been indicated in the foregoing paper.

2. A diagnosis of osteoarthritis may be established before the stage of deformity has been reached.

3. In discussing treatment, the element of time should be clearly understood by both physician and patient. Rapid results are seldom attained.

4. Rest or complete immobilization of affected joints is an essential factor in the treatment of pain.

5. Contracture deformities of the knees and ankles should always be corrected.

6. Innovations in treatment and the hobbies of a single investigator should be avoided by the general practitioner until their value has been proved.

7. A case not entirely ankylosed should never be considered hopeless.

40 East Forty-first Street.

## ?T US SETTLE THE LOOSE KIDNEY QUESTION.*

By ROBERT T. MORRIS, M.D., F.A.C.S.,

NEW YORK.

PROFESSOR OF SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

When men smile and agree nature weeps. Progress depends upon contest. Patients are weeping right now, however, because different members of the medical profession are too widely disagreed over the loose kidney question. Whenever a new subject comes up before us we are prone to polarize our consciousness, scattering the ray of light and sending it along a plane to the right or left according to our individual natures. The first observers of the subject of loose kidney set us to vibrating along the line of the idea that we were dealing with a diagnostic entity and a necessarily surgical condition. Later observers impressed the fact that we were dealing with a symptom only, and diverted our attention along another line of thought. In both instances the patient has had to bear the consequences.

Let us apply synthesis for a moment in an attempt to get back to natural light upon the subject. In order to make a concrete mental picture let us take one kind of a case of loose kidney only for consideration. Not long ago a patient from the West came to the office before going to the hospital for operation upon a loose right kidney. She was to have paid twenty-five hundred dollars for the operation, and everything had been arranged. As the patient was leaving the office I incidentally remarked that she would gain fifteen or twenty pounds in weight after the operation. She asked eagerly if that were true. Upon my responding in the affirmative she said, "Good-by, doctor!" and I have never seen her since that time. There was a patient who preferred to remain fashionably lithe and willowy at the expense of chronic gastrointestinal discomfort.

A woman came into the office one day asking to be informed about "two funny little things" which she felt through her abdominal wall after a hard ride across country following the hounds. She was red-cheeked and in good health, and her two loose kidneys were causing no disturbance. This means that we have different sorts of loose kidney patients.

Now, let us get back to the single loose right kidney in the first case for the purpose of drawing a picture. Why did that kidney ever leave Gerota's capsule? It was because the colon sagged, and sagging pulled upon the nephrocolic ligament which surrounds the kidney fat with its fibers as a mesh surrounds a balloon. When a sagging colon has pulled the kidney out of Gerota's pocket the walls of the pocket collapse, and the kidney never again gets exactly back to its normal position. Why did the colon sag in our patient? When in the course of evolution nature got us up on our hind legs a number of structural weaknesses appeared. Nature made a number of mistakes on this trip with organic life when planning the highest organism. These structural weaknesses are shown in hernial walls, broken down foot arches, loose sacroiliac articulations, up-hill work for ascending colons, and a number of other defects which will likely enough be remedied in the organic life of the next world as a result of nature's experience in this one.

When a right kidney has been pulled out of its pocket it may range in the retroperitoneal plane which brings it against the duodenum. Mechanical pressure will result in various gastrointestinal disturbances. That sort of a kidney should be fixed. When a loose right kidney ranges behind the peritoneum to a point at which it may make pressure upon the common bile-duct, symptoms of biliary obstruction follow. That sort of a kidney needs to be fixed. When a loose right kidney ranges along a caudad plane and the ureter becomes angulated, we have evidence of obstruction to the ureter. That sort of a kidney needs to be fixed. When a loose kidney results in torsion or angulation of its blood vessels and congestive nephritis results, we must

*A paper read on March 13, 1914, at a meeting of the Rochester Pathological Society.

fix that kidney. When a loose kidney places stress upon the great web of sympathetic nerve filaments which carry afferent impulse to the semi-lunar ganglia, efferent impulse as a result of this overstimulation may result in disturbance of all of the organs affected by efferent impulse from the semi-lunar ganglia. That sort of kidney should be fixed.

There are many cases of loose kidney in which this condition represents but one symptom of a neurasthenic condition in patients with a *habitus enteropticus*. All of the peritoneal visceral supports may be relaxed in these cases, and the organs appear to adapt themselves to each other in a way, becoming companions in misery. Under these circumstances fixation of a loose right kidney alone would be harmful. In these cases it is seldom the chief cause for disturbance. It is the chief cause for disturbance in a large class of patients who present symptoms which may be traced directly back to a loose kidney as a precipitating factor.

The question then resolves itself into one of good diagnosis. We are not to proceed to fix a loose kidney simply from the basis of fact that we have found one. On the other hand, we are not to allow patients to continue to suffer unnecessarily because physicians have learned that many loose kidneys are not productive of special disturbance. We are to determine which kidney produces which group of symptoms and act accordingly.

Some of the happiest patients in my clientele are ones for whom kidney fixation has been done. Often enough they had been advised against having any operation performed, and sometimes by first rate authorities. The doctor is identified by the proportion of things which he gets right. We are all so busy these days that we have to be pretty careful about our identification in relation to any subject.

One reason why loose kidneys have not been fixed more frequently is because the operation is too often looked upon as a serious affair. In fact it has been actually made too serious an affair. An operation which combines the ideas of Senn, Longyear, and Goelet may be done in ten minutes—this representing the time between the first incision and the last suture. The only instruments required are a pair of scissors and a needle. I had intended to demonstrate the operation at the hospital this afternoon but the combination of Friday and the 13th was too much for the patients whom members of your society asked to come to the hospital to-day. One of your members knows of a case in which seven minutes were required for fixing the right kidney and six minutes for fixing the left kidney. There are some patients for whom the operation cannot be done in less than twenty minutes, but if we count upon considering the operation as requiring only about ten minutes of time, and the only instruments required being a pair of scissors and a needle, it will lose many of the terrors which have prevented physicians from advising fixation of loose kidney for their patients.

So far as I am aware a fixed kidney does not become loose again after the operation to which I have referred. If it has become loose in any of my patients they went to some one else to make complaint, so I did not learn of the fact.

The question of abdominal supporters belongs particularly to the subject of panptosis. That subject has not been brought up this evening, because an elaboration of points would divert attention from the clearly outlined target which has been presented for quickly marking the aim of a few thoughts.

## SURGICAL TREATMENT FOR REDUCTION OF VACUUM CAUSED BY NASAL OBSTRUCTIONS.

By CHARLES AUBREY BUCKLIN, M.A., M.D.,

GLASGOW, SCOTLAND.

THE oldest operation known for nostril deformity is the submucous resection of the nasal septum. The earliest authorities regarding operations for septal deformities are Heylen,[1] Hartmann,[2] and Petersen.[3] None of these authorities produced an operation for removing cartilaginous defects from the septum which compares with the combination of older operators' efforts by Freer[4] or that of Killian,[5-6] which combines features of Hartmann's and Petersen's operations. Surgeons are now generally using these operations for removing the entire septum.

Suckstorff[7] of Hanover has published an extensive history of submucous excisions of the nasal septum, quoting thirty-three authorities to five only of which reference is made in this paper. These earlier operators did not possess the necessary technique to make their operations successful, while Freer and Killian were the first to attain success.

The submucous resections of the cartilaginous septum are the only operations that are successful in removing deformities of this nature from the septum. Performed with Ballinger's[8] swivel septum knife, the submucous resections leave nothing to be desired in connection with operations for defects of the cartilaginous septum, as they can all be removed in one piece submucously. The bony septum can also be removed by a chisel in one piece or it can be successfully removed in pieces by a bone cutting forceps. A description of the operative methods of Killian with slight modifications has been freely translated into English by Thomson.[9]

The popularity of the submucous operations has been so great in Europe that septal deformities have come to be considered by many as being the only cause of obstructed nostrils. These operations have caused the methods of removing simple spurs from the junction of the vomer and the superior maxillary bone, without removing the entire septum by the same operation, and the method of turbinectomy by means of a nasal saw designed in 1880 to be excluded from the mind of the average specialist.

There are still many specialists in America who prefer the use of a nasal saw for simple spurs in the above mentioned position and also for turbinectomies. Should turbinectomy be performed, the effect should be measured by the respirometer.[10-11-12].

Should successful results be obtained by turbinectomy, the deformity of the septum will not require attention. Regarding partial turbinectomy there cannot be any objection to the use of the nasal saw. The operator can place the saw behind the lower turbinated bone, determine how much he desires to remove, and then amputate the bone by means of the saw in five seconds. The submucous excisions of the septum are endorsed for all deformities of the septum excepting simple spurs.

To remove a spur by the submucous method, it is necessary to remove the entire septum at the same operation. Many object to this extensive operation for the removal of a spur from the septum, and only use it when the cartilaginous septum is also deformed.

It is a natural enquiry to ask why one should be afraid of a scar so small that it cannot be found

two months after the operation. No one hesitates to remove adenoids with Delstanché's improvement of Gottstein's curette, which leaves larger surfaces for scars to form. Since 1880 a large number of patients were examined who had been operated on

FIG. 1.

FIG. 1 shows the saw as first used by the author in 1880 for the removal of spurs from the nasal septum. The saw is a 3 mm., jeweller's saw finished on the distal extremity on a grindstone to prevent it from scratching; the end opposite that toward which the teeth rake has been removed so that the total length of the blade is 4 in.; to give stiffness to this slender blade its proximal end is covered with a folded piece of German silver sheeting 2 in. in length.

with a nasal saw for spurs of the septum; it was not found possible in a single case after two months had elapsed to detect any scab, scar or ulceration by reason of the the close union of the mucous membrane over the sawed surfaces. The above claim is endorsed by Bosworth.[12]

For those who object to leaving a wound in the nose uncovered by mucous membrane, it is proposed to operate submucously by separating the mucous membrane with a cataract knife having a blade two inches in length.

The mucous membrane is incised in front of the spur, flush with the surface of the septal wall; after this anterior piece of mucous membrane has been dissected up, the point of the knife blade is entered with the edge directed upwards, under the spur beneath the mucous membrane and is passed backwards until a proper counter puncture is made.

The membrane is dissected up with this knife blade, either the edge or the back of the blade being used to free the membrane from contact with the septal spur. Both the upper and lower margins of the mucous membrane are left in full contact with the septum. While the saw is being used to remove the same, the mucous membrane is held free from the spur by two delicate right-angled retractors with blades three inches long. The nostril is held open by a third retractor of similar form but greater breadth. Two assistants are required to complete this operation. After the operation the nostril is thoroughly packed with absorbent cotton which should be allowed to remain for two days in order that the correct position of the dissected flap be ensured. These submucous operations have been successfully performed with the nasal saw. Should the mucous membrane be cut by accident no unpleasant complications will exist after two months have passed, even should there be no attempt to make make good the resulting damage from this

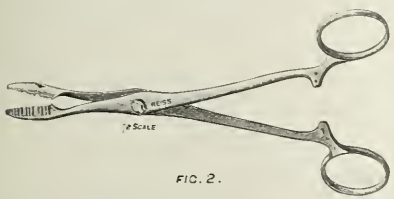

FIG. 2.

FIG. 2.—A clamping bullet forceps by which this saw blade was grasped at an angle of 45° in such a position that it could only cut upon withdrawal; the forceps being shown below this saw blade.

accident. The structure which a nasal saw must possess to remove in the most satisfactory manner spurs of the nasal septum and misplaced turbinated bones is not understood by the specialist or instrument maker, nor has it ever been the subject of a paper. One object of this paper is to give correct information regarding this subject. For this purpose there is here attached cuts showing the details of four nasal saws that have been introduced commencing with 1880.

FIG. 3.

FIG. 3 shows a similar 3 mm. jeweller's saw 4 in. long as used in 1883.[14] The distal extremity of this saw is covered with a drop of solder to prevent it from scratching.

The illustrations given entirely describe the progress of development made with nasal saws until the present date.

Since the author's first operation for turbinectomy (see CASE IV) in 1890 it is known that no other operation for septal deformity is followed by such an increase in weight, or so much ability to overcome defects found in the respiratory tract. It must be recognized as the best treatment for nasal obstructions when it is applicable. After an extensive experience with partial turbinectomy the author has never seen a primary or secondary disadvantage resulting from this operation.

The report of Griffin[17] upon ten thousand operations for partial turbinectomy with the nasal saw without a single unfortunate complication is good confirmation regarding the value of this operation. He has also seen patients gain eighty pounds in weight in six months after partial turbinectomy. In New York a frequent cause of hypertrophic nasal catarrh is an abnormal position of the lower turbinated bone associated with the great swellings which are found in their coverings. These coverings are twice as extensively swollen as any other equal surface of the nasal mucous membrane. The cautery is useless, for this defect will always return after a lapse of time. Every occasion which brings a hot wire in contact with the periosteum causes a troublesome complication of periostitis which will require weeks to disappear. The only operation which can permanently relieve the above described conditions without complications is partial turbinectomy. The respirometer demonstrates this operation to be much more successful in relieving the annoyances experienced by obstructed nasal inspirations than any septal operation. The length of time required to complete this operation is not more than five seconds. It is believed that with proper attention paid to the requirements of this operation, partial turbinectomy, with its simplicity, ease of performance, the absence of complications, combined with the large measurable beneficial results which always follow its use, will make two-thirds of the present septal operations unnecessary.

A partial turbinectomy is required to reduce by one-half the height to which an individual suffering

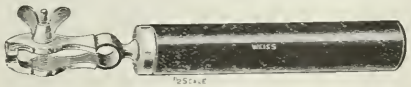

FIG. 4.

FIG. 4.—A pin-vise, driven into a file handle, which grasped at an angle of 45°, so that it could cut only upon withdrawal.

from obstructed nasal inspirations can raise water in the respirometer. This condition is always required for the cure of the simplest catarrhal diseases which are chronic in the respiratory tract. This reduction of the height to which water can be raised means a difference between external and internal atmospheric pressures during inspirations

equal to the difference resulting from a change of the patient's residence to about an altitude of 15,840 feet, or three miles reduced to feet."

The above-described changes in the atmospheric relations are sufficient to cure hypertrophic nasal ca-

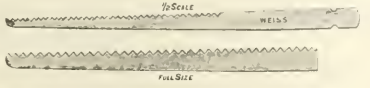

FIG. 5.

FIG. 5—Bosworths' saw.* As the handle is fixed, two saws are required if it be desired to cut with both edges in different directions. This saw does not stick, as it releases its hold on both strokes. Only one blade without a handle is shown in the cut. Bosworth's original description of this instrument is the following: "the blade to be as thin as possible, consistent with strength, an eighth of an inch in width, five inches long, with a cutting edge of three inches, thirty teeth to the inch, each tooth an exact equilateral triangle, with no crosscut, and no set to the tooth; the handle being three inches long, attached at an angle of forty-five degrees." The above saw has been tried; although it did not stick, it was not used after the first trial because it did not cut with sufficient rapidity.

tarrh (see CASE III), diseases of the lacrimal duct (CASE VI), catarrhal otitis media (CASES IV and V), chronic laryngeal and bronchial catarrh (CASE II). This elevation of the atmospheric relations places cases of pulmonary tuberculosis in a favorable condition for a cure by a forced diet of milk.

Russell's[19] experiments were the first to demonstrate the certainty of the removal of tubercle bacilli by a forced diet.

Since 1902 there have been treated by the author 146 cases of pulmonary tuberculosis. There were cured 106 cases. Forty cases died because they would not attach proper attention to what was told them about relapses of their disease, from a lack of forced nourishment. They did not understand that they could be reinfected from the tuberculous deposits which are usually carried about in their lungs. Milk has been found the only diet that can be forced on this class of patients to a sufficient extent without disturbing their digestion, to be of any benefit to them.

A patient with a good appetite can sometimes be cured of pulmonary tuberculosis in three months by the methods described in the above-mentioned journal. Most patients who have had pulmonary tuberculosis must continue their forced nourishment with

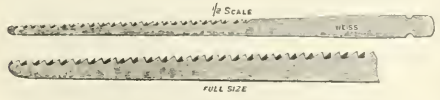

FIG. 6.

FIG. 6 shows the last saw blade of the author,[14-15] designed in 1905. It consists of a blade six inches long, the teeth occupy three and one-half inches, the cutting edge of the blade is made thick enough to clear the back of the saw, the width at the distal extremity is an eighth of an inch, and one-fourth of an inch at the proximal end of the teeth. The teeth are twenty to the inch, so set that they will only cut upon withdrawal, thus eliminating all tendencies to buckle when the saws are used. The butcher's saw, which has been constructed as the result of a great amount of experience, can safely be considered the best for cutting bone; it is the model after which the teeth of this last saw are constructed. The only instructions necessary for the inexperienced users of this saw are that no attempts should be made to force or drive them, as they will surely stick. The saw should be directed to saw upwards, even should one be obliged to enter the saw in a horizontal direction under the spur and turn it upwards before, or during its removal. For the benefit of those desiring to cut with both edges of one saw the blade has been made reversible, so that with one blade the operator is enabled to cut in any desired direction without inconvenience by changing the blade in the handle.

*At a meeting of the New York Academy of Medicine in 1886 Bosworth read a paper on "Deformities of the Nasal Septum." He here acknowledged that priority in the use of the nasal saw belonged to the author. He was mistaken in stating that operations on the nasal septum commenced with the saw designed in 1883.

milk to a sufficient extent to maintain the weight gained by previous treatment for the balance of their lives or they will develop fatal pulmonary disease through the sloughing of tuberculous deposits. The author has frequently seen this disease cured twice in one individual. It was caused the second time by infections from tuberculous deposits which sloughed in the lungs, thus producing pulmonary hemorrhage, and occasionally re-establishing the tubercle bacilli in the sputum.

The only method of protecting the patient against these sloughs is to have him obtain constant access to a scale and then protect himself against the reduction of his weight by sufficient forced nourishment with milk which has been sterilized, to prevent him from losing the weight that was accumulated during the first treatment of his disease. These sloughs will never take place as long as the weight is not allowed to decrease. Usually the tubercle bacilli do not appear in the sputum with these secondary attacks of this disease. Hemorrhage from the lungs appears, and is followed by a chronic inflammatory disease that causes the life of the patient to be lost. Occasionally the author has seen the sputum infected with tubercle bacilli after one of these secondary developments. The fighting of the secondary manifestations of pulmonary tuberculosis frequently means a struggle for a lifetime, which will be victorious if the weight be maintained. The great gain in weight which usually follows turbinectomy is explained by experiments with the displacement vessels.[20] These positively

FIG. 7.

FIG. 7 shows the handle of the author's saws as used since 1887.*

demonstrate that the amount of oxygen presented for absorption with each inspiration has been doubled. A gain of eighty pounds in weight within six months is frequently observed and it is explained by the above-mentioned experiments. The complications of hypertrophic nasal catarrh, adenoids, enlarged tonsils and nasal polypi with their treatment must be considered.

Among the diseases which are annoying in producing deafness hypertrophic nasal catarrhs rank first, adenoids rank second, inflammations of the tonsils rank third, and nasal polypi have never been known to produce deafness. For the treatment of these defects the author's universal snare,[21] designed in 1891, is strongly recommended. It has the advantage of being manipulated with one hand to the conclusion of every operation in which it is used. It is also fitted with a curved cannula for the nasopharynx and larynx which enables one to attack neoplasms and foreign bodies located therein. The cannula can be held in every position by a locknut attached to its proximal end.

The snare should be armed with a No. 6 piano wire having a tensile strain of sixty-seven pounds, which makes the wire loop sufficiently stiff to be readily adjusted about any growth and strong enough to cut through it. Since 1891 the author has used only this make of snare for the simultaneous removal of the tonsils.

Gottstein's curette as modified by Delstanché with

*The nostril deformity usually follows this saw when it is removed, if it does not the deformity should be removed by grasping it with an arterial forceps.

a hood containing sharp hooks inside of it is the most popular instrument with the profession for the removal of adenoids.

Tonsils before removal must always be inspected under a local anesthetic for the purpose of determining whether there are any pathological attachments to them, which must always be removed before any attempt is made to remove the tonsils, or there will be complications resulting in the loss of one-half of the soft palate. A large strabismus hook makes this examination thorough and easy. A pair of curved scissors is always of great assistance in connection with the strabismus hook in freeing pathological attachments from the tonsils. They are always removed simultaneously if both tonsils be diseased, because the patient may not consent to the removal of the second tonsil at a later date. They may be removed by others with a pair of Mathieu's tonsillotomes which also do their work completely with the use of one hand.

FIG. 8.—The author's respirometer.

Should tonsillotomy be followed by an annoying hemorrhage the cut surface should be painted with a solution of 2 per cent. novocain every fifteen seconds for three minutes. Should this not arrest the hemorrhage a piece of absorbent cotton should be taken in the left hand with a long forceps, while an arterial forceps is held in the right hand, an assistant should depress the tongue, and with moderate skill every hemorrhage resulting from the amputation of a tonsil can be promptly arrested by seizing and ligating or twisting the bleeding points. Hemorrhage[25] is an annoying complication, and to avoid it a tonsillotome should not be used for this operation.

The operator should always be provided with a strong, straight pair of scissors which will free the tonsil when the snare becomes disabled on account of a break in its mechanism or when the tonsillotome becomes jammed and disabled. This latter accident is usually caused by the beveled edge of the knife of the tonsillotome being turned toward the tonsil which is being amputated, under which conditions the instrument will frequently become disabled. Experience in the use of the snare will enable the operator to judge if this instrument be working properly. With the straight cannula in use any failure of this instrument can be compensated for by rapidly and continuously rotating the axis of the cannula in one direction, thus causing the wire loop to twist sufficiently to cut through the tissue grasped.

Bosworth[25] in 1897 recommended the abandoning of the tonsillotome and the use of his special snare with a No. 10 piano wire; in no case where Bosworth's snare was used has the hemorrhage been more than of the most trivial character. The only objections that the author offers against this instrument is that both tonsils cannot be removed simultaneously by them. With this endorsement the author recommends any piano wire snare, armed with at least a No. 6 wire, which can be manipulated throughout all operations with one hand as a universal means of removing the tonsils separately or simultaneously.

It was discovered in 1911 that a 1 per cent. solution of 20 minims was the best local anesthetic that could be used. With the use of this solution there is not the tendency of the patient to faint which is generally experienced with cocaine.

Such neurotic disturbances as hay fever (CASE VII), or chronic asthma (CASE VIII), not associated with heart diseases, have always been cured by a double turbinectomy of both lower bones. This reduces the ability of the patient who was able to raise water to 36 inches to about one-fourth, *i.e.* so that he can only raise it 9 inches. This is equal to a change of the patient's residence to an altitude during inspiration of 23,760 feet, which is 4.5 miles.

In using the respirometer the glass tube is removed from the vulcanite disinfecting case, which is 42 inches long, in which it is immersed and stored in a solution of bichloride of mercury of a strength of 1 to 31.25, which means that two commercial tablets of a strength of 1 to 1,000 when one is dissolved in one pint of water to each ounce of liquid used in the disinfecting case are added.

Stand the end of the glass tube which is to enter the patient's mouth in a tumberful of pure water for the purpose of removing the chemical. It is allowed to remain there for one minute before the rod is placed in the patient's mouth. The other end of the tube is placed in one-fourth of an inch of water in a tumbler standing on the floor.

After the patient has made a powerful expiration through the mouth the cleaned end of the tube is placed 3 inches into his mouth, the tongue being depressed with this end of the tube. The patient is then requested to seize the rubber which encircles the glass tube firmly with the lips and to make the quickest, most powerful inspiration through the nose that is possible, while the operator quickly notes and measures the height to which the water has been raised by this inspiration. The operator then divides three miles reduced to feet, which is equal to 15,840 feet, by one-half the number of inches that the patient has raised the water in this instrument. The quotient represents the number of feet that the atmospheric relations have been elevated for every inch that the patient's ability to raise water in this instrument has been reduced by the operation in the nose.

The patient described in CASE No. 1 raised water in this instrument to 36 inches. One-half of this number is 18 inches, by which 15,840 feet, or three miles reduced to feet, are divided, giving a quotient of 880 feet for every inch of reduction of height to which the patient could raise water in this instrument by means of the nasal operation. The partial turbinectomy has in this case reduced this ability to raise water so that the patient could only raise it to 12 inches, which when subtracted from 36 inches, leaves 24 inches reduction in the height to which the patient could raise water. Eight hundred and eighty feet are then multiplied by 24 inches, which gives 21,120 feet elevation of the atmospheric relations during inspiration. This number is divided by the number of feet in one mile, which is 5,280 feet; this gives an elevation in the atmospheric relations of this patient during inspiration as the result of a single turbinectomy equal to 4 miles. The reader can apply the above rules to every case after having observed what his ability for raising water was before and after an operation. No operation on the septum could have produced the above result.

the tonsils is the following: Each tonsil should have a drop of 2 per cent. solution of novocain placed on it above the place where it is anticipated that the hypodermic injection will be made, from a dropper consisting of a large-sized rubber eustachian catheter with a rubber bulb at one end. These drops should be repeated three times in one minute. In five minutes from the time that these drops were first applied an hypodermic injection of 1 per cent. solution of novocain to the amount of 10 minims is made in each tonsil to be removed. Five minutes after this injection of the drug into the tonsils the operation for their removal should be commenced.

CASE I.—B. J. Age twenty-nine years. He has had pulmonary tuberculosis for three years and had consulted several specialists regarding it without any beneficial results. He consulted the author on the 1st of September, 1902. His weight was 110 pounds. He raised water in the respirometer to 36 inches. The author removed one-half of the lower turbinated bone from the right nostril, after which the patient could not raise water to more than 12 inches. This changed his atmospheric relations to an elevation of four miles. His cough ceased within three weeks. He followed his trade, supporting a wife and four children. His weight increased to 150 pounds, making a gain of 40 pounds, which by a continuation of forced nourishment he retained. He never has had any secondary attack of tubercular disease since.

On March 1, 1903, the tubercle bacilli, which had always been present in his sputum, had disappeared. There is no cavity of a pathological nature in his lungs and there is every evidence that he has been cured of pulmonary tuberculosis.

This case and other patients with similar diseases, having the same treatment, demonstrate that when their diseases are not complicated by pathological cavities in their lungs tubercle bacilli will disappear in less than seven months provided they can tolerate the forced nourishment. If the weight gained during the first treatment is maintained there will not be any secondary attacks of pulmonary tuberculosis.

CASE II. W. B. Age twenty-six years. Had chronic bronchitis and catarrhal laryngitis from which he had suffered for years. Weight was 140 pounds. He did not show tubercle bacilli. He was constantly acquiring additional attacks of bronchitis complicated with cough and growing hoarse. The author was consulted August 4, 1902. The patient thought that the disease was pulmonary tuberculosis. Water was raised in the respirometer to 36 inches. After turbinectomy the patient could not raise water to more than 16 inches, which showed his atmospheric relations to have been elevated to 3.33 miles. This operation removed every annoying symptom within one week, and subsequent exposures to the weather did not cause the patient to develop catarrhal diseases in the air passages.

CASE III. C. S. B. Consulted the author on August 23, 1904. He had suffered from hypertrophic nasal catarrh for years. Many specialists had been consulted but all had advised him against submitting to any operation. He had never found a climate that was favorable to his disease in winter. He could raise water in the respirometer to 40 inches; after turbinectomy he could raise it to 15 inches, *i. e.*, his atmospheric relations were raised to 3.75 miles. In ten days every annoying symptom had disappeared.

CASE IV. H. J. Age fifteen years. The author was consulted on the 10th of April, 1890, which was two years before the respirometer had been discovered. He had attacks of suppurative disease in the right middle ear; heard a watch in this ear at two inches. The left ear had chronic catarrhal otitis media. In this ear he heard a watch at four inches. The defects in his nasal passages which caused the deafness were a deformity of the septum and a misplaced turbinated bone in the right nostril. He had consulted many specialists in New York, who had tried to relieve his nasal obstructions with various cauteries, which had left the adjacent surfaces of the septum and the turbinated bone denuded of mucous membrane, in consequence of which they were firmly adherent to each other. The deformity of the septum was first cut free by the saw from the septal side. The saw was next placed behind the turbinated bone, which was amputated. This obstruction when removed from the nostril consisted of the septal deformity, which was firmly united to the lower turbinated bone. The hearing was found within one month in the right ear to be equal to an ability to hear a watch at 30 inches, while the left ear heard a watch at 45 inches. The patient never had any further trouble with his ears.

CASE V. Age thirty-six years. Consulted the author on March 10, 1903. He had been developing catarrhal deafness for ten years, and could only hear conversation through a speaking tube. He raised water in the respirometer to 40 inches. After the removal of a misplaced turbinated bone he could only raise water to 13 inches, so that his atmospheric relations during inspirations were elevated to 4.05 miles. He commenced to improve in hearing within two months. There was no difficulty in carrying on ordinary conversation with him at the termination of three months.

CASE VI. W. H. W. Age forty years. He consulted the author on June 11, 1903. He was suffering from suppurative inflammation of his lachrimal duct, for which the author removed one-half of the lower turbinated bone on the affected side. The bone was covered with intensely hypertrophied tissue, which was considered sufficient cause for this disease. He raised water in the respirometer to 40 inches. After the removal of one-half of a turbinated bone from the affected side he was able to raise water to 10 inches only, so that his atmospheric relations during inspirations were elevated to about 4.5 miles. The operation cured the catarrhal disease of his nose, which had been the cause of the suppurative disease in his lacrimal duct.

CASE VII. J. H. Aged 28 years. Consulted the author on June 2, 1902, regarding attacks of hayfever. She had developed the attack during the second week in August for the past four years. During her first visit she could raise water in the respirometer to 36 inches. After the second week in August until frost appeared the water would be raised into the patient's mouth every time an experiment was made with the respirometer. On January 4, 1903, one-half of both lower turbinated bones were removed, so that she was able to raise water in the respirometer to 6 inches, which was exactly one-sixth of the height to which she formerly raised it. These turbinectomies elevated her atmospheric relations during inspiration to an altitude of five miles.

The hayfever never appeared again after this operation.

CASE VIII. J. S. Age thirty-six years. Consulted the author on December 15, 1903, regarding periodic attacks of asthma. There were no manifest diseases of the heart. He usually turned dark during these attacks, and they usually required a hypodermic injection of sulphate of morphia to relieve these spasmodic attacks of the disease. He raised water in the respirometer to 40 inches in March, 1903, which was reduced by a double turbinectomy to six inches, which raised his atmospheric relations during inspirations to 5.1 miles. These operations cured his periodic attacks of asthma and he has never had another attack of this disease.

## ETHER-OIL RECTAL ANESTHESIA; SOME THEORETICAL CONSIDERATIONS.

By H. CLIFTON LUKE, M.D.,
NEW YORK.
ANESTHETIST TO ST. LUKE'S HOSPITAL.

THE administration of ether per rectum has once more taken on a certain degree of popularity, the present advocates of the method using it in the form of an oil-ether enema. The results here, in the hands of experienced anesthetists, have been variable, some praising, others disfavoring the method. There are some theoretical objections, however, to the procedure, and it is the purpose of these remarks to deal with the subject chiefly from this viewpoint.

The usual technique, omitting special refinements, is in brief as follows: Effort is made to thoroughly cleanse the intestinal tract, especially the large intestine, beforehand; a hypodermic injection of morphine, sometimes in combination with atropine or hyoscine, is usually given one-half hour before injecting the ether; the mixture of ether and oil (olive oil being mostly used), containing about seventy-five per cent. ether in adult cases, is given in a single dose of six to eight ounces by volume very slowly through a small catheter into the lower bowel. This is injected about thirty minutes before operation, the patient being in bed until the unconscious state is reached. If surgical anesthesia is not obtained in thirty to forty minutes, more ether is injected per rectum or administered for a brief time by inhalation.

Can we say that this method is founded on a good scientific basis? In other words, is it exact or accurate? The administration of ether, to be exact within a reasonable meaning of the term, should have the dosage, or amount administered, under direct control, which in turn exercises a fairly definite influence on the dose or amount actually absorbed. This fundamental requirement does not appear to be fulfilled here: (1) because the entire dosage is estimated, and placed in the intestine for absorption before essential information is acquired by the anesthetist regarding, (a) length of time the operation will take (which is often impossible to know), (b) the patient's resistance, susceptibility, or even special idiosyncrasy to the drug; (2) because a portion or all of the mixture may be expelled and lost, in which event an estimation of the amount still retained would be largely guesswork; (3) since there is also a small chance of error if the mixture is given in the usual manner by pouring through an open-topped funnel; over a period of five minutes material loss by evaporation could occur.

Then, in reference to the important question of dose there also appears to be considerable uncertainty, and the reasons for this are: (1) the influence of the inaccurate dosage as pointed out above; (2) the patient's age would have a bearing on the rate of absorption, a given quantity of ether probably entering the blood stream in young people, in considerable less time than it would in those past middle life; (3) position of the solution in the large intestine has, undoubtedly, a marked influence on the rate of absorption. It is impossible to know just how high it goes in any particular case, which adds to the uncertainty; but it seems highly probable that in some cases reverse persistalsis may take place carrying the mixture into the cecum, making its recovery, in case of over dosage, practically impossible and materially increasing the rate of absorption. Practical proof of this possibility is shown in Stewart's case where a lead pencil, inserted into the rectum, soon reached the cecum from which it had to be removed. Also in Chapin's work on babies where *x*-ray examinations showed, after low injections of bismuth solution, that this material practically always reached the cecum. LeWald further states that low rectal injections of bismuth solution pass into the ileum in about 10 per cent. of cases due to incompetency of the ileocecal valve, and that in over 90 per cent. the solution reaches the cecum. That this factor has an important practical side is evidenced by the fact that the Trendelenburg position (the necessity for which cannot always be foretold) is considered by some to contraindicate the use of the method; (4) pathological conditions of the rectum, sigmoid, or descending colon might strongly retard or increase the absorption; (5) an excessive amount of ether is probably absorbed (*a*) because the induction period is prolonged (frequently requiring one-half to three-quarters of an hour), which is due to the slow absorption, the mixture having not yet reached a very high position in the intestine. Likewise, in the administration by inhalation of vapors of insufficient strength, patients can be given excessive quantities of ether without obtaining surgical anesthesia, whereas a much smaller amount expediently administered gives the desired result in very much less time; (*b*) since olive oil is said to hold the ether in close combination and give it up slowly, absorption may continue for a considerable time after operation and delay the recovery, as there is no way of determining how much of the mixture still remains in the intestine after the passage of tubes or irrigation; (6) the varying amount of intestinal surface exposed to the action of the mixture; (7) the claim for even and constant evaporation of ether from the mixture would hardly seem valid, for many surgical cases run more or less severe temperatures, the influence of which toward increasing the absorption must be considerable in view of the low boiling point of ether.

Among other theoretical objections would be the possibility of a special form of toxemia from absorption; for a powerful solvent is placed immediately before it is to enter the blood stream, in direct contact with a variable amount of highly toxic intestinal material. Does it not seem possible, therefore, that definite quantities of toxines may thus be assisted to re-enter the circulation? If so an extra burden is placed upon the eliminative functions, and the vitality of the patient suffers accordingly. Furthermore, the mode of reaching the vital centers by the anesthetic is circuitous, it having to first enter the venous blood and be conducted through the portal system before reaching the right heart and lungs. It would seem desirable to introduce an anesthetic into as clean and accessible a part of the body as possible where it may immediately enter the arterial circulation, and reach the nerve centers by the most direct course. The pulmonary route fully meets these requirements.

The routine use of morphine is said to be necessary with the rectal method, which has the disadvantage of depressing the respiratory center and locking up the secretions; objections which here seem to have special import. Furthermore, the respiratory center cannot utilize its protective function against over-dosage in the rectal method, as it may in the inhalation methods where the administration is under direct control, because with the former depressed and superficial breathing does not automatically lessen the intake of ether, since the dosage is independent of this protection. In fact, the opposite appears to occur since the more ether absorbed the greater the respiratory depression and the less the respiratory interchange, resulting in retarded elimination with consequent cumulative ether effect. Lastly, that a normal anus should often be severely irritated in this procedure seems only natural to expect, and if a fissure or hemorrhoids were present the outcome might be quite serious.

The advantages of the oil-ether method outside of its simplicity seem to be more apparent than real. In fact, with the possible exception of selected cases of bronchoscopy, it is difficult to see any indication for its use that cannot be as well and probably more safely met by the modern pulmonary methods.[2] Its chief advantages are said to be found in surgery of the head and neck, since there is no hindrance to the operator in the way of anesthetic apparatus. The ordinary intratracheal catheter could not inconvenience the surgeon much, either, and the intratracheal method offers a much greater margin of safety to the patient, especially in surgery about the face, mouth, and neck, for several reasons; first, because it affords an efficient protection against pneumonia of the aspiration type; second, because it provides a delicate and even control of the ether dosage, enabling one to maintain a very light narcosis, and establish the coughing reflex at the close of the operation; third, it further conserves the patient's vitality by providing perfect aeration, thus obviating any possibility of obstructed breathing or necessity of packing off the throat, with the use of nasal tubes. In our series of intratracheal anesthesias we note that it has been employed forty times in operations about the head and neck (over half of which were resections of the upper and lower jaw and tongue and plastic procedures), without a single case of pneumonia or anesthetic complication, except one case of subcutaneous emphysema, which recovered. On the other hand, the only jaw resection we have done with the oil-ether method died with an aspiration type of pneumonia twenty-two hours after operation. This patient, a fairly vigorous man of about fifty years, really never recovered from the anesthetic, and was in a most profound state of narcosis for nearly six hours. Six ounces of ether and two ounces of olive oil were administered in the usual manner, and both before and after the operation was completed the colon was repeatedly irrigated without apparent benefit. This case is cited here simply to point out one of the method's shortcomings in this kind of work. Another advantage is said to be the very quiet type of anesthesia produced, which is common in any method where there is a free air-way. But it must be remembered that most patients profoundly under ether behave in this manner. In a good ether anesthesia the depth of narcosis is intelligently and gradually varied to meet the operative requirements during the different stages of the operation. This would appear to be possible only when the dosage is under direct and definite control.

In closing these remarks it may be well to mention some of the undesirable clinical features which must certainly be looked for in a method involving so many theoretical objections. The following are offered for consideration: (1) The rather exhaustive and unpleasant experience accompanying any special rectal preparation, as required here; (2) the occasional necessity and inconvenience of preliminary and subsequent proctoscopic examinations, as a matter of safety and caution; (3) occurrence during the induction period of cramps, with distressing sensations of fullness and pressure in the lower bowel, accompanied by desire for stool; varying degrees of anal irritation occuring early or late; (4) prolonged induction stage with frequent necessary recourse to the inhalation method; (5) any time after the first fifteen or twenty minutes' respiratory depression may rather suddenly or slowly appear, followed by arrested breathing, loss of muscular tone and diluted pupils, with the possibility of fatal syncope supervening; (6) the occurrence of mild to very severe grades of proctitis and colitis, these complications appearing in more aggravated forms where any pre-existent pathological condition is present; (7) delayed recovery, which may be prolonged for many hours; (8) increased toxemia, dependent on a number of factors already discussed and which has recently been pointed out by Coburn.[3]

We believe that any method of administering ether to children, old people, or cases at any age where there is more than the average risk, that does not provide for immediate and definite control at all times, is certainly hazardous. It is also contended that any principle of administration which attempts to figure the dosage of ether on the basis of body weight is unscientific and impractical; because the influence and importance of personal equation in drug dosage is a matter of every day experience, and in operative work there are a number of other factors which always play an important rôle in the amount of anesthetic required.

To point out some of the theoretical shortcomings of a method does not necessarily condemn that procedure; but by presenting the possibility of undesirable or dangerous symptoms and results, it may help to temper with conservatism the light-hearted manner in which many of these new propositions are taken up, especially by those who are inexperienced.

## THE PRACTICAL, SCIENTIFIC DIAGNOSIS AND TREATMENT OF STERILITY IN THE MALE AND FEMALE.

BY MAX HIRSHBERG, M.D.,

NEW YORK

ASSISTANT, GENITO-URINARY DEPARTMENT, BELLEVUE HOSPITAL DISPENSARY.

THE method of procedure generally employed in cases of sterility is far from accurate, even in the hands of the most up-to-date physician. It may be

summarized as follows: A condom specimen of the husband's semen is examined, and if found normal, the wife is examined for any abnormality of the genitals. In case an anteflexion or stenosis is discovered, the woman is subjected to a curettage or dilatation, and to one of the operations on the cervix which the physician may prefer. If this is not successful she may have the operation repeated in part by the same or by another physician, and finally the operation of exploratory laparotomy might be suggested.

The above method of procedure, which is the one generally followed, with the exception that the operative procedure varies with the abnormality discovered on examination, is probably the best that could have been followed heretofore. From the results of my experiments and study of many cases, however, I consider it far from ideal. In the first place I desire to emphasize the fact that the mere finding of normal spermatozoa in the condom does not by any means absolve the husband from being the cause of sterile wedlock. The husband may be suffering from a marked hypospadias or epispadias, in which case the condom specimen would be filled with normal spermatozoa, but on account of the abnormal position of the meatus (unless the cervix be also placed in a peculiar position) the stream of semen is directed away from the genital orifice of the female or even, in particularly bad cases, may not be ejaculated into the vulva at all, but entirely outside the genitals. He may be suffering from premature emissions (where in very bad cases the ejaculation takes place before the penis has a chance to enter the vagina) and still, in such a case again, the condom specimen might be all that can be desired. In certain cases of stricture of the urethra the seminal fluid is not at all ejaculated, but dribbles out after coitus when the penis resumes the flaccid condition, and here again the condom would show normal spermatozoa. But even should it be proven that the husband is absolutely normal in this regard (and I will explain how this can be definitely determined) the operator still does not know that the particular abnormality discovered in the female is the cause of the sterility, or that the relief of such abnormality will cure his patient. In other words, he is working entirely in the dark.

In the following pages I will attempt to show how a preoperative diagnosis of the cause of the sterility may be determined in many cases, and how it may be treated scientifically as a result of such accurate preoperative diagnosis. The method of procedure has been so simplified as to bring it within the reach of the average physician.

This method consists in examining specimens of mucus taken at various times after coitus from the vagina, cervix, and fundus uteri, and examining these for live and dead spermatozoa. From such examinations we can in many cases definitely decide where the seat of the trouble lies. Thus, it would seem ridiculous to blame an anteflaxion for the sterility, when an examination shows live active spermatozoa in the fundus uteri, thereby showing that the flexion, no matter how acute, did not present a barrier to the progress of the spermatozoa. Yet how many women have been subjected to operation for sterility on no more pathological evidences than this.

At first blush one might imagine that examinations of mucus from the fundus uteri would have no value, but if my technique is carefully followed we shall see that this is by no means the case. It is true that if the examination is made shortly after coitus, and if we then find spermatozoa in the cervix, and also in the fundus uteri, we cannot be absolutely sure (even with my instrument) that the spermatozoa found in the fundus uteri may not have been pushed forward with the instrument as it passes through the cervix, or that they may not have adhered to the instrument from the cervix on its way out; but if the investigation be made later, say between one and two days after coitus, and if the precaution has been taken to make first several examinations of the mucus of the *cervix*, we shall find in most cases examined at this time, either no or only dead spermatozoa in the cervical mucus, and then if we find live spermatozoa upon reaching the fundus, we can say that these came from the fundus and have not been brought from anywhere else; in other words, that in this particular case the flexion is not the cause of the sterility. And such cases are not exceptions by any means. It is true that the later after coitus examinations are made the more difficult it is to find spermatozoa, but if they are found we are much more certain where they came from and the information as regards diagnosis and treatment is of much more value. The longer after coitus the examination is made the less likely are we to find live spermatozoa, or indeed, any spermatozoa at all, outside of the fundus uteri and cervix. Those in the vulva, especially around the meatus urinarius, die within a very short time; those in the vagina, in the vast majority of cases, are all dead at the end of one or two hours. It is only those that are protected in the interior of the cervix and body of the uterus that remain alive for several days, so that for accurate diagnosis it is necessary to make several examinations, some at least two or three days after coitus. It may be set down almost as a truism that any spermatozoa found several days after coitus must have come from the uterus.

Inasmuch as the technique of recovering spermatozoa from the female genitals has been described by me in detail elsewhere,* I will not repeat it here, but will refer those interested to my previous work on the subject. I will here describe my method of procedure, which is the result of over five hundred examinations.

My method in a given case of sterility would be as follows: The wife presents herself as soon as possible after coitus, and we take specimens from the mucus of various portions of the genital tract and draw the following conclusions:

If live spermatozoa are found in the cervical mucus we can at once absolve the husband from all responsibility. In this case we do not need to care whether the husband has stricture, old epididymitis, hypospadias, or what not, or whether the husband is somewhat impotent as shown by premature ejaculation. In other words, we need not care what the condition of his sexual apparatus is, for we know at once that as far as impregnation is concerned his organs are satisfactory. Similarly, we need not listen to the wife's complaint that all the semen runs out of her immediately after coitus, for we know enough spermatozoa are in the cervical canal for purposes of impregnation.

If dead spermatozoa are found in the cervical mucus, it is safer to get a condom specimen to see whether the spermatozoa came out dead, or

*Hühner: "Sterility in the Male and Female and Its Treatment," Rebman Co., New York, 1913.

whether they were killed after they had entered the woman by the latter's secretions. If for some reason or other (as when the wife does not wish the husband to know that she is investigating the subject) we cannot get a condom specimen, we determine this point by the observations of Ultzmann, to wit, that when spermatozoa have been ejaculated alive and later died their tails are straight, whereas spermatozoa that have never moved have their tails curled up. If in such cases we find the secretions of the vagina markedly acid and possibly also those of the cervix, we may order a phosphate of sodium douche before coitus, and will then sometimes find the spermatozoa alive at the next examination.

If after careful examination we find spermatozoa in the cervix but never beyond the internal os or angle of flexion in an anteflexed uterus, we may conclude that the flexion is the cause of the sterility as far as can be determined, and a dilatation and curettage are then indicated.

If we find lively spermatozoa in the body of the uterus we may conclude that no matter how acute the flexion it is not the cause of the sterility. In all probability the sterility in such case is due to one of two conditions, either an undeveloped or infantile uterus, which cannot support a growing fetus, or to some trouble higher up, such as either a stenosis of the tubes or some ovarian trouble. The condition of the uterus can be determined from the local examination, with the special precaution not to depend entirely upon palpation, but to determine the size of the uterus by the uterine sound. Very often the uterus is so extremely flexed and doubled upon itself that to the examining finger it appears very small and infantile, but upon introducing a sound we find that the canal is of proper length nevertheless, and that the uterus is only apparently small. In determining the condition of the uterus by the uterine sound we must not be guided entirely by the length, but must determine how much is cervix and how much is body. We often find a long uterine canal by the sound, but on examination with the speculum see that almost the entire uterus is made up of cervix with but an extremely diminutive body. Such a uterus (unless the body can be developed) is obviously unfit for impregnation.

If, however, we find a perfectly well-developed uterus containing live spermatozoa several days after coitus (in the fundus), and if nothing wrong is found on palpation in the adnexa, we may then conclude that there is some stenosis of the tubes or some other pelvic condition not appreciated by palpation, and it is then, and then only, that a laparotomy may be considered and be justifiable. The statistics of the cure of sterility by laparotomy are poor enough as it is, and ought not to be made worse, and the whole procedure discredited by operating before a distinct indication, as outlined above, presents itself. I believe, however, that if we operate only in cases as above indicated, the results will be much better than they are at present.

If we find dead spermatozoa in the body of the uterus, and live ones in the cervix, we may conclude that it is not the flexion that causes the sterility, as the spermatozoa have passed it, but that it is the condition of the uterine endometrium that has killed the spermatozoa. In all these examinations we must take into consideration the time after coitus the examinations are made. As stated above, it is advisable to make the examinations as soon after coitus as possible. Sometimes, however, the patient does not appear until the next day, and then we may examine nevertheless, only making allowance for the lapse of time. In the above case a curettage would be indicated. We must also remember that the endometritis may be the result of a flexion or displacement of the uterus and direct our treatment accordingly.

If no spermatozoa at all are found in any portion of the genital tract, or only dead ones are found in the vagina, but none at all in the cervix, the fault may be either with the husband or the wife. We then request a condom specimen, and if live, active spermatozoa are found therein, the fault may still be with the husband or with the wife. It may be the case of a normal penis with an abnormal position of the cervix, such as a long, conical cervix, a very short cervix, or a cervix pulled out of position by adhesions or otherwise dislocated. Again there may be in the male organ a condition of hypospadias, epispadias, or stricture of the urethra, or any of the functional sexual disorders, such as premature ejaculation, etc. As long as no spermatozoa are found in the cervix it is always advisable to examine the husband, no matter what we may find in the condom specimen.

If we find that the fault is with the husband no operation should be performed on the wife, except if indicated for some other complaint aside from sterility.

If we find that the husband has normal spermatozoa in the condom, but is suffering from hypospadias, epispadias, stricture, or functional sexual disorder, these should be remedied, if possible.

If on several examinations and after long periods of continence there never are any spermatozoa in the semen at all, either dead or alive, the husband should be examined for signs of old epididymitis, atrophic testicles, or tuberculous testicles. It has been noticed that tuberculosis of one testicle causes an absence of spermatozoa from both testicles, and often the absence of spermatozoa precedes by two years the clinical appearance of the tuberculosis. Conversely, therefore, in every case of sterility in the male, without other obvious reason, we must suspect tuberculosis of the testicle. In the vast majority of cases, however, we shall find signs of an old epididymitis, or the history of an acute epididymitis several years before. In rare cases, too, we may find a syphilitic epididymitis which requires the regulation treatment.

If we are in the presence of an old chronic epididymitis of several years' duration, we ought first to determine if either testicle secretes spermatozoa before we can suggest any treatment. We must remember that the sexual function (by which I mean that which determines the sexual passion) and the secretory function of the organ, are each entirely independent, and the fact that the man's sexual passion and ability are normal, does not imply that spermatozoa are secreted. In such a case, therefore, we should first aspirate the testicles† in order to determine if one or both testicles have retained their ability to secrete spermatozoa. If no spermatozoa are found in the testicle after various periods of continence or immediately after coitus, I do not believe anything can be done for the individual, although it may not be wise policy to tell him so, as there are on record cases of

†The technique of aspiration of the testicles is fully described in my book above mentioned.

suicide due to the fact that patients were told that they were hopelessly sterile. There are other reasons also which will readily suggest themselves why the patient should be kept in ignorance; but in any event he must be kept away from quacks. I certainly would not advise operation in these cases. This is very important, as I know of one case where a prominent surgeon wanted to perform the operation of epididymovasostomy, where I had repeatedly found nothing but clear serum in the testicles.

If we do find live, active spermatozoa in one or both testicles, we may attempt to treat the prostatic urethra by deep urethral injections, and also to massage the prostate. Although the authorities assert that nothing can be done in these cases, still in a few I have seen a reappearance of spermatozoa in the condom. This method has the additional advantage that it does not lay the patient up, that it cannot possibly do any harm, and that it does not interfere with any more radical procedure that may be determined upon later on. If anything, it materially improves the chances. I am led the more to this conclusion because I have observed that the more radical operation of anastomosis is mostly unsuccessful, and I therefore would not recommend it until other milder methods have been tried. If there is no reappearance of spermatozoa within six months of treatment I think it may be abandoned.

In this latter condition and before recommending the operation of epididymovasostomy we may attempt the procedure I have recommended elsewhere,* namely, that of injecting the aspirated testicular fluid directly into the cervix of the wife, either with or without the addition of prostatic fluid.

In the foregoing pages I have endeavored to outline the treatment of sterility in the male and female upon scientific principles, so far as our present knowledge permits. When we get more light upon certain obscure physiological problems the treatment may have to be changed. Yet one word more. We must never positively promise a cure, no matter how definite the pathological condition is. In the first place, the removal of an obvious impediment does not guarantee that some more serious impediment does not exist higher up, and in the second place there are cases of sterility where we can find absolutely nothing abnormal in either party (even on laparotomy in the female) and still for some unknown reason the sterility persists.

We also find cases where the parties separate and marry other persons, and both parties subsequently have children with their different mates. On the other hand, we ought not to give an absolutely bad prognosis, except where the husband has no spermatozoa at all. It is not by any means rare for a woman to conceive after years of sterility, even where everything had apparently been done for relief without result, and where all hope (as well as all treatment) had been abandoned for years. Nor is it rare to find a very small uterus that on examination seems positively too small for maternity, develop for some reason or other, without any treatment whatsoever, and the patient conceive afterward.

## FOUR CASES OF MULTIPLE MYELOMA.

By Morris H. Kahn, M.D.,

New York,

Resident Physician, Private Pavilion, Mount Sinai Hospital.

Multiple myeloma has been defined as "a primary neoplasm of the bone marrow, affecting chiefly the sternum, the ribs, the vertebræ, and the skull, the substance of the bone being more or less replaced by tumor tissue."[1] Though its discovery is sometimes dated later, J. von Rustizky[2] first described and christened it in 1873. Since that time various observers have written on the subject. In 1907 Permin[3] recorded forty cases, and in the following year Decastello[4] added two. In the recent literature I have been able to find fifteen additional cases. Of these, eight are reported from Germany, five from the United States, one from England, and one from France. The present report adds four cases, making sixty-one in all.

Pathologically, depending greatly upon the opinion as to the cells of the medulla from which the neoplasm arises, the disease has acquired various designations: Myeloma (Rustizky), sarcoma (Butlin[5]), intravascular endothelioma (Marckwald[6]), lymphosarcoma (Wieland[7]), myelosarcoma (Odenius[8]), lymphadenia ossium (Nothnagel[9]), erythroblastoma (Ribbert[10]), and plasmoma (Hoffmann[11]). Versé[12] recently proposed a nomenclature adequate from a histogenic standpoint. As there seems to be no uniformity in the histological structure of these medullary new growths, he gives the name myeloma a generic signification without regard to the cell type found in the tumor. The name myelocytoma he employs to designate those tumors arising from the specific marrow cells, the myelocytes. The plasma cellular myeloma or plasmacytoma, arising, as Wright also assumes, from an abnormal proliferation of these cells, he considers a type of lymphocellular variety of tumor.

Two of the cases reported by Versé were plasma-cell myeloma. In these, characteristic plasma cells composed the bulk of the tumors; thickly placed, polygonal in form, they produced a mosaic appearance. The nuclei were round and presented two or three clumps of chromatin. Small cells of a different type, granular cells and large giant cells were also present. But these were found only in the less characteristic parts of the tumors, near the periphery, and the author believes the giant cells to be reactive irritation forms. He named his third case diffuse myelocytic myeloma, showing as it did, bone elements microscopically: myelocytes, lymphocytes, polymorphonuclear leucocytes, megakaryocytes of large size, and myeloblasts.

Schmorl[13] demonstrated a case in which plasma cells formed the picture of the tumor, and Simonds[14] names his cases plasmoma. Berblinger's[15] case is of the same nature. Both of Stumm's[16] cases showed, as is recognizable from description, plasma cells predominating. Zinninger's[17] two cases were of a similar nature. Norris[18] recorded a case in which two types of cells occurred in the bone tumors, one a large cell with granular protoplasm, a large nucleus and scanty chromatin network. The other cell, smaller, had eosinophilic protoplasm and a small dense nucleus and was believed to be erythroblastic in origin. The consensus of opinion on this tumor was in favor of its being plasmacytic. Ewing[19] found that in most bone tumors the cells resemble neoplastic marrow cells of various types.

Williams'[19] case was found to be composed of round cells. The case reported by Morax[20] with orbital and cranial involvement showed myelocytic proliferation. A tumor invading the kidney of a ten-month infant suffering from anemia was reported by Tixier[21] to have been composed of nucleated red blood cells, myelocytes, undifferentiated lymphocytes and megakaryocytes enmeshed in a fine reticulum and blood vessels, giving it an embryonal character. He believed this tumor to have been a myeloid growth in the viscus. The case of Hohn[22] is myelocytic in structure. Fischer[23] reported a case in which an epitheliomatous tumor was associated. The case of Austin[24] is interesting, being complicated by healed tuberculosis, pulmonary, pleural, and peritoneal. There followed complete disappearance of the bony substance of the twelfth dorsal vertebra, and there were other foci in the neighboring vertebræ and in the ribs.

The disease is clinically characterized by the presence of irregularities of the surface of the bones involved, leading to spontaneous fractures. It occurs in the latter half of life and affects chiefly males. Of the cases reported during the past three years, only that of Hohn was a woman, forty-three years old. Nine of the cases were between forty and seventy, and five of these were in the seventh decade.

The onset is insidious and the symptoms are extremely puzzling. The diagnosis early either is not made or only surmised by exclusion. A question of considerable interest involves the relationship of trauma to the disease. Often the sequence of events would lead one to construe injury as a direct factor, and it is notable that in several cases first attention was drawn to the existence of the disease by some such cause. In Simmonds' case a fracture of the arm, and in two of Versé's cases trauma seems to have played a rôle. In his first case the lumbar spine was injured, and it was there that the most marked pathological changes were later found, and in the second case a rib was fractured by a blow on the chest.

Pain in the bones and tenderness on pressure over them are important features. Subjectively, this symptom has figured in every case. It is vaguely localized over the chest or spine, and often from there radiates down the thighs. Headache may be an expression of cranial involvement and be very severe. In Schmorl's case the circumference of the skull increased three centimeters during the illness. The pain compels the patient to remain abed, and sometimes precludes movement even while lying down. The malady presents a progressive course with emaciation and anemia. Remissions sometimes intervene. The course of the illness varies from one month to one and a half years, and so far as is known, always proves fatal. Pallor is sometimes a more marked symptom than loss of weight. Together with an obtrusive asthenia the former may suggest pernicious anemia, especially when symptoms referable to the spinal cord supervene. Such symptoms in many cases form the first complaint. Weakness of the lower extremities with sensory disturbances are attributable to spinal complications, as are probably also the involuntary evacuations which later take place. The spinal cord may be affected by pressure from the vertebræ. When these are extensively diseased deformities may result.

Pulmonary complications are comparatively frequent, not only terminal when they seem to be very common, but also during the course of the disease. In three of the cases here reported the lungs gave signs of involvement. Whether the proximity of fractured ribs has any relationship to it is doubtful. Metastatic growths in the viscera are not a part of the clinical picture. Parkes Weber[25] states that the disease nearly always remains limited to the osseous system, though by direct extension it may form localized outgrowths projecting from the bones.

The finding of multiple spontaneous fractures of the ribs is most important in the foundation of the diagnosis.[26] The ribs, sternum, vertebræ and other bones involved become friable and are easily broken as a result of the absorption of the hard osseous tissue. The ribs post-mortem can sometimes be crushed between the fingers, the cortical portion having become attentuated, and the medulla filled with yellowish-gray or reddish-gray neoplastic tissue, pulpy and granular. The vertebræ are frequently easily sectioned.

Space must be allowed for a few words on the occurrence of Bence-Jones albumosuria. It is an excretory phenomenon first described in 1847 in a case of "mollities ossium."[27] This protein differs from the ordinary urinary proteoses, being excreted in larger quantities, soluble in water, crystallizable, and is coagulated at low temperatures. The urine on heating becomes turbid at 50° C. and a flocculent precipitate forms, which clings to the sides of the test-tube and rises up in the froth. It dissolves on heating above 60° C., with the addition of acid, though some turbidity persists. On cooling the precipitate reappears. In Williams' case the urine was first clear, and later quite milky when passed. And an interesting feature of a case of Parkes Weber was the fact that the proteid was occasionally precipitated spontaneously and caused the urine to become turbid when freshly voided.

Not all cases of multiple myeloma have Bence-Jones albumosuria. There have been several cases clinically unmistakable, and some proven by autopsy, which showed no Bence-Jones protein in the urine. On the other hand, according to Garrod,[28] it has not been met with apart from disease of the bone marrow. Rosenbloom[29] states in his study of the subject that in cases of excretion of the Bence-Jones protein unaccompanied by multiple myeloma, disease of the blood-forming organs or of bone was present. Parkes Weber has expressed the opinion that cases of multiple myeloma with albumosuria are essentially different from those without it. Its origin is attributed to either abnormal metabolism of the protein of the food, as held by Magnus-Levy,[30] Senator,[31] and others, or to an abnormal metabolic or degenerative process in the myelocytes and their related and derived tumor cells, as held by Virchow,[32] Hutchinson and Weber.[33] Possibly in cases in which its presence was intermittent there was the same error of metabolism, but this has been arrested at different stages. Rosenbloom[34] has proven its possible derivation from osseoalbumoid by the action of enzymes present in the bone marrow. In a recent study of Bence-Jones proteinuria, Boggs and Guthrie[35] report three cases of its occurrence in chronic myelocytic leucemia and one in chronic lymphatic leucemia. The small amount of the albumose in the urine seems to be characteristic, according to the authors, when it occurs apart from multiple myeloma. They express the view that Bence-Jones proteinuria is not essentially dependent upon one disease, but is a manifestation of disturb-

ances in the bone marrow affecting endogenous metabolism.

The following four cases are clinically typical. The onset in all was gradual. They all complained of pain over the bones involved, had multiple costal fractures, became progressively cachectic and anemic, had spinal symptoms, pulmonary implication, and died of the disease. Bence-Jones albumosuria was present in two of the cases. In one case which did not show it during a prolonged period of observation, autopsy was performed and showed the characteristic lesions in the bones. Pulmonary tuberculosis complicated one case.

Case I.—Thoracic and spinal pain; anemia; cachexia; multiple costal fractures; spinal symptoms; pulmonary complication; coma, and death. L. M. B., a widow, fifty years of age, gave a negative family history. There were no family tendencies or susceptibility to disease. During her childhood the patient had measles. At the age of eighteen, scarlet fever was followed by otitis media, since when hearing in the left ear had been lost. Her habits were normal. Menstruation was regular. She had no children; there was one miscarriage. The patient was apparently well until seven weeks before she came to the hospital. At the time of admission her history dated from the time when, while riding in a train, a sudden jolt caused sharp, sticking pain in the lumbar spine; she fell on her back, unable to bear it. She had chilly sensations, felt weak, and after a few days took to bed. The pain was localized over the left half of the chest and over the twelfth dorsal vertebra. The patient characterized it as tearing and burning, radiating around the lower abdomen and groins, extending down the thighs to the legs and feet. This had been the most constant symptom. It was aggravated by coughing or straining. From the onset there had been marked weakness, the asthenia being general. The lower extremities, and of these the left more, were extremely weak. The patient lost 30 pounds in weight, having been normal at 190. Yet the pallor and asthenia appeared to the observer to be out of proportion to the emaciation. About one month after the onset, the patient developed a sensation of falling directly downward as she lay in bed when she attempted to turn toward the left. She also had vertigo and frequent headaches just behind the eyeballs. The eyesight was weak, but had not recently troubled her. The bowels, previously normal, were costive since she took to bed. Urination was undisturbed. Until two weeks before she came to the hospital, the patient had fever, cough and pain in the chest. The diagnosis of bronchopneumonia was made, during which illness she frequently vomited bilious material.

In the physical examination after admission the following facts were noted: General condition poor. Marked weakness and pallor. Mentality clear. Patient responsive, though somewhat somnolent. Eyes: Show slight exophthalmus. No petechiæ present. Ears: Chronic otitis media sinistra with perforation in the membrana tympani. Mouth: No pigmentation of the mucous membranes. Pharynx and tonsils normal. Thyroid gland palpable, soft, not enlarged. Muscles: Visible atrophy of the thenar and hypothenar eminences, and of all the skeletal muscles of the extremities, flabby and doughy to the touch, probably from disuse. Bones and joints: Patient generally hyperesthetic to pressure over the sternum, ribs, thighs and legs, arms and spine. Ribs: Over the upper three ribs, on each side of the sternum, on careful palpation, one discerns smooth, elevated irregularities. There is also marked irregularity and a resilient depression over the fifth rib, just outside the left midclavicular line, recognizable as the point of a fracture. Over this point the skin presents a small ecchymotic area. Spine: Tenderness over the twelfth dorsal vertebra. Flexion of the head produces pain along the spine. Chest: Expansion fair and equal. Lungs: Left lung normal. Over the right lung, from the angle of the scapula to the base are numerous subcrepitant rales, chiefly on inspiration, the remains of the former bronchopneumonia. Heart: Area of dulness normal. Action regular, fair force; soft systolic blow over the apex and pulmonic area, and louder and slightly rougher over the aortic area and right subclavian region. *Bruit de diable* audible in the vessels of the neck. Arteries show no sclerosis. Abdomen. No masses felt. No tenderness. Kidneys: Not felt. Liver: Dulness from fourth rib to free border; edge not felt. Spleen: Does not percuss large; edge not felt. Extremities: Left lower extremity very weak and flaccid. Right also weakened. Knee jerks obtained only by Jendrassik method. No ankle jerk obtainable. No Babinski. No sensory disturbances, except general hyperesthesia to pressure. Rectal examination negative. Vaginal examination: Uterus involuted, atrophic; no masses felt. The picture was that of gradual progress in the disease. The patient would lie without much moving, rather apathetic. Cough produced severe pain in the left chest and lower aodomen, and was suppressed on that account. Sometimes she vomited after her nourishment, simultaneously with a feeling of dizziness. When moved she moaned plaintively.

Gradually the patient became delirious and comatose. The delirium was low and muttering, and later she no longer spoke. Two weeks before death she still recognized individuals, but was not communicative. For two weeks she lay in coma, at times muttering unintelligibly. Then Biot's type of breathing ensued, with respirations irregular in rate and depth, long pauses and frequent deep sighing inspirations. There was slight rigidity of the neck, and the patient was still reactive to pressure on the chest. The cardiac murmur became less audible, the pulse became more rapid. Mucus collected freely in the bronchi and a monotonous gurgling in the throat attended the respirations. The pallor increased. The spleen and liver were not palpable at any time. Involuntary urinations commenced. Throughout the course of the illness the temperature ranged between 99.4° and 101° F., and the pulse between 106 and 120. The blood pressure remained normal (120 to 130 mm. Mercury, by the Rudisch sphygmomanometer). The urine was clear, light amber, acid; specific gravity averaged about 1010; a trace of albumin was present: urea was 1.8 per cent.; there was no bile, a faint trace of indican; no sugar, and negative tests for acetone and diazo bodies. Microscopically, there were many epithelial cells, a moderate number of leucocytes, and few hyaline and granular casts. No Bence-Jones albumose could be demonstrated in the urine, though several single specimens and twenty-four-hour collections were examined. The blood showed a secondary anemia. The red cells showed marked pallor and slight variations in shape and size. Erythrocytes, 3,200,000. Hemoglobin, 34 per cent. (Sahli-Gower instrument). Color index, 0.5. Leucocytes, 10,200. Polynuclear neutrophiles, 63 per cent. Lymphocytes, 35 per cent. Large mononuclears, 2 per cent. The coagulation time was seven minutes (method of Sabrazes and McGowan). The stool was green, unformed, with mucus; no ova or parasites. Tests for occult blood were negative.

Case II.—Thoracic pain; sternal and costal tenderness; anemia; emaciation; multiple costal fractures; pulmonary involvement; kyphosis; Bence-Jones albumosuria; pulmonary edema and death. G. R., fifty-eight years old, suffered for ten months from multiple myeloma before she died. Her family history was blameless. She had smallpox as a child, but no other diseases that she could recall. She had three living children, while four others died of acute febrile conditions in their childhood. She had no miscarriages. On admission the disease had been of eight months' duration. It began insidiously with pain, at first of dull character, later more acute, over the upper left chest in front and posteriorly. The pain gradually extended downward over the precordium and left hypochondrium, and laterally to the axilla and side of the chest as far downward as the lumbar region. This persisted more or less constantly, but radiated at times around both sides, producing a girdle pain at the level of the diaphragm. The pain was worse on coughing, deep inspiration, or on walking about. The patient had lost some weight and felt very weak though the appetite remained fair. She also had an occasional dry cough. There was nausea at times, but no vomiting, no hiccoughs, no fever, no dyspnea or cardiac symptoms. The bowels were costive; urination normal. The patient was in bed ten weeks before death. The physical examination revealed the following: General condition fair. Signs of senility and emaciation. There is a sudden stop at the end of inspiration, apparently due to pain. Eyes and ears normal. Mouth: Teeth and gums in very poor condition. Thyroid gland not felt. Lymph nodes not palpable. Chest: Expansion slight, equal bilaterally. Marked sternal tenderness, and also on pressure over the ribs on both sides. Marked tenderness on antero-

posterior compression of thorax. Ribs: Over the lower part of the left chest a slight depression is seen during inspiration. This area is about 3 inches in diameter, and covers the third, fourth and fifth ribs with apparent mobility and softening of the thoracic wall, with crepitus. This area is extremely tender to pressure. The cardiac pulsation is readily palpable in this region. Pressure backward on the sternal end of the first and second right ribs evinces crepitus and abnormal mobility. Spine: Marked rounded dorsal kyphosis. Lungs: At the left base over a small area near the spine there is exaggerated harsh breathing and râles. In the left axilla there is marked dullness, almost absent tactile fremitus, diminished breathing and distant voice. Elsewhere the breathing is hyperresonant. Posteriorly over the right lung there is dulness from two fingers below the angle of the scapula to the base, with a few crepitant râles at the end of inspiration. Heart: Apex beat in fifth space in the midclavicular line. Area of dulness is not increased. Short soft, systolic murmur at apex, not transmitted. Arteries show a moderate amount of thickening. Abdomen: Lax, tympanitic; no masses felt; no tenderness. Liver: Dulness extends from fourth rib down; edge is not felt. Spleen: Not felt. Extremities: Slight tenderness over both tibæ; knee jerks present; no edema. Vaginal and rectal examinations were negative. The temperature ranged between 99° and 101° F. during the greater part of the illness. The pulmonary signs became aggravated and more defined with consolidation over both bases, and for a short period the fever reached 102° and 103° F. There was a moderate expectoration of purulent sputum. The respirations were 26 to 30 per minute. Meanwhile there appeared abnormal mobility and tenderness over the upper four ribs on each side, and crepitus over the outer part of the third right rib. Later there was also observed thickening at the junction of the ribs and cartilages, especially on the right side. Anemia and loss of weight became evident. For two weeks before death the patient vomited frequently and finally there was blood in the vomitus. The thoracic pains were persistent and the lung signs unchanged. Cardiac weakness rapidly progressed, the pulse became imperceptible, and a slow extinction of life followed upon pulmonary edema. The urine was amber, clear, acid, and varied in specific gravity from 1010 to 1030. Albumin was present in large quantity. Microscopically, a few epithelial cells and leucocytes were found. Bence-Jones albumose was present in every uranalysis and persisted to the end. The blood count on admission was as follows: Erythrocytes, 4,832,000; hemoglobin, 98 per cent. (Sahli-Gowers); color index, 1.0; leucocytes, 10,200; polynuclear neutrophiles, 70 per cent.; lymphocytes, 17 per cent.; large mononuclears, 13 per cent. The anemia progressed and the count gradually changed to the following: hemoglobin, 78 per cent.; leucocytes, 8,000; polynuclear neutrophiles, 56 per cent.; lymphocytes, 37 per cent.; large mononuclears, 6 per cent.; eosinophiles, 1 per cent. The sputum, which was examined three times, showed no tubercle bacilli.

Case III.—Abdominal pain and gastric symptoms; sternal and costal tenderness; asthenia; emaciation and marked anemia; spinal symptoms; pulmonary tuberculosis; no albumosuria; death; autopsy. S. K., a Russian peddler, forty-six years of age, was ill for nine months before he came to the hospital for treatment, and died there after a stay of three months. His family and previous histories were apparently unrelated to the disease under description. He had measles in childhood and malaria when thirty years old. His wife and six children were well. His habits were good. For nine months before the patient had been complaining of severe cramp-like pains in the epigastric region. These came on about one-half hour after eating and lasted about one hour. His appetite was steadily becoming poor. Three months ago while at work, he felt dizzy and vomited several times that night. He had chilly sensations, diarrhea, and fever for a week after. The stools were watery, brown, and contained no macroscopic blood or mucus; evacuations occurred about four or five times daily. These diarrheal attacks recurred about every week for two days, with intervals of constipation. He felt nauseated at times, but did not vomit after the original attack. Since then he had a continuous sticking pain extending from the right lumbar region down the right side of the abdomen to the groin. This was worse after exertion. For some time after the attempt to urinate produced pain at the urethral meatus, but the urine had never been bloody nor contained gravel. Micturition had become more frequent, compelling the patient to rise once at night. He perspired profusely, especially at night, often with fever and chilly sensations. There was no cough or hemoptysis. For one month he had headaches, dizzy spells, cardiac palpitation and dyspnea on exertion. No syncopal attacks, precordial pain, or edema of the feet. No jaundice, rash, epistaxis, or bleeding gums. The patient had been feeling very weak and had lost much in weight since the onset. For two months he noticed tenderness on pressure over the lower part of the sternum. During the physical examination the following data were recorded: General condition fair. Some emaciation, anemia, and slight puffiness of the eyelids. Eyes: Show marked arcus senilis. Mouth: Teeth and gums in poor condition; marked pyorrhea and fetor exore. Glands: Some large anterior cervical glands; small glands in axillæ and groins; small left epitrochlear glands. Bones: Tenderness on pressure over sternum and lower ribs on the right side. Tenderness on pressure over the lower dorsal and lumbar spine. Chest: Marked supraclavicular retraction, more on the right side. Lungs: Hyperresonant note over both sides anteriorly and posteriorly. Heart: Borders obscured by pulmonary resonance. Apex beat not felt. Action slow and regular. Sounds weak and distant, with faint systolic murmur at apex and also over base. Arteries show considerable thickening and tortuosity. Abdomen: Flat, generally tympanitic, some slight general sensitiveness. Liver: By percussion, extends from sixth rib down to two fingers below the free border. Spleen: Felt two fingers below the free border. Extremities: Knee jerks exaggerated; no edema; no tibial tenderness; no irregularity of tibial crests. Genital and rectal examination negative. During the one and one-half months in the hospital, the one unremitting symptom was the tenderness over the sternum, lower ribs and the spine in the mid-dorsal, lower dorsal and lumbar regions. In addition, the patient developed tenderness on pressure over the posterior half of the iliac crests. It was attempted to get him out of bed, but the pain in the affected regions interdicted.

About one month after admission the patient began to have lung signs which were steadily progressive. At first an area was present at the base of the left lung over which there were dulness and almost bronchial breathing and voice with crepitant râles, and over the rest of both lungs were audible moist and dry râles. The area at the base of the left lung increased in size, extending up to the angle of the scapula. Then there developed râles and bronchi anteriorly over a dull area below the right clavicle. These lung signs persisted throughout until the patient's death. The respirations were between 20 and 26, but with increase of the lung signs they rose sometimes to 30, and antemortem to 34 and 40. Several times during his stay the patient had abdominal cramps for several days, relieved by movement of the bowels. Diarrhea also occurred. The abdomen showed no signs of importance. Twice after a few days of administration of Fowler's solution, he developed puffiness of the eyelids, complained of thirst and pruritus and had abdominal pain. The heart action was regular throughout. The rate was usually between 84 and 108, a few times rising higher and up to 120. There was a faint apical systolic murmur, and a murmur over the pulmonic area which became later louder and rougher. The patient rapidly emaciated and weakened. The temperature ranged between 98° and 100° F., hovering most often just above 99° F. It rose twice to 101° F., but for two weeks before death it did not go above 99° F. Just about one year after the onset of his illness the patient developed pulmonary edema and died. The urine was clear, pale amber, acid, specific gravity ranging between 1010 and 1020. There was no reduction of Fehling's solution. The urea in twenty-four-hour specimens was 15 to 20 grams and between 0.7 and 2.0 per cent. Albumin was present in faint traces at first, almost daily examinations being made. It gradually increased until it was recorded as a "heavy trace" when the patient was near death. There were present hyaline and granular casts in varying numbers in almost every examination, together with a few leucocytes, epithelial cells, and uric acid crystals. The casts increased in number with the progress of the disease. The amount of urine averaged 45 to 50 ounces daily. Repeated examination for Bence-Jones albumose in single and twenty-four-hour collections of urine were negative. The urine was examined

and found negative for tubercle bacilli. Soon after admission a few unmistakable tubercle bacilli were found in the sputum though numerous subsequent examinations were negative. The blood on admission revealed: Erythrocytes, 2,000,000; hemoglobin, 30 per cent.; color index, 0.7; leucocytes, 4,800; polynuclear neutrophiles, 49 per cent.; lymphocytes, 42 per cent.; large mononuclears, 9 per cent. The hemoglobin and erythrocytes gradually diminished. The differential count remained unchanged for some time, then varied and was as follows: Erythrocytes, 1,584,000; hemoglobin, 18 per cent.; color index, 0.6; leucocytes, 4,800; polynuclear neutrophiles, 60 per cent.; lymphocytes, 36 per cent.; large mononuclear and transitional cells, 3 per cent.; basophiles, 1 per cent. There were no nucleated red corpuscles; anisocytosis and poikilocytosis were slight; there was no tendency to megalocytosis. Seven examinations of the stool were negative for blood, ova, parasites and tubercle bacilli. Proctoscopy showed a pale normal mucous membrane. Ophthalmoscopic examination[26] during life was negative. Ewald test breakfast, removed after fifty minutes, showed a free acid content of 20 and total acidity 30; it was otherwise negative. Two other test meals showed the stomach empty at the end of one hour. Two radiographic examinations of the chest and abdomen, taken on admission and after three months respectively, were reported negative. The post-mortem examination showed typical lesions of multiple myeloma. Permission was obtained only for the removal of the involved ribs. Soft grayish white tissue was found about the ribs that could be exposed and grayish infiltration of the marrow. Microscopic examination of the tissue obtained showed the presence of plasmacellular myeloma.

Case IV.—Thoracic pain; sternal and costal tenderness; spontaneous costal fractures; clavicular involvement and fracture; scoliosis; Bence-Jones albumosuria; anemia; emaciation; death. J. W., was sixty-two years old when he was admitted to the hospital. Two months before, he had been a patient in the Presbyterian Hospital, and the case was there diagnosed multiple myeloma. His family and personal history was negative. His present illness commenced insidiously three months before with pain in the upper and lower portions of the left half of the chest anteriorly, and all over the thorax on deep breathing and coughing; in bed also on changing position. There was slight unproductive cough. The appetite was fair. The bowels were costive. There was no vomiting. Urination was frequent, but no hematuria occurred. There was no loss of weight. The physical examination revealed the following: General condition: Patient well nourished, but anemic. Eyes and Ears: Normal. Mouth: Teeth and gums in poor condition. Lymph Glands: Axillary glands felt. No lateral thoracic glands felt. Skin: Negative. Bones and Joints: There is general tenderness on pressure over the thorax. There is an insensitive swelling of the inner end of the left clavicle. The left sternoclavicular joint seems loose, permitting of greater mobility than normal. There is a depression over the inner part of the second right rib, one inch from the sternum, corresponding to a point where the rib is fractured. There is, however, no crepitus over it. A hard swelling is felt involving the sixth right rib in the anterior axillary line, two inches in its long diameter, not tender. No other bones or joints are involved. Spine: There is a prominence over the lower dorsal spine with scoliosis toward the left in this region and bulging of the left side of the thorax. Chest: Barrel-shaped; expansion poor. Depression over upper right chest as noted above, especially over the second intercostal space. Lungs: Show signs of emphysema. Heart: The right border is one finger's breadth to the right of the right sternal border. The apex beat is in the fifth space. Action is regular, of normal rate and fair force. At the apex, over the aortic area and at the base there is heard a soft, blowing systolic murmur, heard also in the vessels of the neck. The second aortic sound is accentuated. Vessels: Very tortuous and sclerotic. Abdomen: Soft, tympanitic; no masses felt. Liver: Percusses flat from the fifth rib to the free border, and its edge is felt one finger's breadth below the free border; it is hard, tender, and has a smooth surface. Spleen: Not felt. Extremities: Normal. There is no tenderness over the long bones of the limbs. Knee jerks normal; no ankle clonus or Babinski sign. No edema. Genital and rectal examination: Negative. The illness progressed in its osseous manifestations, though the patient complained only of radiating pains in the chest. A swelling developed at the inner end of the right clavicle, producing pain on motion extending down the right arm. The clavicular masses on both sides increased in size. A fracture was found of the second left rib about one inch from its sternal end with crepitus. Another fracture occurred of the left third rib about two inches from its sternal end, also with crepitus. Later there developed thickening of the fourth and fifth ribs in both axillæ. The dorsal kyphosis seemed to have grown a little larger. An early *x*-ray showed a rarefying bone process over the eleventh left rib with considerable necrosis of bone. Four months after the onset the eighth left rib was found by *x*-ray to be very irregular and thickened near its angle. One week later fracture was reported present at the sternal end of the left clavicle.

Two months after the onset of the illness, the patient's blood count was as follows: Erythrocytes: 4,600,000. Hemoglobin: 70 per cent. Color Index: 0.7. Leucocytes: 7,700. Polynuclear neutrophiles, 59 per cent. Lymphocytes: 30 per cent. Large mononuclear and transition cells: 9 per cent. Basophiles: 1 per cent. Eosinophiles: 1 per cent. After four weeks elapsed, the blood count was: Erythrocytes: 2,900,000. Hemoglobin: 52 per cent. (Sahli-Gowers). Color index: 0.9. Leucocytes: 5,400. Polynuclear neutrophiles: 62 per cent. Lymphocytes: 28 per cent. Large mononuclear and transitional cells: 10 per cent. Morphologically the cells were normal. Wassermann and Noguchi tests for syphilis were negative. The urine was light, amber, clear, acid; the specific gravity varied from 1022 to 1030. Albumin was present in large amount. The estimated urea content (hypobromite method) was 13.5 grams daily output. Bence-Jones albumose was present in all specimens examined, almost daily tests having been made. The patient died after he was discharged from the hospital with progressive anemia and finally pulmonary edema.

I desire to express my sincere thanks to Dr. Morris Manges, Dr. N. E. Brill, and Dr. Henry Heiman for their kind permission to publish these cases.

## A CASE OF VINCENT'S ANGINA, TREATED WITH NEOSALVARSAN.

BY H. H. AMSDEN, M.D.,

CONCORD, N. H.

THIS disease was first recognized by Vincent[1] in 1898, who gave a very complete account of its pathology and symptomatology; he described the fusiform bacillus and spirillum. Bruce[2] also gave a thorough résumé of the disease. Vincent[3] in 1905, also Klopstock and Kowarsky[4] describe two forms; one the ulcerous, more common, in which both the fusiform bacillus and spirillum are found; the other, the membranous or diphtheroid, much more infrequent, in which only the fusiform bacillus appears. Tunnicliffe[5,6] and Wright[7] believe that the fusiform bacillus and spirillum are different stages in the development of the same micro-organism. Various authors describe different forms or rather different degrees of severity, from a mild transitory form of sore throat, self-limited in a week or less with little constitutional disturbance, to a severe destructive process affecting tonsils, pillars, and uvula, with prostration, fever, and other marked general symptoms. Rolleston and Goodall[8] report cases illustrating different types of the disease. Coplin[9] states that recent investigators are of the opinion that the various forms of spirochetæ and spirilla found in syphilis, Vincent's angina, and relapsing fever, are not bacteria in the true sense of the term, but are animal parasites closely allied with the trypanosomes. If this be true, it would seem probable that a therapeutic agent having a curative action on a disease caused by one member of this group might have a similar action on other diseases caused by members of the same family, so to speak; hence salvarsan has been recommended by Gerber[10] and Rumpel[11] in the treatment of Vincent's angina.

The following case illustrates some phases of the disease described above:

C. A., age 20, nurse, was in charge of diphtheria cases in contagious ward of hospital. Two days after being released from duty, she was admitted to the hospital with sore throat, headache, backache, and general malaise. Objectively, the right tonsil showed a small ulcerated area covered with a thin grayish slough; there was no perceptible fetor. A slight cervical adenitis was present. Pulse, temperature, and respiration were normal. Cultures from throat were negative for diphtheria, and two Wassermann tests were also negative. Examination of smears from tonsil showed presence of fusiform bacillus and spirillum of Vincent's angina, and practically no other bacteria could be detected. During the next ten days various local and general measures were tried, including solutions of silver nitrate from 5 to 50 per cent., tincture of iodine, tincture chloride of iron, and argyrol 20 per cent., with no improvement in symptoms; the ulceration gradually extended until it covered nearly the whole faucial surface of the tonsil. It was then determined to try the effect of neosalvarsan, and accordingly 0.6 gram was injected intravenously. Following injection there was a rise of temperature to 99.2° and patient was much nauseated. The following day, throat was much improved, subjectively and objectively, and the ulceration was entirely healed inside of three days. On third day following injection, left side of throat became sore; practically the same conditions were present as on right side, though less marked. Local treatment as before was instituted, with no effect, and one week from first injection, a second of same dose was given, followed by rise of temperature as before to 99.2°, and marked nausea and vomiting, which persisted for nearly three days. Throat symptoms were relieved subjectively and objectively within twenty-four hours, and patient was discharged well on fourth day after last injection.

## A BIOLOGICAL TREATMENT FOR CANCER

BY CHARLES F. D'ARTOIS FRANCIS, M.D.,

BROOKLYN, N. Y.

THYROID gland has materially assisted those suffering from cancer (Bishop and Page, *Lancet*, May 28, 1898; Hermann, *Lancet*, June 11, 1898; Jones, *British Medical Journal*, February 25, 1911). In the *Medical Council*, May, 1912, I described an oxidizing mixture that is harmless to the organism and will effect a cure in cancer. Thyroid gland fulfills the function of such an oxidizing agent. It increases the nitrogenous and purin output of the body. Thyroid, in combination with the deficient salts, hemoglobin and the antihemolysin cholesterin seems to be a rational mode of treatment. Ross of Liverpool states kreatin, one of the purin bases, with globin, prevents the proliferation of the cancer epithelium. Hemolysis being a frequent phenomenon in cancer, I use the antihemolysin cholesterin. With the following mode of treatment I have effected what seem cures in some twelve cases. Some of these cases were inoperable cancer of the breast others abdominal cases. The length of time of treatment was three months. Cancerous ulcers of a superficial type scabbed over in a week.

FORMULA I.

℞ Thyroid gland, desiccated, 0.12 to 0.25 gram.

This should be taken an hour before the following hemoglobin mixture:

FORMULA II.

℞ Sodium chloride, 2 grams.
Potassium sulphate, 0.070 gram.
Sodium sulphate, 0.063 gram.
Calcium phosphate, 0.075 gram.
Magnesium phosphate, 0.055 gram.
Manganese dioxide (intravenously 0.008), 0.032 gram.
Cholesterin, 0.3 gram.
Hemoglobin, 3.25 gram.
Boiled water, 250 c.c.

Dissolve the soluble salts in the boiled water, filter, then add the other ingredients. This dose should be taken an hour before meals. If the intravenous injection is desired, it may be employed once a day, tricresol 0.2 per cent. being added as an antiseptic. Thyroid gland may be given intravenously or hypodermically in the dose of 0.06 to 0.12 gram once a day. If Formula II is put up dry in containers, one should add thymol 0.008 gram as a preservative; when it is to be used one should add 250 c.c. of sterilized water. With this mode of treatment one may prevent proliferation of the cancer epithelium and hemolysis, increase oxidation, and favor the action of the protective ferments.

951 St. Marks Avenue.

## Medicolegal Notes.

**Action for Compensation—Practising in Another State—Authority of Wife to Employ—Amount of Compensation.**—A physician executed a mortgage which was assigned to a personal friend, who died a bankrupt. The trustee in bankruptcy sued to foreclose the mortgage, which had been reduced by payments to $2,000. The physician set up a counterclaim for $2,500 for medical services rendered to the deceased bankrupt in his last illness. The plaintiff argued that the services in question were rendered as a friend, and not for compensation. The deceased bankrupt was a lawyer, practising in the State of New York. He attempted to commit suicide in a hotel in Newark, N. J., and was removed to the Newark City Hospital. His wife was communicated with and started from New York to Newark by automobile. On the way she requested her brother, who accompanied her, to get out and telephone to the defendant, who had rendered professional service to herself and husband for many years, and to ask him to come over to the hospital where her husband was. The defendant came the same afternoon, which was Sunday, and remained in constant attendance upon the patient until Thursday evening. He then was absent from the hospital until Friday morning, and remained until Friday night, when he finally left, having given up hope. The patient died Saturday morning. When the deceased was first taken to the hospital, which was a public hospital, treating patients without pay, he was put in a ward with other patients; but after the defendant's arrival he was transferred to a room reserved for special cases. While the rules of the hospital did not permit the defendant formally to take charge of the case, the hospital physicians and surgeons extended to him every courtesy, and all the freedom which the rules of the hospital permitted. He was in constant attendance at the bedside of the patient, and his suggestions as to treatment were complied with, and he administered some treatment himself. At his suggestion an operation for transfusion of blood was performed.

It was held that the evidence did not warrant the inference that the defendant rendered his services as a friend, and not for compensation. He had been the deceased's physician for years. It was also true that he had been an intimate friend of the deceased. While that circumstance might have had the effect of rendering his professional services to his friend more assiduous than they might otherwise have been, it manifestly did not change the character of the services. The failure of the defendant to make any charge on his books for this service and to render a bill therefor had no particular significance, because he knew that the estate was bankrupt, and, as he explained, he did not until afterwards understand that he was entitled to make a charge for his services as a counterclaim to the mortgage.

It was held that the wife had authority to employ the defendant. The case was a critical one. If the patient's life was to be saved, the unremitting attention of a skilled physician was called for; and such attention could not, in the nature of things, be received from the hospital physicians, there being between 300 and 400 patients in the hospital at the time.

The plaintiff also argued that, although a licensed physician of another State not licensed in New Jersey may act as a physician or surgeon in that State if he desires without rendering himself subject to punishment, yet he may not recover fees for such service. The court was of the opinion that the New Jersey statute was not intended to prevent the recovery of compensation for medical services rendered under the circumstances proved. Section 23 of the statute (3 Comp. St., N. J., 1910, p. 3328) provides: "That nothing in this act shall be so construed as to prevent any physician or surgeon in good standing and legally qualified to practise medicine or surgery in the State in which he or she resides, from practising in this State, but all persons opening any office, or appointing any place where he or she may meet patients, or receive calls, shall be deemed a sojourner in this State, and shall conform to the first section of this act." The court construed this section, along with section 36, providing for certain exemptions, as meaning that only those who either reside or sojourn in the State of New Jersey are subject to the requirements of the act. In any event, it held that the case might, if necessary, be decided irrespective of the New Jersey statute. The parties were all residents of the State of New York, the contract was made in that State and the action was brought in that State.

The court held that the defendant should be compensated rather upon the scale of charges for services of a family physician than the much higher scale of services of an operating surgeon. He performed no operation. On consideration of the widely varying testimony of the medical experts and the facts of the case, the compensation was fixed at the sum of $750.—Prentice v. Ladinski, 81 Misc. (N. Y.) 42, 141 N. Y. Supp. 1005.

**Implied Promise To Pay for Services to Adult Daughter.**—Action was brought for compensation for medical services rendered to the defendant's adult daughter while living in family with the defendant. The defendant was a widow, and her daughter had an interest in her father's estate. The plaintiff was called in to operate upon the daughter as the result of a family council. Three operations were performed. The defendant had paid for the first and for the consultation; the action was for payment for the other two operations. The defendant testified and the trial court found that the payments made by the defendant for the first two visits, though paid out of the defendant's funds, were made for the patient at her request, and were charged against her inheritance. No promise by the defendant to pay for the services herself was proven. The plaintiff's theory of an implied contract of the defendant to become liable for his services rested, therefore, on the facts that the patient was a member of the defendant's family, and that the plaintiff's compensation for a part of his services was paid by the defendant apparently out of her own funds, though, in reality, out of funds belonging to the patient. It was held that no implied promise was raised by these facts, following the rule that a mere request from a father to a physician to attend a child of full age, and for whom he is not bound to provide, and though sick at the father's house, raises no implied promise upon his part to pay for such medical services. The court, however, did not hold that the parent of an adult child might not, under certain circumstances, become bound to pay for medical services rendered the child upon an implied promise.—Crowell v. Donoho (Mo.), 153 S. W. 1082.

**Medical Experts: Extent of Testimony.**—In an action for personal injuries it was given as a general, though not inflexible rule, that a medical expert who has never treated an injured party, and only makes an examination after the injury was inflicted, and then solely for the purpose of qualifying him as an expert witness, may not give his opinion as to the cause of the present condition of the party, the extent and effect of the injuries, and their duration, when such opinion is based largely upon a history of the case given by the injured party to the expert for the purpose of qualifying him as an expert witness. Testimony of a medical expert, the court said, should in general be confined to the result of his actual investigations; and, when he has never been called to attend or prescribe for the party, should be limited to the conditions he finds on the examination, and to his opinion based thereon.

Testimony of a medical expert that the plaintiff whom he examined to qualify him as a witness could not deceive him as to her condition was held to be improperly received, for the reason that that question was for the jury.—Hintz v. Wagner, North Dakota Supreme Court, 140 N. W. 729.

## THE NEW YORK QUARANTINE.

At the annual meeting of the Medical Society of the State of New York, held in this city last week, the Committee on Public Health made a recommendation that the Legislature be urged to appropriate $2,000,000 for the physical rehabilitation of the quarantine station at this port. With all due respect to the Committee on Public Health and to the State Society, which apparently without consideration endorsed the recommendation, we earnestly hope the Legislature will do nothing of the kind. Two million dollars is a considerable sum of money for even such a rich State as New York to throw away, or to give away, and that is what it would be doing if it spent it on repairs on Hoffman and Swinburne Islands at the present time. A State or municipal quarantine is an anachronism, and sooner or later—the sooner the better, if the State can thereby save two million dollars—the quarantine service at this port will be put under the control of the Federal Government.

There are fifty ports of entry in this country, and twenty-one years ago all were under local (municipal or State) control; now there are forty-seven under Federal control and only three (Baltimore, Boston, and New York) under local authority. Philadelphia and Providence have quite recently transferred their quarantine to the keeping of the Public Health Service, and Baltimore is seriously considering the move, waiting apparently only for Boston and New York to take the initiative. As it is, these ports are practically already under Federal control, for Congress has empowered the Secretary of the Treasury through the Public Health Service to promulgate uniform quarantine regulations which must be observed at all ports, whether or not nominally under State or municipal control. In case of the refusal or failure of any local quarantine officer to carry out the regulations, the President is empowered to detail Federal officers for that purpose. The act also gives the Public Health Service the power to examine at any time the quarantine stations under local control to see whether they are observing the regulations imposed. The Federal government can assume temporary control at any time when the local quarantine is unable to meet an emergency, and in fact, more than once it has had to send Federal officers to the New York quarantine station. The New York quarantine therefore is only nominally independent; the State has the doubtful privilege of paying large sums for its support and all that it gets in return is that the party in power has some good jobs for its workers. If the State will transfer the quarantine to the Federal authorities it will not only save the money absolutely needed at once to make the station effective as well as a large annual appropriation for running expenses, but will be paid by the Federal government what the present plant is worth.

Of the twenty governments of the world which are signatories to the International Sanitary Agreement for uniform quarantine rules and administration, the United States is the only one which has not continuous control of all its quarantine stations. It has absolute control, however, in times of crisis so that the local health officer exercises his authority only at the tolerance of the Federal government although at the expense of the State government. Why the citizens of this State should be willing and seemingly anxious to pay a large amount of money each year for work which the Public Health Service is ready and willing to do better for nothing is a mystery of politics.

## FULL-TIME PROFESSORS.

The announcement that Dr. Theodore C. Janeway has abandoned his chair at Columbia to accept the call to a full-time professorship of medicine at the Johns Hopkins calls attention anew to this somewhat doubtful experiment in medical instruction. It will be remembered that the Rockefeller General Education Board announced last autumn an appropriation of $1,400,000 for the Johns Hopkins Medical School, Baltimore, the appropriation being granted for the purpose of reorganizing the Departments of Medicine, Surgery, and Pediatrics in the school. Through this reorganization the professors and instructors in these departments will be compelled to withdraw from paid practice and devote their time entirely to teaching, hospital work, and research. In other words, they will approach the condition of laboratory men rather than remain practitioners.

The teaching of the elementary branches, such as anatomy, physiology, bacteriology, chemistry pathology, and pharmacology is usually thought to be better in the hands of men devoting their entire time to instruction and research in these branches, though even here one fails to see how a chemist's or a bacteriologist's worth as a teacher would be depreciated by occasional outside analytical work. Indeed he might thereby gain some experience which his laboratory would not be able to give him and so broaden his horizon and indirectly help his students.

The question is different, however, when one has to do with the so-called practical branches of medical science, with clinical medicine, surgery, obstetrics, and pediatrics. Here the broader the outlook and the wider the experience of the teacher the better is the quality of the instruction which he has to give. Any man with ordinary intelligence

and a fluent tongue can deliver an acceptable didactic lecture before a class of students after cramming for an hour or two in three or four standard treatises on medicine or surgery or whatever his subject may be. But a good clinical instructor is another kind of man; the broader he is and the more contact he has with the world the more knowledge will he have to impart to his students.

The laboratory worker is a necessity in these days and he has his place and a very useful one in the world of medicine, but like all pure specialists he is and must be more or less narrow; he has neither the inclination nor the time to study in other fields or sometimes even to know to what practical purpose the results of his research may be put. The clinical professor whose practice must be limited to hospital and dispensary patients will have a broader view than that, but he will be in danger of losing the intimate knowledge of disease and of the patient which one can acquire only in private practice. Hospital practice, in the hands of even the most enthusiastic and the most conscientious man, always becomes more or less perfunctory and a matter of routine; much of the detail is left to the assistants, and moreover there is absent the stimulus to close and accurate work which, say what we will, is afforded by the prospective fee. We doubt not that students under full time professors will be well up in the science of medicine, but whether they would not learn just as much of the science and more of the art from a professor who lives and practises in the world is something for the future to reveal.

## A NEW APPLICATION OF CUTANEOUS REACTIONS.

Skin reactions have hitherto been employed almost entirely as aids to diagnosis. The field of prophylaxis is rapidly becoming more prominent and now some of these reactions are being used as guides in the application of prophylactic measures. With the introduction of the use of diphtheria antitoxin for immunizing purposes it became the custom to give an immunizing dose to every person who had been exposed to the disease. It was, of course, recognized that all were not equally susceptible, but there was no method whereby the susceptible could be separated from those who were not liable to acquire the disease. Such a test seems now to have been devised. Schick (*Münch. med. Wochensch.*, 1913, ix, 2608) injects intracutaneously one-fiftieth of a minimum lethal dose for the guinea-pig of diphtheria toxin. If the individual has no antitoxin in his blood there appears within twenty-four hours a local reaction of redness and induration about the site of injection. The absence of any reaction is taken to indicate that the person possesses diphtheria antitoxin probably in sufficient quantities to protect him against infection. He finds that nearly all the newborn have this natural immunity and that the percentage of the protected decreases as the children grow older. By using this test he is able not only to save large quantities of antitoxin, a distinct economic advantage, but also to avoid a certain amount of serum sickness and the possibility of anaphylaxis.

One of the difficulties in the application of typhoid prophylaxis by means of vaccines is the impossibility of determining how much protection an individual has against the disease. How many injections are necessary to protect and when the course should be repeated are questions that have so far lacked a satisfactory reply. It is well known that the agglutinating power of an individual's blood-serum is not necessarily an indication of the degree of his immunity, although it is the test which has been largely used to determine the immunity. Gay and Force[1] have been using an allergic reaction for this purpose and conclude that it is of presumptive value in indicating protection against typhoid fever. They employed a modification of the von Pirquet method of tuberculin testing. The "typhoidin," as they call it (prepared from a killed and concentrated culture of the typhoid bacillus by a method similar to that of the preparation of Koch's old tuberculin), is applied to an abrasion of the skin in the same manner as in the von Pirquet test, and the reactions are observed six and twenty-four hours later. The positive spot measures from 4 to 12 mm. in diameter and is usually somewhat indurated. The test was positive in practically all individuals giving a history of typhoid and uniformly negative in those in whom typhoid could definitely be excluded. The majority of individuals who had been vaccinated against typhoid gave a positive reaction and the authors think that the presence of this reaction is evidence of their immunity. If this is so this test will correct the most marked defect in the present methods of typhoid prophylaxis. The cutaneous reactions are so easy of application that they are accessible to all practitioners and, therefore, the addition of any accredited member to their ranks is a welcome thing. It is to be hoped that both these new members on further trial will prove to be as valuable as they promise.

## THE MIDWIFE IN AMERICA AND IN ENGLAND.

The situation as regards the midwife in this country is unsatisfactory. On this point there is general agreement, but as to the manner in which adequate and comprehensive reforms are to be introduced, there is a somewhat wide difference of opinion.

From many points of view the existing condition of affairs is serious. In the first place, it is a fact that a large number of cases of ophthalmia neonatorum, not infrequently leading to total blindness, are due to the ignorance and lack of skill of the attending midwife. Other accidents of a more or less grave nature are apt to occur, and do occur, both to mothers and infants, when a labor is attended by an untrained midwife. However, these statements are too obvious to require emphasis, and the crucial question is how is the problem of the midwife to be solved? Three courses with the object in view are open: To abolish the

[1] University of California Publications in Pathology, Vol. 2, No. 14.

midwife, to leave the situation as it is, which, by the way, would not be a solution, or to educate the midwife for her duties and not to permit her to pursue this calling until she has satisfied competent examiners by sufficient tests and has proved that she is a fit person to be granted a license to practise as a midwife. It may be objected that if this were done medical practitioners would be deprived of a certain amount of income, but it is doubtful if this would happen to an appreciable extent, for it must be borne in mind that there will always be a large proportion of the population who will be unable to pay the midwifery fees asked by medical men and resort will be had to midwives in any event. So that if midwives were abolished some scheme must be evolved whereby the services of medical practitioners for midwifery cases could be secured by the poor at a very much smaller fee than is asked at the present time.

Miss Carolyn Conant Van Blarcom, R. N., Secretary of the Committee for Prevention of Blindness, has recently published an account[1] of a visit to England taken in order to investigate the working of the comparatively new midwife act of that country. Miss Van Blarcom was in England for only six weeks, but during that period she appears to have investigated into and studied the matter earnestly, and therefore her conclusions are worthy of close consideration.

Up to 1902, the year in which the English act was passed, midwives in England were in much the same position as they are here now. The act enacts that midwives practising one year prior to the passing of the act are certified by virtue of their existing status, otherwise women wishing to practise as midwives must be certified because of holding certificates issued by the London Obstetrical Society, or as having been trained in one of the several designated schools, or certified after having passed the Central Midwives' Board examination. It would be impossible within the limits of an editorial article to refer more than very briefly to Miss Van Blarcom's account of her English investigations and her reasons for thinking that it would be possible and highly desirable to enact similar regulations regarding midwives in New York State, and America generally.

As a proof of the excellent results which have accrued from the passage in England, it is stated that during the nine years following the enactment the percentage of deaths among infants dropped from 151 per 1,000 during 1901 to 106 per 1,000 in 1910, and the deaths from puerperal sepsis and accidents at childbirth dropped from 4.65 per 1,000 in 1901 to 3.69 per 1,000 in 1909. It should be said that the midwives themselves in England are efficiently supervised by competent persons.

Miss Van Blarcom concludes that the practical value of the act was convincingly demonstrated by the three following results of the administration:

1. The substitution of clean, intelligent women for the old, unfit midwives, which is gradually being accomplished.

2. The encouragement of a superior class of women to train as midwives.

3. The ability of the authorities to control practising midwives and limit their work to attendance on normal cases, which constitute about 80 per cent. of all cases.

It is argued that the midwife would not compete with the obstetrician, but would rather be in the position of a thoroughly competent nurse, permitted only to attend normal cases, and sufficiently well trained to be able to recognize when the services of a medical practitioner are necessary. So far the act appears to have had good results in England, and there would seem to be no valid reasons why similar enactments regarding midwives should not be brought into force in this country.

[1] "The Midwife in England," being a study in England of the working of the English Midwives Act of 1902, by Carolyn Conant Van Blarcom, R.N. With an introduction by J. Clifton Edgar, M.D.

## The Sex Instinct.

Many attempts have been made to define the sexual instinct, but without much success. Freud and his followers attribute to this instinct the production of many if not the majority of nervous disorders, but, as a rule, the English-speaking psychologists do not agree with the far-reaching views of the Freudian School. At a joint meeting of the Section of Psychiatry of the British Royal Medical Society and the British Psychological Society, on March 10, Dr. William McDougall read a paper on the "Definition of the Sexual Instinct." He said in part that the present attitude of both academic and medical psychologists on the nature and rôle of instinct in general, and the instinct of sex in particular, was chaotic; and it was only by cooperation of medical with other psychologists that a right understanding of sex instinct could be hoped for. The erroneous views could be classified into two groups: (1) Those which were unduly simple, representing the sex instinct as merely the tendency to respond to certain disagreeable sense-stimuli with movements which abolished the disagreeable and produced pleasurable sensations; and (2) Those which ascribed to the sex instinct a variety of mental and bodily processes which originated in other and distinct roots. The Freudian doctrine, in his opinion, comprised several errors. Against the view that the sex instinct arose from the desire for pleasurable gratification was the fact that in some cases the instinct continued after complete castration. The speaker strongly disagreed with Freud's contention that the sex instinct was normally present in infancy; it really appeared to have its earliest beginnings at about the eighth year and progressed steadily to puberty. Though the sex instinct was admittedly complex, it should not be regarded as comprising two distinct impulses.

## Destructive Action of Weak Electric Currents on Tumor Cells and Trypanosomes

At a recent meeting of the Society of Naturalists and Physicians of Strasbourg (*Münchener medizinische Wochenschrift*, March 31) Seyderhelm stated that through the action of a constant current of 10 volts, with devices to exclude electrolysis of the electrodes, the tumors of mice and rats could be necrotized and exfoliated. A number of daily sessions was necessary. *In vitro*

cancer cells were acted upon in analogous fashion. A very low amperage, however, seems to stimulate all growth. The action of electricity resembles that of *x*-rays. Uhlenhuth stated that these currents also kill trypanosomes *in vitro*. It is questionable whether these discoveries will lead to therapeutic utilization at the expense of *x*-rays and radium.

### Cancer of the Rectum in an Adolescent.

A case of this very rare occurrence was recently reported to the Verein für wissenschaftliche Heilkunde zu Königsberg by Carl (*Berliner klinische Wochenschrift*, 1914, No. 12). The patient, a Russian youth of 17, had complained of rectal trouble for a year or more. There were difficult and painful evacuations, and eventually passage of pus and blood. Full examination under narcosis gave the impression of local tuberculosis. Only a diagnostic excision showed the cancerous nature of the mass, which involved the entire circumference of the gut above the anus. A final diagnosis was made of colloid cancer. As the growth was inoperable an artificial anus was established.

## News of the Week.

**A Large Cancer Hospital.**—By an agreement between the Cornell Medical College and the General Memorial Hospital, New York, made possible by the generosity of several philanthropists, there will shortly be established in this city a hospital for the treatment of cases of cancer which will be the largest of its sort in the world. The General Memorial Hospital buildings will be used, ninety beds thus becoming at once available, and any cases of cancer of interest in study or open to treatment will be received. The laboratories will be fitted with the latest appliances, such as *x*-ray apparatus, etc., and large amounts of radium will be available through the generosity of Dr. James Douglas, who has turned over to the hospital his half interest in the radium output of the mines owned by himself and Dr. Howard A. Kelly in Colorado. The pathological work of the hospital will be under the direction of the Department of Pathology of the college, and the attending staff of the hospital will shortly be announced.

**Civil Service Examinations.**—The United States Civil Service Commission announces a competitive examination, open to men only, for the purpose of filling vacancies in the position of technical assistant in pharmacology in the Division of Pharmacology, Hygienic Laboratory, Public Health Service, at salaries of $1,800 to $2,000 a year. The duties comprise research work in pharmacology, including original investigations in the physiological assay of drugs and of the action of drugs by means of the electrocardiograph. The degree of M.D. and at least two years subsequent experience in experimental pharmacology or physiology are prerequisites for this position. Persons meeting the requirements and desiring the examination should at once apply for Form 304 and special form to the United States Civil Service Commission, Washington, D. C.

The Commission also announces for June 3, 1914, an examination, open to men only for the purpose of filling a vacancy in the position of dental interne in the Government Hospital for the Insane, Washington, at a salary of $600 a year and maintenance. Applicants must be recent graduates of a regularly incorporated dental school, unmarried, and twenty years of age or over. Candidates should apply at once for Form 1312 to the United States Civil Service Commission, Washington, D. C.

**Health of the Philippines.**—The report of the Director of the Bureau of Health for the Philippine Islands for 1913, calls attention to the fact that the total number of deaths last year was 60,000 less than during 1905. This reduction, which has stood for several years, has occurred almost entirely among the preventable diseases, and therefore may be regarded as an index of the effect of health work in the Philippines. It is further stated that if the knowledge which is now available could be applied, at least 100,000 deaths per annum additional might be avoided by reducing the ravages of tuberculosis, malaria, beriberi and its indirect effects, and the intestinal diseases. The organization which has already brought about a reduction of 60,000 deaths per annum is believed to offer the best hope, if permitted to work along unhampered, of bringing about this further improvement; but in order to achieve any considerable results the cooperation of the entire public is essential.

**Street Accidents.**—During the month of April twenty-five children and twenty-one adults were killed in New York by automobiles, wagons, and street cars, according to the report of the National Highways Protective Society. Automobiles were responsible for seventeen deaths, wagons for fifteen, and street cars for fourteen. In addition to these, there were 146 serious accidents. In the State, outside of New York City, automobiles killed nine and injured eighty-three persons, and street cars killed four and injured fourteen.

**Hospital Saturday and Sunday Association.**—In its annual accounting on May 1, the Hospital Saturday and Sunday Association of New York apportioned $110,000 among the forty-seven non-municipal hospitals belonging to the association. This is the largest sum which the association has handled in the thirty-five years of its existence. The money was distributed as follows: General hospitals, $58,227.78; special hospitals, $18,645.75; women and children, $20,432.98; convalescents, $12,693.49.

**Exhibition at Lincoln Hospital.**—An exhibition of the industrial work done in the Home department of the Lincoln Hospital and Home, 114th Street and Southern Boulevard, New York, was held on April 22, 23, and 24, at 655 Fifth Avenue. The exhibition comprised the product of the industrial department, consisting of woven rugs, baskets, etc.

**First Typhus Death.**—Health Officer O'Connell, of New York, on April 27 reported the first death to occur from the present invasion of typhus fever. The patient was a Greek who boarded the steamship *Madonna* at Naples, and had been under treatment at Swinburne Island, with eighteen other typhus fever patients, all of whom have responded to treatment.

**City Death Rate.**—The death rate in New York City for the week ending April 25 was 15.30 per 1,000 of population, representing a total of 1,637 deaths, as compared to a rate of 16.28 per 1,000 and a total of 1,677 deaths for the corresponding week of 1913. For the seventeen weeks of this year the death rate was 15.46 per 1,000, as against a rate of 15.68 in the same period of last year, a decrease of .22 of a point.

**State Sanitary Supervisors.** — Commissioner Biggs of the New York State Department of Health

has announced the following appointments of sanitary supervisors: Dr. Edward Clark, Buffalo; Dr. Frederick W. Sears, Syracuse; Dr. Harry S. Crum, Ithaca; Dr. John J. Mahoney, Jamestown; Dr. Frank Overton, Patchogue; Dr. Charles S. Prest, Waterford; Dr. Samuel D. Hubbard, New York; Dr. Leroy W. Hubbard, Mount Vernon; Dr. John Archibald Smith, Saranac Lake; Dr. John A. Conway, Hornell; Dr. Charles C. Duryee, Schenectady; Dr. Charles V. Patchin, Dansville.

**More Plague in Havana.**—Two additional cases of bubonic plague were reported in Havana on April 28, and on the following day the third death from the disease during the present outbreak occurred.

**Personals.**—Dr. I. H. Goldberger has been appointed assistant director of educational hygiene to the public schools of the City of New York.

Dr. Alexander Lambert has moved to 43 East 72d street.

A report that Dr. Edward A. Ryan, an American physician working in Mexico, had been arrested and sentenced to death on April 30, caused considerable alarm among his friends in Scranton, Pa., and activity in the State Department at Washington. As a result of the latter, Dr. Ryan's safety was speedily assured, and at latest reports he was about to leave the country. Dr. Ryan was graduated from the Fordham University Medical College, New York, in 1910.

**A Bust of Dr. Wyeth.**—On the evening of Friday, May 1, the medical staff and Woman's Auxiliary Board of the New York Polyclinic Medical School and Hospital presented to that institution a portrait bust of Dr. John Allan Wyeth, the founder of the school and its surgeon-in-chief. The bust is life size, of bronze, and was executed by the eminent sculptor, Mr. Herbert Adams, of New York. Addresses were made by Drs. Charles H. Chetwood, John A. Bodine, D. Bryson Delavan and John A. Wyeth. The occasion marked the second anniversary of the occupancy of the new building of the Polyclinic.

**Gifts to Charities.**—By the will of the late Elizabeth B. Jeffries of Philadelphia the sum of $5,000 is bequeathed to the Germantown Hospital and the same amount is given, as a memorial to her husband, to St. Luke's Homeopathic Hospital, Philadelphia.

**American Protologic Society.**—The sixteenth annual meeting of this society will be held at Atlantic City, N. J., on June 22 and 23, 1914, under the presidency of Dr. Joseph M. Mathews of Louisville, Ky. The secretary of the association is Dr. Alfred J. Zobel of San Francisco.

**California State Medical Society.**—The fifty-fourth annual convention was held at Santa Barbara on April 14 and 15, when the following officers were elected for the ensuing year: *President*, Dr. Harry M. Sherman, San Francisco; *Secretary*, Dr. Philip Mills Jones, San Francisco; *Vice-Presidents*, Dr. George A. Hare, Fresno, and Dr. Rexwald Brown, Santa Barbara.

**Pan-American Medical and Surgical Association.**—Under this title a new medical society was recently formed in New Orleans, having for its objects the development of a high standard of professional efficiency, the encouragement of medical and surgical research, and the association of medical men throughout the country in the discussion of medical topics. The officers of the association are as follows: *President*, Dr. Stephen W. Stafford; *Vice-Presidents*, Dr. Joseph A. Estopinal, Dr. C. Grenes Cole, Dr. Charles V. Unsworth and Dr. E. W. Mahler; *Secretary*, Dr. Joseph J. Wymer; *Treasurer*, Dr. G. F. Patton.

**Hospital Investigation.**—A sweeping investigation under the direction of John H. Delaney, Commissioner of Efficiency and Economy, of the New York State Hospitals will result, it is reported, in the removal of a number of hospital employees and the displacement of several officers of these institutions. The report of the investigation is now being compiled, and it is said that it will contain severe criticisms of the conditions in many of the hospitals.

**Fight Against Cancer.**—The *Times* of London has made an appeal for the imitation in England of the American campaign against cancer, and urges the establishment of a society similar to the American Society for the Control of Cancer.

**Typhus on Liner.**—The steamship *Celtic* of the White Star Line, which arrived in New York on April 13 from Mediterranean ports, was held at Quarantine because of the discovery of four cases of typhus fever among the steerage passengers. The patients, three adults and one child, were removed to Swinburne Island for treatment and 554 steerage passengers were taken to Hoffman Island for observation.

**Health of the Canal Zone.**—During the month of February, 1914, the total number of deaths from all causes among employees in the Canal Zone was 30, of which 22 were due to disease and 8 to violence, giving an annual average per thousand of 5.34 and 1.94 respectively, or a total of 7.28. This is the lowest rate on record for the month. For the cities of Panama and Colon and the Canal Zone, including both employees and civil population, the annual average death rate for the month was 23.67 per thousand, an increase of two points over the rate for February, 1913. Among employees the deaths from the principal diseases were as follows: Lobar pneumonia, 4; organic heart disease, 1; tuberculosis, 7; typhoid fever, 1. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

**Medical Society Elections.**—Fairfield County (Conn.) Medical Society: 122nd annual meeting at Bridgeport on April 14. Officers elected: *President*, Dr. George H. Noxen, Darien; *Vice-President*, Dr. F. W. Stevens, Bridgeport; *Secretary*, Dr. Eli B. Ives, Bridgeport; *Treasurer*, Dr. Philip W. Bill, Bridgeport.

Plymouth District (Mass.) Medical Society: Annual meeting at Brockton on April 16. Officers elected: *President*, Dr. Charles E. Lovell, Whitman; *Vice-President*, Dr. Nathaniel C. King, Brockton; *Secretary-Treasurer*, Dr. Francis J. Hanley, Whitman.

Bristol North District (Mass.) Medical Society: Annual meeting at Taunton on April 15. Officers elected: *President*, Dr. Ralph D. Dean, Taunton; *Vice-President*, Dr. William H. Allen, Mansfield; *Secretary*, Dr. Arthur R. Crandell, Taunton; *Treasurer*, Dr. William Y. Fox, Taunton.

Hornell (N. Y.) Medical and Surgical Association: Annual meeting at Hornell on April 6. Officers elected: *President*, Dr. Frederick C. Robbins; *Vice-President*, Dr. George W. Mitchell; *Secretary-Treasurer*, Dr. J. Raymond Kelly.

Middlesex County (Conn.) Medical Society: The 122d annual meeting at Middletown on April 9. Officers elected: *President*, Dr. Howard T. French,

Deep River; *Vice-President*, Dr. Arthur B. Coleburn, Middletown; *Clerk*, Dr. Charles A. McKendree, Cromwell.

Bronx County (N. Y.) Medical Society. This was incorporated at Albany on April 13, with the following directors: Dr. S. Carrington Minor, Dr. Gustave H. E. Starke, Dr. Arthur C. Palmateer, Dr. Joseph J. Smith, Dr. Edwin C. Podvin, and Dr. William E. Howley.

**Obituary Notes.**—Dr. James D. Madeira of Reading, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1883, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Berks County Medical Society, died at his home from pneumonia on April 20, aged 58 years.

Dr. Herman Canfield, formerly chief sanitary inspector at Ancon, Canal Zone, a graduate of the New York University Medical College in 1876, died at Saint George, Fla., after a lingering illness, on April 9, aged 60 years.

Dr. Morris Wolf, former health officer of Yonkers, N. Y., a graduate of the Eclectic Medical College of the City of New York in 1893, and of the University of Rostock, Germany, in 1899, and physician to St. Joseph's Hospital Dispensary, died at St. Joseph's Hospital, from intestinal disease, on April 17.

Dr. Benjamin F. Spencer of Weston, Tex., a graduate of the University of Louisville, Medical Department, in 1874, and a member of the State Medical Association of Texas and the Collin County Medical Society, died at his home on March 25, aged 61 years.

Dr. John B. Wurtz of Philadelphia, a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1876, and a member of the Germantown Medical Society, died at his home from apoplexy on April 2, aged 60 years.

Dr. Francis L. Gerald of Warren, N. H., a graduate of the Eclectic Medical College, Cincinnati, in 1873, for many years active in the health and school boards of Warren, and a member of the New Hampshire and Grafton County Medical Societies, died at his home from angina pectoris on April 5, aged 76 years.

Dr. Charles Arthur Derby of New Bedford, Mass., a graduate of the Tufts College Medical School, Boston, in 1909, superintendent of the New Bedford Emergency Hospital, and a member of the Massachusetts and Bristol South District Medical Society, died at the Emergency Hospital after a short illness, from abscess of the lung following pneumonia, on March 30, aged 37 years.

Dr. Frank Kelly Roarke of Troy, N. Y., a graduate of the Albany Medical College in 1891, laryngologist to the Samaritan Hospital, consulting laryngologist to St. Joseph's Maternity Hospital, and a member of the American Medical Association, the Medical Society of the State of New York, and the Rensselaer County Medical Society, died suddenly at his home on April 19, aged 45 years.

Dr. William H. Seip of Bath, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1859, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Northampton County Medical Society, died at his home on April 13, aged 77 years.

Dr. Benjamin W. Kimball of Minneapolis, Minn., a graduate of the Medical School of Maine, Portland, in 1857, died at his home on April 11, aged 85 years.

Dr. Herman Milbacher of Aurora, Ill., a graduate of the University of Munich, Germany, in 1881, attending physician to the Aurora and St. Charles Hospitals, died suddenly at Sarasota, Fla., on April 12, aged 63 years.

Dr. Charles Pickering Putnam of Boston, Mass., a graduate of the Harvard Medical School in 1869, a member of the American Medical Association, the Massachusetts Medical Society, the Suffolk District Medical Society, the American Pediatric Society, and the New England Pediatric Society, and well known as a specialist in children's diseases, died at his home, after a short illness, on April 22, aged 69 years.

Dr. Charles H. Brockway of Worcester, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1873, and a member of the Massachusetts Medical Society, and the Worcester District Medical Society, died at the Worcester Hospital after a brief illness on April 17, aged 62 years.

Dr. Charles J. Spratt of Minneapolis, Minn., a graduate of the Bellevue Hospital Medical College, New York, in 1869, and a member of the Minnesota State Medical Association, the Hennepin County Medical Society, and the Minnesota Academy of Ophthalmology and Oto-Laryngology, died at the Asbury Methodist Deaconess Hospital, on April 12, aged 65 years.

Dr. Ferdinand O. Kauffmann of St. Louis, Mo., a graduate of the Missouri Medical College, St. Louis, in 1873, and a member of the Tri-State Medical Society, died at his home from heart disease on April 14, aged 67 years.

Colonel Daniel M. Appel, Medical Corps, United States Army, in charge of the Department of Hawaii, a graduate of the Jefferson Medical College, Philadelphia, in 1875, and a member of the American Medical Association, died at Honolulu, Hawaiian Islands, from heart disease, on April 22, aged 59 years.

Dr. William Triplett Harris of Richmond, Va., a graduate of the Medical College of Virginia, Richmond, in 1907, and a member of the Medical Society of Virginia, and the Church Hill District Medical Society, died at his home, after a long illness, on April 18, aged 39 years.

Dr. James R. Reitzel of High Point, N. C., a graduate of Southern Methodist University, Medical Department, Memphis, Tenn., in 1892, and a member of the Medical Society of the State of North Carolina, and the Guilford County Medical Society, was instantly killed by the overturning of the automobile which he was driving, on April 17, aged 49 years.

Dr. Carl Wirth of St. Paul, Minn., a graduate of the Northwestern University Medical School, Chicago, in 1873, died suddenly at his home on April 17, aged 70 years.

Dr. John A. Jones of Altona, Ky., a member of the Kentucky State and Marshall County Medical Societies, died at his home from pneumonia after a short illness on April 14, aged 75 years.

Dr. Morris Stroud French, of Woodville, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1876, died suddenly in Philadelphia on April 26, aged 59 years.

Dr. William Walker Brackett, of New Britain, Conn., a graduate of the Jefferson Medical College, Philadelphia, in 1896, formerly health officer of the town and medical inspector of schools, attending surgeon to the New Britain General Hos-

pital, and a member of the Connecticut State and Hartford County Medical Societies, died at his home from malignant endocarditis on April 21, aged 41 years.

Dr. CHARLES EDWIN SANFORD, of Bridgeport, Conn., a graduate of the Medical Department of Yale University, New Haven, in 1853, and a member of the Connecticut State and Fairfield County Medical Society, died at his home on April 26 from apoplexy, aged 84 years, having been in practice up to the time of his death.

Dr. FRANCIS ALVIN WEIR, of Pasadena, Cal., a graduate of the Rush Medical College, Chicago, in 1879, and a member of the American Medical Association, the Medical Society of the State of California, and the Los Angeles County Medical Society, died at his home on April 15, aged 75 years.

Dr. JAMES B. MCFATRICH, of Chicago, a graduate of the Bennett Medical College, Chicago, in 1884, a former president of the Chicago Board of Education, professor of ophthalmology and clinical surgery at the Bennett Medical College, and president of the Northern Illinois College of Ophthalmology and Otology, died at his home on April 25 from heart disease, aged 52 years.

Dr. WILLIAM JOSEPH O'REILEY, of Boston, a graduate of the Bellevue Hospital Medical College, New York, in 1883, died at his home after a short illness on April 22, aged 55 years.

Dr. HIRAM L. CHASE, of Cambridge, Mass., a graduate of the Harvard Medical School in 1846, and a member of the Massachusetts Homeopathic Medical Society, of which he was president in 1868, and of the American Institute of Homeopathy, died at his home on April 24, aged 89 years.

Dr. OSMORE O. ROBERTS, of Northampton, Mass., a graduate of the Homeopathic College of Pennsylvania, Philadelphia, in 1853, and first president of the Western Massachusetts Homeopathic Medical Society, died at his home on April 26, aged 85 years.

Dr. ELLIOTT E. FURNEY, until recently of St. Louis, Mo., a graduate of the Missouri Medical College, St. Louis, in 1885, and a member of the American Medical Association, the Missouri State Medical Association, and the St. Louis City Medical Society, died recently at St. Petersburg, Fla., aged 66 years.

Dr. ANNIE M. BROWN, of Brooklyn, N. Y., a graduate of the Woman's Medical College of the New York Infirmary for Women and Children in 1880, died at her home, after a long illness, on April 30, aged 72 years.

Dr. EUGENE F. PEARCE, of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1883, and a member of the Medical Society of the State of New York and the Kings County Medical Society, died at his home on April 30, aged 55 years.

Dr. EDWARD MINTURN ASSENHEIMER, of New York, a graduate of the College of Physicians and Surgeons, New York, in 1904, a member of the Medical Society of the State of New York and the New York County Medical Society, and assistant physician to the Cornell Dispensary, died at his home suddenly on April 30, aged 34 years.

Dr. PAUL EHRHART, of New York, a graduate of the New York University Medical College in 1878, and a member of the Medical Society of the State of New York and the New York County Medical Society, died at his home on April 30, following a general breakdown, aged 59 years.

### FULL-TIME MEDICAL PROFESSORS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the fact of Dr. Theodore C. Janeway's appointment at Johns Hopkins University as full-time professor of medicine, while we deplore the great personal loss, we should not be unmindful that such a position might not be desirable for New York. Already we have the Rockefeller Institute and Hospital for scientific research. Would it be advantageous to our city to have a university and another hospital with similar objects in view?

To my mind it would not. I believe that any physician is broadened and improved in his pursuit, by having a limited number of patients outside the hospital. He cannot with them, it is true, follow altogether rigid rules of investigation and simple authority must give way, not infrequently, to the humane aspect of things. Symptoms must be treated to relieve pain, distress, and annoyance, though it be not scientific to do so. In thus acting, the attending physician will, however, often accomplish beneficial results which, even from a curative viewpoint, are remarkable.

In my experience, it is the remedy long lost sight of which has occasionally worked wonders, when the one upheld by science has failed. Medicine is, and must be, as much an art as a science. To practise the art successfully, we should recur to wise empiricism. This empiricism, based upon the experience of many practitioners, counts much and endures. Science changes rapidly and what to-day is truth, to-morrow is not. Witness what is said and done with regard to radium and the *x*-ray. On the other hand, alcohol, fifty years ago the recognized dressing of all wounds, banished from surgical practice by carbolic acid and bichloride of mercury, has again come to the front, as the innocuous and effective local disinfectant. In its use, primarily, empiricism ruled.

DISTURBANCES OF THE CHEMICAL RELATIONS OF THE BLOOD—HUNTERIAN SOCIETY'S DEBATE ON BLOOD PRESSURE—THERAPY OF POTATO JUICE AND OF PARAFFIN WAX.

LONDON, April 17, 1914.

PROFESSOR F. G. HOPKINS, in his Oliver-Sharpey lectures at the Royal College of Physicians, discussed certain effects which follow "Disturbances in the Chemical Reactions of the Blood." The great progress which has been made in chemistry has enabled us to apply its principles to the interpretation of many changes in living organisms and to more accurately explain the results obtained by observation and experiment. In fact, the whole subject of the chemical reactions in the body has entered on a new phase. Professor Haldane and his fellow workers at Oxford, said the lecturer, had shown that carbon dioxide, in stimulating the nerve center which governed respiration, acted as an acid. That nerve center responded vigorously to a concentration of the gas of such slight degree as would correspond to only a trace of hydrochloric acid—the two-millionth of a milligram in a hundred cubic centimeters of water. Further, there were

reasons for believing that the kidney was no less sensitive. Thus the influence of both the respiratory center and the kidney on the blood is to keep its composition constant. But in addition there are the buffer salts contained, which tend to prevent deviation in the direction of its becoming either acid or alkaline.

The Hunterian Society's annual clinical debate was also concerned with the blood—or rather with a deviation of its pressure—the subject being announced as the "Causes and Treatment of High Blood Pressure." It was opened by Dr. de Haviland Hall, who said the normal pressure varied with age and sex. Putting the figure 1 before the age of anyone under 40, he said, gave in millimeters of mercury his normal pressure. Over 40 the resulting figure would be too high. In woman the figure ranged 10 mm. below that of man of the same age. A strong, healthy man would have 5 to 15 mm. above a weakly one. Active exertion raised the pressure, as did ingestion of much food and liquid, especially beer, onset of fever, severe pain, gastric disturbance, kidney disease, gout, lead poisoning, malaria, oral sepsis, alcohol, mental strain or worry. Other causes were mentioned and some dwelt upon more fully, so that altogether a listener might well conclude that the pressure was affected, as he had been accustomed to regard the pulse. As to treatment, Dr. Hall said, so far from being an enemy, high tension was often the patient's best ally, the very means of maintaining the activity of the kidneys and preserving his life. Disaster might therefore result from attempts to reduce pressure, but, on the other hand, there was danger in stimulating treatment of arterio-sclerotics with high pressure. A pressure of 200 mm., with any sign of cardiac failure, called for absolute rest. The skin required attention, baths of various kinds suited to the cases, Turkish, electric, Manheim, etc. Diet must be regulated, both as to quantity and quality. Alcohol was almost always injurious. Tea and coffee in moderation only should be allowed. Abundant drinking of pure water was indicated. Tobacco most moderately indulged in; with original symptoms, not at all. Of drugs, calomel, blue pill and saline aperients were useful, and iodides in small doses over a considerable time. In Wassermann reaction, mercury, preferably by inunction. Powerful, quickly acting vaso-dilators, as amyl nitrite, nitro-glycerine, erythrol tetranitrate, should be reserved for emergencies. Blood-letting was of greatest service in some cases, as nature often indicates by copious epstaxis.

A number of interesting statements were made in the discussion, of which I can only cite a few examples. Dr. Langdon Brown mentioned the difficulty of securing a correct pressure in nervous patients; a fall as age advanced in men over 80 down to 140 often. He also named some additional causes, as over-action of ductless glands and putrefactive diamens formed in the intestines. Rise of pressure very conservative. If immediate lowering became necessary, as in anginal attacks, amyl nitrite was best, for nitro-glycerine only acted about 40 minutes; erythrol tetranitrate in half gram doses, 6 hours, but was apt to give headache. Dr. Russell Wells urged the recording of the diastolic as well as systolic pressure, and related some experiments he had made. He cautioned against lowering even a very high systolic pressure in arterio-sclerosis. The general condition of the patient was important. One of his with 300 mm. fell off with a dcrease to 250 and improved again on a return to the former level. Dr. O. Williamson insisted on the value of the finger, which he had found at times corrected the sphygmomanograph. He named cases in which the instrument alone would have seriously misled. Dr. Calthrop of Woodhall Spa attributed good effect to the polass. iod. contained in the mineral water, in which, too, the bromide was a valuable adjunct. Dr. Thorne Thorne had become convinced that the record of minimum was almost as important as the maximum pressure. Two distinct classes of hypertension could only be differentiated by comparing the maximum and minimum pressures. In one, both were raised, but the ratio between them also changed from the normal difference of about 50 mm. to over 100 mm., indicating definite vessel degeneration. In the other class both were raised but the ratio unaltered, indicating hypercontractility of arteries and capillaries, a presclerotic condition.

Has the potato become recognized on your side as a remedial agent? I do not mean internally or as seen on the table. Very seldom has it been spoken of here as possessing therapeutic value. But now Mr. Heaton Howard of Clapham tells us in the *Lancet* that for years he has been using it with great success as an external application which gives prompt relief to pain and causes rapid absorption of fluid from inflamed joints. He uses the expressed juice, concentrated (ext. *solani liq.*). Hydraulic pressure of the raw potatoes will give about one-half their weight of juice, which is reduced to one-fifth by heat and a little glycerine added. This can be used pure, as a liniment, or diluted with one-third of *Lin. Saponis;* or an ointment can be made with lard or ampullæ filled, etc. Mr. Howard admits there is no alkaloid in the potato and attributes the efficacy to the salts of potass contained. But if so, why not employ a simple solution of the salts of similar strength? His most striking cases are synovitis of the knee, but lumbago and all forms of rheumatism are quoted. Also the local pain of acute gout in the toe arrested by the liquid applied with hot water as a fomentation. But it is not supposed to have other than local influence.

The potato seem cold comfort for a rheumatic joint compared with an application brought forward by M. Barthe de Sandford at Paris, viz., molten paraffin wax heated to a temperature of 122° F. Of course, heat in some form is in constant use, and every rheumatic becomes expert in the use of hot water. But the wax enclosing the painful part retains the heat a long time. Dr. de Sandford says it will often be found 110° F. at the end of twenty-four hours. Firmly applied, he attributes some effect to the pressure maintained, and he speaks of the "dry heat" as permitting a higher temperature than otherwise. He spoke of having tried the experiment of immersing himself in liquid paraffin wax at 122° F. and letting it solidify on him, describing the effect as exhilarating.

**Noma and Its Infective Basis.**—Alfonso Montefusco reports two cases of noma in young children, secondary to typhoid fever and diphtheria respectively. He states that many different microorganisms have been isolated from cases of noma, including staphylococci streptococci, leptothrix, and streptothrix. As regards the treatment of noma, although many different methods, including medical and surgical measures, have been tried, all of these have been ineffective. The author believes that noma belongs to the group of diseases caused by the fusiform bacilli and spirilla, and that a true specific should be found in salvarsan.—*Giornale Internazionale delle Scienze Mediche.*

RADIUM TREATMENT OF CANCER—ITS VALUE IN INOPERABLE CANCER OF THE UTERUS AND IN SUPERFICIAL TUMORS—RADIUM AS A PALLIATIVE MEASURE—TREATMENT OF WOUNDS OF THE HEART—OBJECTIVE SIGNS OF CARDIAC WOUNDS AND TECHNIQUE OF SURGICAL INTERVENTION.

PARIS, March 15, 1914

THE radium treatment of cancer was the subject of a number of interesting communications before the Society of Surgeons of Paris and before the Surgical Society. M. Gazin has obtained encouraging results in inoperable cancer of the uterus. Inoperable cancer of the rectum has also been helped with respect to the pain and the obstructive symptoms. The radium treatment has been effective in suitable cases in sparing the patient the discomfort of an artificial anus. Pierre Delbet and A. Herrenschmidt cite the statistics obtained from the study of fifty cases of cancer in different parts of the body, but chiefly of mammary and uterine tumors treated with the aid of radium. The majority showed regression during the first phase. Some cases were completely cured. Cancers of the neck of the uterus, particularly, have been rapidly improved so far as functional troubles and the general condition are concerned. Locally this method produced as a rule a cicatricial contraction of the tumor and then after a longer or shorter time a renewed development of the tumor, and this time the radium treatment was ineffective. It may be fair to state that the latter treatment has been applied in the case of inoperable cancers, which fact explains the large percentage of relapses following a transient amelioration.

M. Thevenard reported the treatment of a case of inoperable epithelioma of the uterus by means of three applications of radium tubes. He obtained a retardation in such manner that it was possible to perform hysterectomy at a later date. During this operation he observed that the parametrium was of a ligneous character. This action of radium which transforms the uterus and its neighboring tissues into a fibrous mass has enabled Desjardins and Dominici to adopt the following technique in their extensive operation: Two applications of radium were made as a preoperative treatment and then a more extensive intervention was resorted to. The tubes of radium whose rays are well filtered and which are enclosed in No. 20 rubber drains must be kept exactly in the place chosen, and should be removed at the end of forty-eight hours. At the end of two or three weeks the tubes are placed anew in the posterior portion of the vagina. M. Peraire has obtained the best results in the case of superficial tumors. He cites the cure of a case of sarcoma of the vagina, a cure which persisted at the end of three years. In the case of deep cancers he has had nothing but failures.

Georges Luys reported that in a case of atypical pavement-celled epithelioma of the bladder which developed just behind the posterior ureteral orifice he succeeded in making applications of radium at the end of a No. 19 crutch sound and obtained an undoubted amelioration, so far as the general condition was concerned. The hematuria disappeared, the pain diminished, but the tumor continued to increase in size and led to the death of the patient. Legueu and Cherin reported the case of a young woman twenty-six years old affected with an inoperable ureterovaginal epithelioma. Four applications of radium were made within the period of six months. One application was external, one was in the midst of the tumor, and two applications were intraureteral. The growth disappeared completely, but the ureter had been destroyed, allowing a constant extravasation of the urine. At the end of thirty months following the termination of the treatment, the patient died following an attempt at anastomosing the ureter with the intestine. The most careful autopsy revealed no trace of cancer in the body. The short résumé of the above reports enables one to conclude that radium treatment is a good palliative and sometimes a distinct cure of cancer, and it is to be hoped that reports along this line will be continued to be made. The paper by Legueu furnishes the point of departure for an extensive discussion which will be referred to in a later communication.

At a recent session of the Surgical Society there was an important discussion upon the diagnosis and treatment of wounds of the heart. Picque reported three cases of wounds of the ventricles treated successfully by suture. From the viewpoint of diagnosis a majority of surgeons are of the opinion that in cases in which there is a suspicion of a wound of the heart, it is necessary to be as careful as possible in the clinical examination of the patient to avoid moving him. On the other hand, Lenormant believes that the patient should always be completely examined. No accidents are so urgent that one should not take time to make a rapid and complete examination. It is of the greatest importance to establish the diagnosis of wounds of the heart and of the lung, for intervention is necessary in the former case and contraindicated in the latter. As to the symptoms, the immediate subjective signs are of no value. They may indicate a slight injury without any grave omen or they may be associated with the most serious outcome. The objective signs are very important. In the case of hemopericardium these signs consist in the increase in the cardiac dulness together with the signs of the compression of the heart. But these symptoms may be entirely absent, when, for instance, there is a communication sufficiently large between the pericardium and the pleura, which will enable the blood to flow from the pericardium into the pleura.

Robineau regards as a probable sign of wound of the heart a disproportion between the general symptoms which are those of extreme anemia and the absence of a serious internal or external hemorrhage. Riche accords little value of the smallness or frequency of the pulse, but he attributes considerable importance of the irregularity of the rhythm and of the force of the pulse. The extreme pallor of the face coincident with the absence of internal or external hemorrhage is, according to Savariaud, a good sign of compression of the heart. In one case he has seen this pallor disappear with the suture of the heart. This mortal pallor has also been observed by others. The auscultatory signs are useful only in exceptionally rare cases. According to Lenomant the best guide in the diagnosis of wounds of the heart is a progressive aggravation of the general symptoms and especially of the circulatory troubles. In doubtful cases puncture of the pericardium, possibly by the epigastric route, a procedure recently described by Marfan, appears to be more dangerous than useful.

According to Morestin it would be better to make a short incision, opening the pericardium in the region of the xiphoid cartilage. In doubtful cases it is best to follow the course of the original injury, enlarging the wound and cutting away as much of the neighboring tissues as may be necessary. An opening thus made will facilitate exploration and, if necessary, treatment. It suffices to resect the first cartilage and the fifth rib and to fracture the fourth rib after resection of its own cartilage. Robineau in one case found it sufficient to resect the fifth rib. Morestin and Riche are of the opinion that it suffices according to the case to resect one or two ribs.

In the course of the intervention Picque recommends that a search be made for the posterior orifice, which procedure is extremely difficult. Occasionally there is only one orifice, in which case the bullet remains in one of the cavities of the heart, or it may strike the heart tangentially, or cut a groove that opens up a cavity of the heart. If the ball remains in a cavity of the heart it must be extracted. If it lodges in the wall of the heart it may be left there, the heart having a marked tolerance for foreign bodies. In sewing up the heart the operation is facilitated by holding the organ in the palm of the hand. All of the surgeons avail themselves of this method. Two cases in which death followed arrest of the heart upon the operating table are reported by Morestin. This emphasizes the need of handling the heart with great care! As regards the best time to insert the stitches into the heart, whether during systole or during diastole, none of the surgeons makes any distinction. Sometimes it may be better to insert the stitches while the heart is contracted, and at other times while it is realxed. Most of the surgeons close the pericardium without drainage. As to the pleura some surgeons perform drainage, but the general tendency is to close as soon as possible the pleura and the pericardium.

(From Our Regular Correspondent.)

MODERN TROPICAL PATHOLOGY—QUININE-FAST MALARIAL ORGANISMS—DIAGNOSTIC VALUE OF MONONUCLEOSIS IN MALARIA—SALVARSAN IN MALARIA—BLACKWATER FEVER—TUBERCULOSIS IN THE TROPICS—DISEASES OF THE CECUM.

BERLIN, March 15, 1914.

At the Berlin Medical Society on February 11 a very interesting address was delivered by the chief surgeon of the military forces in the German colony of Kamerun on the West coast of Africa. His subject was "Problems and Aims of Modern Tropical Pathology." In the case of malaria the quinine-fast condition of certain parasites is the cause of the relapses which furnish the greatest difficulties in the treatment. The quinine-fast parasites propagate whenever the body for any length of time has passed through a stage of diminished resistance. In the cultures, pictures of which the speaker demonstrated, the end-forms of the parasites were readily studied. The cultivation of the parasites in the test-tube has been effected by means of a modification of the Bass method. We are as yet in the dark as to why at certain times sexual forms arise in the blood.

Perhaps the greater incidence of malaria in Germany during the spring of the year is to be attributed to the fact that at this season the rural population is compelled to work very hard. At any rate one can be certain that the malarial parasites are not able to hibernate in the pupa stage. On this account the diagnosis has hitherto been difficult owing to the fact that it has not been possible to find the malarial organisms. A diagnostic aid is the enumeration of the large mononuclear cells of the blood. For instance, it has been shown that in the case of protozoal diseases these cells are increased to the extent of 12 per cent. or more. If other protozoal diseases can be excluded one can conclude from the presence of such an increase of mononuclear cells that malaria is present. The speaker has attained the best results in the prophylaxis of malaria by administering quinine every third day in doses of 1 gram. The quinine acts upon the plasma of the malarial organisms and is quickly eliminated by the body. Whenever the condition of quinine-fastness arises the administration of salvarsan or salvarsan-copper has proved to be very effective.

In the case of blackwater fever the state of affairs is particularly far from gratifying, inasmuch as it is impossible to diagnose the predisposition to this condition. In the cases that have been observed in the hospital, in which cases anuria did not arise, the prognosis was relatively good. In the cases with anuria the speaker found no benefit in the operation of splitting the kidney, since in spite of the disappearance of the hemoglobinuria the hemolysis became stronger and stronger. One can conclude that a certain ferment is concerned in this process. The administration of cholesterin in no case had any effect upon the hemolysis. Since it has been possible in dogs suffering from piroplasmosis to influence the disease from the viewpoint of immunity by the administration of attenuated cultures of the organism one may possibly obtain good results with the use of this method in human beings.

The speaker's immunization experiments with the *Trypanosoma gambiense* have wholly failed with reference to the prevention of sleeping-sickness. In the beginning good effects are obtained with atoxyl and arsenphenylglycin; later these remedies as well as salvarsan are ineffective, while the efficacy of trixidin and tryasofal is as yet to be determined. Salvarsan has proved to be an ideal remedy in many diseases of the tropics caused by spirochetes. The results in frambesia are marvelous. In some cases the remedy has been efficacious in leishmaniosis. In leprosy nastin was effective at the beginning of the disease in the case of a European leper but in the case of a native leper the remedy, although partly successful in the beginning, was ineffective at a later stage.

Tuberculosis is of special significance with reference to the tropics, for the disease arises in its most severe types among the natives. On the other hand diabetes is almost wholly unknown among the natives. In the Indes this disease is, however, widespread. In spite of the wide diffusion of syphilis among the natives tabes and paresis are unknown. Disease of the cecum is particularly rare among these people. The speaker did not believe that the diet which is poor in meat is responsible for this immunity, nor did he believe that the simple structure of the appendix resulting from the slight mixture of the races serves to protect the appendix from inflammation. In many autopsies the speaker detected changes in the appendix of natives similar to those present in Europeans.

5. Fracture of the Clavicle. F. E. Peckham.

**1. Treatment of Cases of Mental Disorder in General Hospitals.**—P. C. Knapp believes that the mental patient has a claim upon the benefits of a public hospital just as well as the surgical, the gastric, or the renal patient. The reception of such cases means some extra trouble, a few more nurses, and more anxiety for the staff and the administration. The adoption of aseptic methods in the surgical wards means much more trouble and vastly greater expense. There are certain risks involved, but experience has shown that they are not very great. Every good hospital for the insane has its escapes, its suicides, and its acts of violence. The general hospital may expect them as well, but the benefits to the community outweigh these disadvantages. It is not practical to receive and care for such patients in a general hospital unless there be a special service under the charge of a visiting neurologist familiar with mental diseases and their treatment. The average American internist is too ignorant of mental and nervous diseases to deal properly with such cases. Something more is requisite than restraint while in the hospital and commitment at the earliest opportunity. The visiting physician must be able to make a sound prognosis as well as a diagnosis and must be ready to assume risks and take proper precautions. He must have the control of his patients and their treatment without interference from administrative officers, and must be alone responsible for the treatment, the stay in the hospital, the restraint, and the commitment. Only under such conditions can the reception and treatment of cases of mental disorder in general hospitals be of full benefit to the patient and to the community.

**2. Medical Inspection of Immigrants.**—A. J. Nute states that the medical examination is divided into two parts, primary and secondary. In the primary the efforts of the examiner are directed toward segregating those immigrants suspected of having disease, defect, or abnormality of any kind in order to enable the healthy to proceed without unnecessary delay. In the secondary examination a systematic inquiry should be made as to the signs and symptoms in those turned aside in order to determine a diagnosis and proper certification. It is impracticable under the present law and facilities to consider every alien a possible mental defective and subject him to complete examination unless on primary inspection there have been some signs of mental disorder. With the feeble-minded, the facial expression and attitude constitute a valuable index except in the high grade types where these are negligible and are then a matter for the judgment and experience of the examiner to decide how much lower the suspect is in the mental scale, considering all the factors of race, previous environment, and education. The complexion of the Slavish peasant woman would suggest chlorosis if possessed by a Scandinavian or English woman of the same class. On the other hand the red cheek of the Scandinavian would arouse thought of a hectic flush if seen in the Polish woman. The excitability of the southern Italian and the Hebrew are well known. It is easy to excite in them almost maniacal action. The stolidity and indifference of the Slav would suggest melancholia if presented by the Hebrew. The sanity of an Englishman would be questioned if on slight provocation he evinced the external manifestation of emotion that would occur in the Sicilian. The German girl takes her examinations seriously and her sanity would at once be suspected if she saw the same reason for light remark and laughter as the girl from Ireland. Some races are extremely emotional and others are stolid, and unless the normal is known it is impossible to pick the abnormal. In determining mental conditions by inspection the first essential is to determine the race or type of the individual and to have a good knowledge of his racial characteristics.

**1. The Prophylaxis of Measles.**—J. Ruhräh states that an important point in the prophylaxis of measles is the closing of schools in the face of threatened epidemics. In order to be of any service the isolation should be started early, and in order to do this it is necessary to make at least a tentative diagnosis. If measles is in an institution already, or if there is much just outside of it, and there is reason to believe that infection may occur, the children may be examined with reference to several signs, the first of which is loss of weight. This begins as early as the fifth or sixth day before the appearance of the catarrhal symptoms, and generally amounts to about ten ounces for children up to four years of age, and in some the loss may amount to as much as three ounces a day. The loss is independent of age or the severity of the attack. An examination of the blood will show that during the incubation period there is a leucocytosis. It should be borne in mind, however, that this leucocytosis lasts only into the first day or two of the stage of invasion, when the leucocyte count falls to normal or even below. When the stage of invasion is reached the disease may be suspected if there is fever, especially if accompanied by catarrhal symptoms affecting all or almost all of the mucous membranes. Conjunctivitis, coryza, pharyngitis, and bronchitis are usually all very apparent. In addition, there is almost invariably marked drowsiness. Heim, many years ago, called attention to the odor of measles, which has often been described as like that of a mouse trap, and while there is undoubtedly a more or less characteristic odor about measles patients, this mouse trap odor is usually due to lack of care and cleanliness rather than anything characteristic of the disease. Two other signs are of value; one, the cyanosis of the tongue which is seen a day or two before the eruption appears, and the other, of the greatest possible value, is the presence of Koplik's spots. These spots sometimes may be seen as early as four days before the appearance of the eruption and usually two days or one day before it appears.

3. Treatment of Diabetes and Glycosuria.—L. N. Boston notes that the amount of carbohydrate food that a given individual may take during the twenty-four hours is a most important factor in preparing to treat one suffering from glycosuria. In order that we estimate approximately the quantity that each patient should take daily it is first necessary that he be permitted to eliminate from his system all excess of sugar.

It has been found that a most satisfactory way to accomplish this end is to withdraw as much carbohydrate food as possible, and to encourage the patient to take liberally of liquids, particularly of water. Through this method of treatment an existing hyperglycemia will usually be overcome within the course of seven to ten days. In all cases in which through diet alone it is possible to obtain a negative reaction with Fehling's solution, the first step in the treatment is completed. The second step in this variety of cases is to ascertain how much carbohydrate the patient can take at each of three different meals during the day and his urine still give a negative reaction for sugar. In the event of being able to affect a negative reaction for sugar with the patient's urine through diet alone, it becomes necessary to use certain drugs. Through the use of such drugs together with diet it is commonly possible to accomplish the desired result. At this point the treatment of diabetes becomes vastly different in practically every individual case. In some cases results are obtained through the liberal use of codeine sulphate. In other cases codeine seems to have but limited, if any, influence upon the sugar excreted. Extract of ox gall and pancreatic extract are drugs that often prove most effectual. When using ox gall and pancreatin it is well to direct that they be placed in a pill which is coated with keratin, and which has a second coating of salol. The two substances used for the coating of the pill do not under ordinary conditions dissolve in acid solutions, consequently when taken into the stomach they remain intact and protect the ox gall and pancreatin from being acted upon by the gastric juice. Pills properly coated with salol or keratin become immediately available as soon as they have passed into the alkaline solution in the duodenum. The author has employed the Bulgarian bacillus, with apparently good results.

4. **The Surgeon as Autocrat of the Operating Room.**—J. W. Kennedy refers to certain criticisms caused by the alleged unnecessary exposure and rough treatment of the anesthetized patient. The surgeon is the autocrat of the operating room and is responsible for the anesthetic, nurses, assistants, attendants, and visitors. There is but one solution for the vexed question of the sponge count which is the commonest source of legal complication; the operator must have a definite number of sponges and this number must be counted by the operator before and after each operation. The author's technique is simple. He works with three gauze sponges and three gauze towels. Before beginning the operation these sponges and towels are held to him for inspection, and these are the only ones which are permitted to remain in the abdomen during operation. He can count at a glance the three sponges which are held in a basin for inspection before he closes the abdomen. When the author has finished the intraabdominal work, the nurse counts these sponges by taking them out of the basin one at a time and placing them in another basin, they are then counted back to the first basin and this basin is then held to him for inspection. His final inspection clinches a sacred duty. It is never necessary to use more than three gauze towels and a like number of sponges at any operation. The absorbable ligature is not a necessity. The author notes that nothing but silk and silkworm gut need be used, as the sterilization of these materials depends upon one's self. Some of the most recent foreign textbooks on gynecology have recommended discarding all forms of absorbable ligatures. Kocher uses almost entirely silk and silkworm gut, and many of the leading institutions of this country are using silk and linen in operations for which one has often been criticised in the past.

1. **Inflammation of the Gall-Bladder.**—J. Tyson reports three cases of cancer following this condition. The fulminating form often terminates in abscess and if unrecognized may terminate in perforation. Next to the typhoid bacillus the colon bacillus is a frequent cause. Adhesions are now recognized as a frequent cause of pain in the right upper abdominal quadrant. Other predisposing causes are sedentary habits, lack of exercise, tight lacing, childbearing, and abdominal tumors, which contribute to explain the four times greater frequency of the condition in women. The most important consequence on account of its frequency is gallstones, and the relation of these to cancer is now recognized, hence the necessity of prompt operation. Other results of neglected cholelithiasis are hardly less serious, such as abscess of the liver and biliary fistulas into various organs, including the veins, the intestine, the stomach, the bronchi, and the external integument. Atrophy of the gall-bladder is not infrequent. Tyson believes that in doubtful cases exploratory operation is sometimes justified, the more so since other conditions may be discovered which would also require operative relief. He does not deny that cancer may precede gall-bladder inflammation, but there is as much reason to believe that they were consequences in the cases reported by the author.

3. **"Renal Diabetes," Possibly Traumatic in Origin.**—S. Strouse and A. H. Beifeld report the case of a healthy young man in whose urine glucose was accidentally discovered during a life-insurance examination. The discovery of glucose followed about one year after a cranial trauma, but whether the two are related belongs entirely to the field of speculation. There were never any symptoms of diabetes mellitus. The excretion of dextrose was practically independent of carbohydrate intake. The blood-sugar twice determined in von Noorden's clinic was normal. Furthermore under condition which in a man of his age would certainly intensify the symptoms and increase the severity of a true diabetes mellitus, the patient has continued to remain in perfect health, and the urine has not taken on the characteristics of urine in diabetes mellitus. Not only does the patient meet the standards of renal diabetes, but also the clinical course of the case excludes the diagnosis of diabetes mellitus.

4. **Roentgen Rays in the Diagnosis of Gallstones and Cholecystitis.**—G. E. Pfahler concludes that gallstones can be shown by the *x*-rays only when they are composed of a substance of greater or less density than the surrounding tissues. This will usually mean that they must contain some lime-salts, though this quantity may

be small. The author's records show positive findings in 74 per cent., but in general one cannot count on more than 50 per cent. being demonstrable. A negative diagnosis at present has no value. It is possible that with the improved technique when one finds the gall-bladder small and still finds no stone, the *x*-rays may become of some value in negative diagnosis. The estimation of the value of this method of diagnosis must be based only on the work of roentgenologists who have mastered a good technique and who are thorough in their work. Definite information will be obtained only by continued cooperation of the surgeon and the roentgenologist.

**8. The Effect of Operation on Kidney Excretion.**—F. B. Block reports a series of cases which seem to indicate that the effect of ether anesthesia on healthy kidneys is practically nil so far as reducing the excretory power of these organs is concerned. Traces of albumin in the urine before operation should not give much concern, but clouds of albumin accompanied by casts should be considered seriously before the performance of elective operations. The duration of anesthesia, in any given case, does not in itself signify the amount of injury which the kidney will sustain. The position of the patient on the table, the character of the operation, and the administration of proctoclysis have not shown any effect on the percentage of phenolsulphonephthalein excretion after as compared with that before operation. In at least one-third of the cases, the author says, there is an increased excretion after operation.

**11. Plantar Warts.**—R. L. Sutton states that while the subject of plantar warts has been carefully studied by several authors within recent years, the true nature of the condition is seldom recognized even today. These cases are notoriously resistant to treatment and recurrence frequently takes place after excision. Of all the methods of removal the author gives first place to carbon dioxide snow. Fulguration comes second and Roentgen treatment third. Before the snow or electric current is applied, the epidermal lids of the little tumors should be removed by a 10 per cent. salicylic acid plaster. Roentgen treatment is especially applicable when there are numerous lesions, which frequently disappear as if by magic. In the case reported by the author all three of the methods mentioned were used and the cure of the warts was apparently complete in three weeks.

9. Elementary Training of Children to Remove Mental Faults and Lessen Mental Deficiency. F. Warner.

**1. Gangrene of the Lung.**—H. B. Shaw states that this disease is a comparative rarity. Eichhorst has found it to occur in only 34 out of 27,472 cases coming under his clinical observation, i. e., in less than 0.1 per cent. Gangrene of the lung is a very serious malady, for according to Lenhartz 80 per cent. of the cases treated by medical measures die. The author reports a series of seventeen cases in which gangrene of the lung was secondary to hydatid of the lung, a fistula connecting the left bronchus with a tuberculous interbronchial lymphatic gland, traumatism, eclampsia, cylindrical and saccular bronchiectasis, pneumonia, pulmonary tuberculosis, bronchitis, spinal caries, empyema, abscesses of the lung, carcinoma of the esophagus, enlarged interbronchial gland, acute pneumonic tuberculosis, and Litten's traumatic pneumonia. This list is sufficient to show the varied causes that give rise to gangrene, but there are others. Infarction of the lung may be followed by gangrenous changes in the infarcted area, and possibly this was the cause of the gangrene in the case of eclampsia. If the embolus giving rise to the infarction is infected with putrefactive organisms the gangrene will occur at once in the infarcted area of the lung; such is the sequence of events in gangrene of the lung following gangrene of the leg or following endocarditis in puerperal cases. Gangrene of the lung occurs in cases of aspiration of food or other foreign bodies, and then forms a feature of aspiration or deglutition pneumonia, and gangrene has closed the scene in cases of bulbar paralysis and in cases of carcinoma or suppuration about the upper air passages. Aspiration following vomiting after the use of a general anesthetic has also caused gangrene of the lung. Gangrene is a not unusual occurrence in the insane and is associated with the difficulties of feeding these cases. Gangrene of the lung occurs in diabetes mellitus, and in this case the expectoration may be free from offensive odor. It is also met with in diphtheria. Gangrene of the lung occurs in typhus and typhoid fever, and is a well known accompaniment of aneurysm or of growths or strictures interfering with the patency of the bronchus. Lymphogenous gangrene of the lung has been noted in cases of carcinoma of the esophagus occurring independently of direct extension into the lung of the original growth. Subphrenic and hepatic abscesses may also cause gangrenous pneumonia, and operations on the stomach and duodenum may also be followed by it. Alcoholism and renal disease are important as strongly predisposing the individual to gangrenous pneumonia. Gangrene of the lung may be suspected when in the course of some one or other of the maladies above referred to, there is a sudden onset of expectoration of very offensive odor, associated with symptoms of severe toxemia, as shown by rise of temperature, rapid pulse, anemia developing rapidly, anorexia, rigors and wasting. The course of the malady may be very brief (ending in death or recovery) or the symptoms may go on for many months and still not be fatal, as cases may recover after many weeks of illness. Not only may the symptoms cease, but the lesion in the lung may entirely disappear.

**3. Intraspinous Treatment of General Paralysis.**—E. Mapother and T. Beaton report an analysis of their cases and of those treated by other observers, mainly American, which analysis shows little ground for the generally hopeful attitude adopted in regard to the treatment, for in none of the cases did the treatment produce changes in the mental or physical conditions other than such as are to be seen with almost equal frequency during the untreated course of the disease. While in several of the published cases changes in the cellular and globulin content of the cerebrospinal fluid have been noted, in none has any claim been made that the Wassermann reaction has been abolished in either the blood or the cerebrospinal fluid. Even if the disappearance of the Wassermann had been found during the treatment the cure of the disease would be unproven, as periods in which the reaction is temporarily absent have been shown to occur during its ordinary course.

**4. Tonsils and Adenoids in Children.**—T. B. Layton

believes that when the rule is made of having all carious teeth in children attended to before an operation on tonsils and adenoids is done, a very large number of these operations is avoided; this is so, both in the cases seen after an acute attack and in those which come up with slight symptoms of snoring and deafness from adenoids associated with enlarged tonsils. The author emphasizes the importance of breathing exercises. No operation is completed unless those be done regularly and deeply for two or three months afterwards. He believes that in a very large number of cases the operation is unnecessary if the exercises are efficiently done, and that very many operations are useless unless they are done. No operation equally small carries with it so many risks. There is the undoubted risk of the anesthetic. Hemorrhage may be severe. Infection is the cause of the other sequelæ. The least of these is a severe sore-throat which makes the child thoroughly ill for from several days to a fortnight; such a complication is sure to occur in some cases, and it is one's business to make these cases as few as possible. Acute otitis media, pneumonia, and metastatic abscesses are the most serious complications. Measles, scarlet fever, and diphtheria may also be looked upon as postoperative complications. In rheumatism and allied conditions the case is different from the other acute fevers. Here the operation determines the attack. The author has had three cases of attacks of chorea definitely beginning after an operation on the throat; one of these attacks was most intractable and kept the child away from school for somewhat over six months.

7. The Possibilities of Domiciliary Treatment in Phthisis. G. Jessel.

**1. Laryngeal Tuberculosis.**—Sir St. Clair Thomson, as the result of three years' sanatorium experience, reaches the following conclusions: The larynx is frequently involved in pulmonary tuberculosis. Even in the selected cases sent to the sanatorium it is met with in 25.6 per cent. A considerable number of cases (102 out of 795) are sent to a sanatorium without their showing active tuberculosis. These cases, if included in statistics, would largely help to invalidate the foregoing conclusion. In patients of the middle class laryngeal tuberculosis may be met with as frequently in females (28.3 per cent.) as in males (24 per cent.). Laryngeal tuberculosis occurs much more frequently (13.7 per cent.) in the early favorable cases of Group 1 than is generally recognized. In the more decided cases of Group 2 this proportion is doubled (27.1 per cent.) and in the advanced cases of Group 3 it is trebled (40.8 per cent.). The expectation of life amongst consumptives is markedly decreased by the complication of laryngeal tuberculosis. As a factor in prognosis the laryngeal condition deserves much more regard than it has hitherto commanded. Laryngeal tuberculosis may not infrequently be present, although the patient may make no complaint of the throat, and although the voice be unaltered. Hence: The larynx should be carefully inspected in every case of pulmonary tuberculosis. Improvement in lung and larynx frequently, but not necessarily progresses pari passu. In certain cases the larynx improves while the lung retrogrades. The converse rarely takes place. Arrest of laryngeal tuberculosis can be effected in a sanatorium in 20.7 per cent. of all cases. Limited and slight laryngeal lesions, particularly in Groups 1 and 2, may become arrested spontaneously with sanatorium treatment. The galvano-cautery is the best weapon we have at present for local treatment. It was only indicated in 20.22 per cent. of 178 cases, and it completed the cure in 40.60 per cent. of the cases in which it was employed. These satisfactory results have not so far been secured by any methods outside a sanatorium. Sanatorium treatment is at present the first and most valuable method we have for arresting laryngeal tuberculosis. Local measures are much more promising under sanatorium conditions. At present, in many cases, the diagnosis of tuberculosis is too long delayed, or the patient is sent to a sanatorium much too late to effect a cure. Hence, with one's present therapeutic resources one must, to get better results, urge the importance of early diagnosis and then prompt sanatorium treatment.

*March* 24, 1914.

**A New Method of Artificial Separation of the Placenta.**—Gabaston of Buenos Aires refers to a method devised in the University obstetrical clinic, the principle of which he terms the hydraulic. Sterile physiological saline infusion is injected into the divided umbilical vein. This problem was naturally first attacked by experiments conducted on ordinary expelled placentæ. The fluid first distends the large placental vessels; then the organ as a whole becomes much larger, suggesting distended erectile tissue. At last the small vessels in the cotyledons are unable to withstand the pressure and rupture and the fluid escapes at the uterine surface. In the natural condition some differences are necessarily present. Thus the uterus has contracted down upon the placenta, an act often held responsible for the normal separation of the latter by contracting the uterine surface at the placental site. The distention with water aids in detaching the placenta. In certain cases a retroplacental hematoma is the cause of premature detachment and this action of a fluid is of the same mechanism as the preceding artificial procedure. There are several advantages in the new method—among the chief of which is that it does away with the introduction of the possibly nonsterile hand. In many cases of puerperal fever, there is a history of manual delivery.

**Pulmonary Tuberculosis in Childhood.**—It used to be taught that up to puberty or thereabouts the average child did not suffer from the adolescent or adult types of pulmonary phthisis. We were to fear chiefly tuberculosis of the bronchial glands, acute miliary tubercle, etc., and especially the meningeal location. To-day Rach, an assistant of von Pirquet shows that such teachings are largely antiquated. Children and even nurslings present lesions which do not differ essentially from those of much older subjects. We are now able to isolate six types of pulmonary tuberculosis in childhood. I. Ghon's primary focus, which may appear anywhere in the lung. II. The intumescent tuberculosis of the bronchial glands. III. The intrapulmonal hilus tuberculosis. IV. Miliary tuberculosis. V. Nursling's phthisis and VI. apex tuberculosis. This classification is largely the result of studying radiographs. Nursling's phthisis includes cavitary lesions and caseous pneumonia. Apex tuberculosis may begin as early as the seventh year.

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### THE MORTALITY AMONG WOMEN.

MEDICAL examiners are apt to approach the examination of women with a feeling of more or less diffidence and nervousness and, consequently, fail to ply some of the pointed questions which appear on the blanks or make a thorough examination. The writer proposes in this and following contributions to show the importance of careful work in examining among this class of applicants.

It was formerly the custom to charge an extra premium to women, or to place them in a special class as to dividends which amounted to the same thing. The custom was justified by the statistics available at that time which showed a higher mortality among insured women than among insured men. The higher rates and the restrictions made it comparatively difficult to solicit insurance among women than men, and the agents preferred to work where their efforts were more likely to meet with success. One of the large companies published a synopsis of its experience several years ago. This company had been insuring women for ten years on the same terms as men, and the results had been fully as satisfactory as among men. The experience of this company, as well as that of others, indicates that, provided sufficient care is exercised in eliminating undesirable risks, the mortality is lower when insurance on the lives of women is actively solicited and the rates are the same as those charged to men. On the other hand, when women were charged an extra premium and were not actively canvassed for, most of them who bought insurance did so voluntarily with the widely extended exercise of self selection that must be expected under such circumstances.

The Medico-Actuarial Investigation Committee have made a study of the mortality among 393,032 women who had been insured in a number of companies, dividing them into four classes: (1) spinsters; (2) married women, beneficiary husband; (3) married women, beneficiary other than husband; (4) widows and divorced. Under-average, impaired or substandard cases were excluded. The great majority of the cases had been accepted under modern conditions, as only one-eighth of the policies had been in force more than ten years and less than one-half more than five years in force.

The general mortality among the 393,032 women studied under the four classes is indicated in the following table:

| Class | Actual Deaths | Expected Deaths | Ratio of Actual to Expected Deaths, per Cent |
|---|---|---|---|
| Spinsters | 3,557 | 4,412 | 81 |
| Married women, beneficiary husband | 3,235 | 2,566 | 126 |
| Married women, beneficiary other than husband | 4,403 | 3,869 | 114 |
| Widows and divorced | 4,312 | 4,124 | 105 |
| Total | 15,507 | 14,971 | 104 |

These tables can give only a general idea, as the lives are classified according to the conjugal condition at the date of the issuance of the policies; a certain percentage of the spinsters and widows marry afterward, and some of the married become widows.

If a further analysis is made according to the age of the policy and the ages at entry, it is seen that the greatest divergences between the ratios of the actual and expected deaths among the four classes are found in the earlier years. The influence of the hazard of child bearing probably accounts for a part of the high mortality at the younger ages of entry.

ALL AGES AT ENTRY COMBINED

RATIO OF ACTUAL TO EXPECTED DEATHS BY M. A. TABLE

| Policy Years | Spinsters per Cent | Married Women Beneficiary Husband, per Cent | Married Women Beneficiary Other than Husband, per Cent | Widows and Divorced, per Cent |
|---|---|---|---|---|
| 1 | 82 | 146 | 135 | 104 |
| 2 | 72 | 143 | 133 | 106 |
| 3 | 81 | 129 | 117 | 108 |
| 4–5 | 85 | 127 | 115 | 107 |
| 6–10 | 81 | 111 | 106 | 104 |
| 11–24 | 80 | 108 | 104 | 102 |

ALL POLICY YEARS COMBINED

| Ages at Entry | Spinsters, per Cent | Married Women Beneficiary Husband, per Cent | Married Women Beneficiary Other than Husband, per Cent | Widows and Divorced, per Cent |
|---|---|---|---|---|
| 15–24 | 100 | 150 | 158 | 210 |
| 25–29 | 83 | 147 | 144 | 129 |
| 30–39 | 73 | 129 | 123 | 109 |
| 40–49 | 70 | 109 | 102 | 104 |
| 50–62 | 68 | 98 | 100 | 103 |

The ratio of 210 per cent. in the case of widows and diverced, ages 15-24, is of little value, as there happened to be only 50 deaths recorded in this class. The deductions regarding these four classes which should prove useful to the examiners, as well as the home office forces, may be summed up as follows:

Among spinsters the mortality is favorable, adverse selection is evidently exercised to only a very small degree, if at all, and the mortality, compared to that of men, decreases with advancing age at entry.

Among married women, the mortality is distinctly higher than that among men and decreases with the advancing age at entry. A powerful self selection against the interests of the companies is indicated by the heavier ratio of actual to expected deaths in the first and second policy years. The aggregate experience is less favorable among married women with husband as beneficiary than with some other beneficiary.

Among widows and divorced women, the mortality lies between that of spinsters and married women. It progresses according to policy year about the same as spinsters and gives no material evidence of self selection.

With the knowledge gained through a study of these tables which point out the cases in which careful examinations and searching selection are especially needed, there is no reason why women in the four classes should not be insured on the same terms as men. Adverse selection must be guarded against and strict attention must be given to the insurable interest of the beneficiaries. The spinsters, for instance, had been in receipt of good incomes and had not followed occupations requiring long hours and hard work, and took out insurance in favor of some dependent. On the other hand, one company reported that married women who paid the premiums out of their own incomes and whose children were the beneficiaries, showed a mortality of 90 per cent. of the standard, while married women with no children and whose husbands paid the premiums and were the beneficiaries, had a mortality of 126 per cent.

# Book Reviews.

PRINCIPLES OF SURGERY. By W. A. BRYAN, A.M., M.D., Professor of Surgery and Clinical Surgery at Vanderbilt University, Nashville, Tennessee. Octavo of 677 pages with 224 original illustrations. Price $4.00 net. Philadelphia and London: W. B. Saunders Company, 1913.

THIS book is written in easy colloquial style with no apparent attempt at imposing verbiage and for this reason is one of the most interesting as well as instructive contributions to this subject that has appeared in recent years. In many ways the style reminds one of that facile writer, the late Nicholas Senn. It is more than a treatise on the principles of surgery, for the author not only presents the results of the latest researches along the lines of surgical pathology and bacteriology and discusses the etiology, pathology, and diagnosis of the various surgical conditions, but also suggests methods or lines of treatment, and that, too, sometimes at great length; while in many instances the author's ideas as to prognosis and after-treatment are freely given. In the first two-thirds of the book surgical bacteria, inflammation, suppuration, gangrene, burns, thrombosis, embolism, erysipelas, tuberculosis, and other subjects usually found under this title are discussed. The final third is devoted to the consideration of tumors and the author brings out very forcibly the need for early recognition and operation when there is any suspicion of present or possible future malignancy.

The frequent overstepping of the bounds naturally imposed by the title adds very materially, in the opinion of the reviewer, to the value of the book, as the suggestions for treatment are based on sound common sense and good surgical judgment. This latter quality is exemplified on many occasions, as, for example, in the recommendation of surgery in cases of gastric and duodenal ulcer during the *first* attack is marked improvement or cure does not result after six or eight weeks of medical treatment; and the further suggestion that "if, after apparent cure, recurrence takes place, the case becomes surgical." Again, recognizing the occasional tendency of sperficial moles to undergo malignant degeneration under the influence of irritation, he says "Deal with them summarily or leave them absolutely alone." Bryan has not hesitated to express his opinions. Thus, in the chapter on Sepsis, we find the following: "There is no place in modern work for the ignorant, heavy handed, careless surgeon." The newest methods of diagnosis are amply referred to and in all departments the book seems up to date. The illustrations, all original, are good and to the point, but their effectiveness is impaired in many cases by poor printing. Occasional slight errors, mostly typographical, have been noted by the reviewer; but one to which attention should be called occurs in the 13th line on page 409. The author advises us that the word "arteries" is intended instead of "veins." The sentence *should* read: "The most common type of the condition (embolism) is that affecting the pulmonary arteries."

The book is full of "meat"; the style is graceful and easy, and the facts are presented in a way that compels the attention of the reader. It is an interesting book—one that will be carefully read and not quickly consigned to the practical oblivion of the book-case.

THE STUDENT'S HANDBOOK OF GYNECOLOGY. By GEORGE ERNEST HERMAN, M.B., F.R.C.P. (London), F.R.C.S. (England); Consulting Obstetric Physician to the London Hospital, Consulting Physician-Accoucheur to the Tower Hamlets Dispensary, late President of the Obstetrical Society of London and of the Hunterian Society, formerly Physician to the General Lying-in Hospital and Examiner in Midwifery to the Universities of London, Oxford, Cambridge, Durham, and the Victoria University, the Royal College of Physicians, and the Royal College of Surgeons. Second Edition. Revised by the Author, with additions by K. Drummond Maxwell, M.D. (London), F.R.C.S. (England), Assistant Obstretric Physician to the London Hospital, and Physician to Queen Charlotte's Lying-in Hospital. With six color plates and 194 figures in the text. Price $2.50 net. New York: William Wood & Company, 1914.

IN this manual the author has taken common symptoms and described under each the principal diseases which cause it. Anatomy, anesthetics, asepsis, and antisepsis are not considered because these subjects are of such vital importance that they could not be compressed into incidental chapters. The book is well illustrated and is to be highly commended. It will appeal to those who wish a comprehensive handbook on gynecology.

THE PATHOLOGY OF GROWTH—Tumors. By CHARLES POWELL WHITE, M.D., F.R.C.S., Director, Pilkington Cancer Research Fund; Pathologist, Christie Hospital, Manchester; Special Lecturer in Pathology, University of Manchester. Illustrated. Price $3.50 net. New York: Paul B. Hoeber, 1913.

WHILE there are many excellent books in German on the subject of tumors, and a few in French, there is a great scarcity of modern material from the English side. The volume under consideration is welcome, therefore, because of the lack of rivals as well as on account of its own real qualities. The writer, well known as a student of the subject with which he deals, has produced a volume of singular freshness and originality of treatment, while still keeping within the standard lines of classification and etiology. The pictures are largely photomicrographs, and, therefore, show what is really in the sections, and not what some artist thinks is there. They are well selected, and the only criticism which can possibly be raised is that the technical part of the half tone reproductions is not of the same quality as the original photographs. The type is good; the book is well bound, and there is a very useful appendix explaining some of the weird Greek compounds used in describing tumors. The volume can be commended, both as a student text for collateral reading and as a book of value to the surgeon.

TROPICAL MEDICINE AND HYGIENE. By C. W. DANIELS, M.B. (Cantab.) F.R.C.P. (London); Lecturer on Tropical Diseases, London Hospital; Formerly Director London School of Tropical Medicine; Director Institute for Medical Research, Federated Malay States. In Three Parts, with colored and other illustrations. Part I—Diseases due to Protozoa. Second Edition. Price $3.00 net. New York: William Wood & Company, 1913.

IT is five years or thereabouts since Dr. Daniels published the first edition of Part I and the marked progress of tropical hygiene and the knowledge gained of the nature and treatment of tropical diseases has rendered the issue of a second edition opportune. The reputation of the author, both from the standpoints of practice and theory so far as tropical sanitation and the treatment of tropical diseases are concerned, stamps a work from his pen as in many respects authoritative. While in the present volume all due attention has been paid to the chemical features of maladies more or less peculiar to the tropics, special prominence has been given to their etiology and prevention. As far as possible the diseases discussed have been grouped according to their known or probable causation, and the author states that experience has justified this method of grouping. In the first part those diseases are dealt with which, like malaria, are known to be due to protozoa and others, such as yellow fever, which are probably due to these organisms. The volume presents in concise form a large amount of information calculated to be of much value to practitioners and students of tropical medicine.

THE INTERVERTEBRAL FORAMEN—An Atlas and Histologic Description of an Intervertebral Foramen and Its Adjacent Parts. By HAROLD SWANBERG, Member American Association for the Advancement of Science. With an Introductory Note by Prof. HARRIS E. SANTEE. Illustrated by 16 full page plates, none of which have ever before appeared in print. Price $3.00. Chicago: Scientific Publishing Co., 1913.

THIS book contains an atlas and histological description of an intervertebral foramen and adjacent parts, with special reference to the relations of the nervous structures. Clear and unique plates are shown of the spinal canal, intervertebral foramen, and portions external to the foramen illustrating the course of the anterior and posterior roots, white and gray rami communicantes of the sympathetic, etc. The relations of the various parts of the spinal nerve and sympathetic fibers to bone, fibrous tissue, fat, muscle and blood-vessels are seen and thoroughly explained. Every effort has been made to give the reader a clear and concise idea of the normal structure and situation of these parts. A study of this work helps to determine whether there is substantial ground for the doctrine that compression in the foramen is the immediate cause of all or of a considerable number of pathological conditions.

### SECTION ON OBSTETRICS AND GYNECOLOGY.

*Tuesday, April 28—First Day.*

DR. ROSS MCPHERSON IN THE CHAIR.

**Sterility in Women.**—Dr. E. WILLIS FORD of Utica read this paper. He called attention to the fact that one marriage out of eight among people who were apparently in good condition failed of offspring. Various theories had been propounded to account for these failures, none of which seemed to be of much value. There were a few cases of young women who were apparently healthy and had never had any serious illness, excepting menstrual pain and generally a troublesome leucorrhea, usually with an undeveloped neck of the uterus. These women were very liable to develop serious uterine disorders later in life and sterility was one of them. In the early stages of scientific gynecology the attention of the profession was largely directed towards conditions of the cervical canal, flexions, versions, and stenoses, that suggested operations upon the cervix and uterus, such as dilatations, divulsions, and the slitting of the lip of the uterus, in the effort to straighten the cervical canal. It was found that the scar tissue after various surgical procedures often contracted and was generally inelastic, and sometimes proved as much of an obstruction as the original deformity. It was later the fashion to dilate and curette the uterus and pack it. In the observation of most men, however, a small contracted uterus with an unhealthy endometrium followed a severe curetting. Hope had been entertained that conservative surgical procedures would relieve many cases of dysmenorrheal sterility, independent of slightly abnormal positions and conditions of the uterus. But the number of cases that afterwards conceived on account of such conservative treatment had been disappointingly small. After hearing Pozzi five years ago, his surgical procedure commended itself to the writer. Throwing out all cases of former infection, or the possibility of irregularities of living, or lesions about the uterus or adnexa, otherwise than what was found by vaginal examination as depending upon the lower segment of the uterine canal, he began the operation on a limited number of cases and now had thirty-five to report. The cases of dysmenorrhea with perverted secretions and sometimes sterility, due to a small conical neck, with a round pinhole opening, could be converted into a normal looking vaginal cervix by the Pozzi operation and the true function of the uterus might be restored in many instances. The operation, it must be confessed, was sometimes difficult to do, and required more time than the average cervical operation. In the opinion of the essayist the entire point of procedure was to cover any raw surface with mucous membrane, so that no scar tissue would follow. In making the slit in either side of the canal the important thing was to have it so that the anterior lip was as nearly as possible the same size as the posterior lip. The removal of a bit of muscle, or even of exudative tissue of each raw surface, so as to give room to bring the membrane over and cover in the spaces, was sometimes difficult to do. Pozzi used a knife, but, in the experience of the writer, sharp pointed scissors were better. The catgut used was chromaticised and very small. But little tension should be put on the sutures. It was usually necessary to use a small sharply curved needle to catch up a bit of muscle at the edge of the open cervical canal in order to make the stitches hold. It was not necessary that the dilatation which preceded this operation should have been extensive. This operation was not of much use in septic cases. If there was a cicatricial band at the internal os, it was incised forward to the anterior lip, and a very little iodoform tape was necessary to hold it open, while the two newly formed lips of the cervix were held apart, and surrounded by small strips of iodoform gauze. Formerly galvanism was used for a considerable period in these cases, and in the history of many of the cases pregnancy followed. This treatment had to be carried on for several months, and the results were good for a time, but they did not compare with the shorter and more simple procedure of Pozzi. The speaker felt convinced that if early and complete drainage was secured by this simple procedure in these cases of cervical deformity, many of the conditions met with in later life could be prevented and sterility might be avoided in many instances.

Dr. A. J. RONGY of New York called attention to the change in our conception regarding primary sterility in women that had come about during the past few years. They had just begun to realize that they were unable to cure every woman who was sterile by some operation on the cervix. A review of the literature strongly impressed one with the fact that the results of the various operations on the cervix were not at all pleasing and that the percentage of recorded cures was small. The confidence of this class of patients had been abused and operations had been performed too often on them. He had not yet seen a woman who had been sterile for a number of years who had not had some form of operation on the cervix. The harmful effects of these operations, especially in the presence of infection, need not be pointed out, for they had all seen them, and knew the great number of cases which developed such severe pelvic infections as to become invalids for life. They must realize that they did not understand every physiological process associated with conception and pregnancy, and therefore it was not in every case that the cervix or the cervical canal was at fault. There was a class of sterile women who showed a train of symptoms denoting lack of ovarian secretion. This class of patients were usually relieved by large doses of lutein extract. This tended to regulate the menstrual flow, lessened the dysmenorrhea, and improved the circulation in the uterus, thus putting the endometrium in a better condition. He had given as much as thirty grains a day of luetin extract in order to accomplish the desired effect. The action of this drug must be watched, and as soon as slight pain appeared in the lower abdomen or in the joints it must be temporarily discontinued to be resumed later. In the study of sterility the male aspect of the subject was frequently overlooked. In some instances where the husband was apparently healthy the spermatazoa were of feeble motility and died before they reached the internal os. In order to overcome this obstacle it had been the custom of the speaker to inject the seminal fluid into the uterus. Two patients were at present pregnant as the result of this procedure. In properly selected cases this method was very useful. It was their duty to point out to the profession that the operative results in primary sterility were not good, so that every sterile woman should not be subjected to one of the accepted operations for this condition.

**Uterine Hemorrhage in Young Girls.**—Dr. HENRY C. COE of New York presented this paper. He declared that the ambition of the gynecologist to vie with the general surgeon in the development of operative technique had led to the neglect of what might be called the scientific side of their specialty. The operating table had always been more popular than the dead house and the laboratory, and thus our foreign confrères, admitting the boldness and originality of our surgical work, had less respect for our scientific observations in the direction of pelvic pathology. Uterine hemorrhage was the most familiar symptom of all and the most significant. The subject of menorrhagia and metrorrhagia at puberty had attracted little attention in this country, though it had been carefully studied abroad. A large number of the causes which operated to produce hemorrhage in older women had been found to be responsible for the hemorrhage of girls at the time of puberty, but it was not of these cases of obvious etiology that he would speak, but rather of those cases in which no discoverable cause, either local or general, could be found. He considered the anatomical, physiochemical, and ductless gland theories as to the etiology of these hemorrhages as too theoretical to bear the clinical test. The statement of Klein that hormones from the internal secretion of the ovary acted directly upon the vasodilators in the uterine mucosa, causing the menstrual flow, was slightly more plausible as an explanation of amenorrhea in poorly developed young girls in whom the ovaries were hypoplastic. Mathes applied the general term asthenia to subjects whose pelvic as well as other organs were not only maldeveloped but did not respond to those stimuli of the sympathetic system which kept them in a state of normal to-

nicity, hence he despaired of the value of local treatment in such patients. It seemed to the writer that the well-known intense pelvic congestion often accompanying early menstruation in perfectly healthy subjects should be considered in the search for unusual and hypothetical explanations of hemorrage in young girls. Every surgeon who was familiar with the appearance of the pelvic viscera during the height of the menstrual wave, as well as every physiologist who had studied sphygmographic tracings, would admit that this condition bordered on the pathological. Lawson Tait had called attention to the extreme congestion of the normal ovary which might precede the flow, at times so extreme that it had been known to result in ovarian apoplexy, fatal in a few instances. It required no stretch of the imagination to conceive of such a pathological degree of pelvic congestion in children who developed rapidly and beyond their years, which, through some impalpable cause, anatomical, psychical, or otherwise, would express itself not only in profuse menstrual flow, but in a more or less constant metrorrhagia. This class of cases should be of special interest to the general practitioner and he should not trust them, as he had too frequently done, to the care of nature. He was the one really fitted to carry out the proper course in such cases. He could regulate the entire life of the young girl at this critical period as to the gastrointestinal tract, education, amusements, athletics, and all conditions, both psychical and physiological. Medication during the establishment of the menses, if indicated at all, would not include any of the drugs which might disturb the equilibrium of the pelvic circulation. When metrorrhagia assumed pathological importance, hydrastin and stypticin might control the hemorrhage. Adrenalin and the other glandular extracts which increased blood pressure had seemed to be of value in certain cases. A combination of strychnine would suggest itself when muscular atony was present. Ergot would not seem to be indicated in the undeveloped state of the uterus. At the best the use of all drugs was empirical. Astringent douches were sometimes beneficial, but there were anatomical reasons why they were distasteful and difficult to apply. Examination of the pelvis, preferably under anesthesia, should not be unduly delayed, and this included diagnostic curettement in most instances in order to clear up the diagnosis. The choice of operation would depend on the severity of the symptoms and the local condition. The writer had not found it necessary to do more than curette. Care should be exercised in making caustic applications to the endometrium, which were not absolutely controllable and might cause irreparable injury to the delicate organ in subjects of tender years. A colleague had met with success in the treatment of obstinate hemorrhage in young women by ligating the uterine arteries *per vagina*, which was practically out of the question in children. There might be cases in which explorative abdominal section might be elected, even when the pelvic examination was negative, but it would be a desperate case indeed in which both ovaries would be removed, not to speak of supravaginal amputation of the uterus.

Dr. Harvey R. Jack of Hornell said that he had had experience in many of these cases. In several of them repeated curettements, hygienic measures, parotid gland, thyroid, and styptol had been administered without relief; those patients seemed scarcely to recover from the exhausting hemorrhage of one menstruation before another began. Thyroid extract long continued in small doses had been of benefit in a few instances, but the thing that had cured every one of these patients so far was calcium chloride. One case in particular had been brought from the condition of a bleached out nervous wreck to brilliant health by the use of this drug alone.

*Wednesday, April 29—Second Day.*

**Retrodeviations of the Uterus in the Puerperium and in Nulliparous Women.**—Dr. Francis C. Goldsborough of Buffalo read this paper, in which he affirmed that the percentage of retrodeviations occurring in hospital patients examined two weeks after delivery was much smaller than in private patients examined at the end of four weeks. This would indicate that the displacement occurred rather late in the puerperium. For several years he had been examining patients at the end of two weeks and again two or three weeks later with the idea of determining what were the points in the causation of the retropositions, and how they could be prevented. The writer's notes on ninety-one examinations made at the end of two weeks and again at the end of a month showed that the predictions made at the end of the two weeks of what the position would be at the end of a month were correct in seventy-six cases; of these in fifty-seven cases it was predicted that the uterus would be in normal position; in nineteen it was predicted that the uterus would be back. This left fifteen in which the prediction was incorrect. From these figures it would seem that in many cases one could determine at the end of two weeks whether or not the uterus would become retroverted or retroflexed. It might be argued that there was no use in examining the patient at the end of two weeks if she was to be examined at the end of four weeks; but this was not the case, as the earlier the displacement was found the easier it was to correct it, other things being equal. At the end of two weeks there was no difficulty in getting the uterus in proper position. The position of the cervix was the best guide as to whether the fundus would go forward or backward. If the cervix was found far back in the pelvis, near the sacrum, as involution progressed the intra-abdominal pressure would cause the fundus to tip slightly forward, whereas if the cervix was about mid-pelvic at the end of two weeks, or a little anterior, the fundus would be on the promontory of the sacrum; in such cases as the uterus became smaller it would be forced backward by the intraabdominal pressure. Here, if a pessary was introduced which would hold the cervix in the posterior part of the pelvis, as the uterus involuted the fundus would not have room posteriorly and would be forced into an anterior position. The amount of relaxation of the vaginal outlet did not seem to play any part in the process, for, in many cases with considerable relaxation, the uterus would be found in normal position, while in others with an intact perineum the uterus would be found retrodisplaced. The length of the anterior vaginal wall seemed to play a part; when this was short the cervix was held near the symphysis and the fundus went back. The amount of relaxation of the uterosacral ligaments probably also played a part. The percentage of cases of retroposition that could be cured by the use of a pessary in the early weeks of the puerperium was quite large. The ordinary pessary served the purpose very well. In the majority of the cases of retrodeviations the malposition of the uterus could have been prevented or corrected during the early weeks of the puerperium. The question as to whether retrodeviation in nulliparous women caused symptoms was open to argument. From his study of the behavior of the uterus during involution the conviction had grown that in many, if not all, nulliparous women with a retrodeviation the position must be considered normal. In nulliparous women a very careful study of a case should be made before attributing symptoms to a retrodeviation.

**The Effect of Subsequent Labors of Operations for Uterine Displacements.**—Dr. George W. Kosmak of New York read this paper, in which he presented certain abnormalities in labor as noted in a series of cases in which various operations for the relief of uterine displacements had previously been performed. He cited several instances where after the Kelly or Gilliams operation there was some difficulty in getting the head to engage; when this was once accomplished there was no further trouble. In these cases no adhesions had resulted, as the uterus was found freely movable through a restricted area after the operation. In another class of cases in which fixation of the fundus of the uterus had occurred either by deliberate intention or from accidental adhesions following Kelly or Gilliam operation, dystocia was somewhat more serious and an operative delivery was often found necessary to avoid dangerous consequences to the mother. After citing several illustrative cases the writer spoke of a third group of cases in which an interposition operation had been done without effective means having been taken to sterilize the patient at the time of operation. Here the degree of dystocia was apt to prove of serious consequence to the mother, and the number of cases of this kind which had thus far been reported constituted a serious warning to those who had done this operation without the precautionary measure referred to. DeLee stated that where adhesions of the uterus to the abdominal wall had resulted from ventrosuspension or fixation serious dystocia was possible, and his own experience had noted the following complication: Abortion, shoulder and breech presentations, obstructed labor requiring cesarean section, placenta prævia, inertia uteri, retention of placenta, and postpartum hemorrhage. He concluded that the frequency of these complications should forbid the practice of any form of ventral fixation in child-bearing

women. The worst forms of dystocia occurred in those cases where the fixation involved the fundus. Vagina fixation he considered equally serious during pregnancy for the thinning of the posterior wall of the uterus and the extreme upward displacement of the cervix might lead to serious interference with the progress of labor and even induced uterine rupture. After quoting other authors to show the deleterious effects on labor of the various operations for the correction of retrodisplacements of the uterus, where this organ was not permitted to enlarge at will during pregnancy, the essayist called attention to the fact that notwithstanding all these warnings one still met operators who did not take into account the possible complications of pregnancy where deformity required operation. The operator was not sufficiently interested in what would happen to his patient later on. In many hospitals the gynecological service was attended by the surgeons who performed the gynecological operations as a matter of necessity rather than choice. Not having a proper obstetrical training they went about their work without a knowledge of what it might entail later. While not condemning the Kelly and Gilliam operations, which the author said had served a useful purpose in his hands, he commended the various operations which plicate the round and broad ligaments, and thought it preferable to resort to these rather than to operations which created artificial supports for the uterus. The various vaginofixation operations should not be resorted to in childbearing women, or, if used, should be accompanied by effective means of sterilization.

**Asphyxia Neonatorum and Its Sequelæ.**—Dr. WALTER P. MANTON of Detroit presented this communication. He regretted that statistics were so deficient that no reliable data could be had as to the frequency of asphyxia and its sequelæ in this country. In the recording of still births, boards of health should insist on the report of causes of death, and no certificate should be accepted unless this was definitely stated. Poppel had estimated that the death rate of asphyxiated children within the first week of life was seven times that of those born normal. The customary division of asphyxia neonatorum into livida and pallida was a very convenient one. The former condition was usually ephemeral but the "blue" variety might pass into the pale anemic form with immediate or near future death. Even resuscitation in such instances did not insure the continuance of life, for a large percentage of these children perished within the first eight days. Among the most important and serious manifestations of neonatal asphyxia were those of cerebral pressure, which must be differentiated from those arising from asphyxia of a purely suffocative type. When death resulted autopsy revealed small punctate hemorrhage into the meninges of the brain and cord. Under timely and proper treatment children survived this state. There might be pressure symptoms showing more extensive and serious involvement of the brain structures. In these cases the face and body surface was extremely pale; there was absence of muscle tonus; the extremities were relaxed, and external reflex excitability was wanting. The heart's action was extremely feeble and rapid, but was sometimes slowed; and respiration, once established, was irregular, spasmodic, and shallow. The pupils were contracted, strabismus might be present, and hemoplegia and convulsions might develop. There were other cases in which the intracranial hemorrhage was slight at birth but gradually increased until the severe symptoms showed themselves and the child succumbed. Alienists had laid special stress on these hemorrhages as causing the paralyses of children. Mendal and Mitchel stated that 4 per cent. of asphyxiated children became idiots from involvement of the frontal lobes. Other authorities had emphasized the relation between asphyxia and subsequent nervous affections. From his own experience he was inclined to believe that these statements had been greatly exaggerated. While not denying the influence of difficult and assisted labor in the production of these post-natal and nervous conditions, Konig had shown that diseases of the individual lues, alcoholism, heredity were really of greater importance. However, the fetal death rate from neonatal asphyxia was large and it seemed that more careful obstetrical supervision could and would reduce the mortality from this cause. After making a plea for the care of the mother during gestation and for the prenatal care of the infant, the writer urged the obstetrician to ascertain the state of the pelvic floor and the parturient canal long before the expected confinement and thought that pelvimetry was too infrequently employed. In elderly primipara and in women whose vaginas had a reduced distensibility from natural conditions or from disease, cesarean section offered the best chance for the child, and was not more serious for the mother than a prolonged and tedious labor terminated by high forceps. With increasing experience he thought that placenta prævia and in suitable cases eclampsia would be placed in the same category. He was also convinced that pregnancy should not be allowed to continue much, if any, beyond its estimated date of termination, while in mild contracted pelves it should be started from two to three weeks before that date in the interests of the child. As protracted delivery was a promoter of asphyxia, the integrity of the membranes must be preserved until their purpose was accomplished. To prevent the head being driven repeatedly against too stiff unyielding tissues the rubber bag dilator should be more frequently employed. Excessive overlapping of the bones and the misuse of forceps were a frequent cause of intracranial hemorrhage and asphyxia. To avoid undue continuous pressure and permit of the readjustment of the circulation in the brain and meninges traction should not be too long continued; the forceps blades should always be locked between pulls, and a sufficient interval allowed for circulatory reestablishment. When properly employed the forceps were valuable preventives of those accidents which led to fetal asphyxia and death. The position of the cord was also given too little attention. In 868 cases of asphyxia studied by Wicke the condition was found to be due to misplaced cord in from 10.7 to 33 per cent. In all cases the fetal heart rate should be watched during the whole of labor and when danger threatened timely application of the forceps should be effected. When the life of the child was threatened ordinary maternal lacerations should not be considered. The immediate aseptic repair of cervical lacerations of moment and perineal tears gave good results and were worth doing to save the life of a live and lusty child. The essayist advocated the gentler methods of resuscitation, as the Ahkfeld bath, Sylvester's, Laborde's, and Bird's methods. In intracranial hemorrhage such rough methods as that of Schultze should be avoided, since nothing could thereby be accomplished except perhaps to increase the hemorrhage. The use of the pulmotor was too recent to warrant positive conclusions regarding its efficiency. In better obstetrics lay to a large extent the prevention of neonatal mortality.

*Thursday, April 30—Third Day.*

**Infection with the Bacillus Coli Communis, Complicating Pregnancy, Labor, and the Puerperal State; Its Medical and Surgical Treatment.**—Dr. EDWARD P. DAVIS of Philadelphia referred to the characteristics of the colon bacillus and stated that its action in pregnancy had been extensively studied in pyelitis. The germ gained access to the kidneys through ascending infection from the bladder, or by its passage from the wall of the bowel through the continuous ureter to the pelvis of the kidney. It might also enter the kidney through the blood current. Appendicitis and cholecystitis had been shown to be due at times to the invasion of the colon bacilli, and colon bacilli infection of the large intestine had been seen complicating pregnancy in women who had neglected hygienic precautions during pregnancy, or who had taken irritant drugs to empty the bowels. It might remain latent during pregnancy and become active after the uterus was emptied and was responsible for many of the symptoms of puerperal septic infection. Colon bacillus infection complicating the puerperal state might be mistaken for typhoid fever or malaria. This organism might also be the cause of septic abortion. In prophylaxis, as the colon bacilli were most abundant in the colon, the parturient woman demanded special attention to the condition of the bowels. The writer had seen fatal infection with this germ follow the use of very irritating purgatives taken by the patient in the hope of producing miscarriage. Laxatives which produce a competent daily evacuation and could be used over long periods should be employed. Such were compound licorice powder, or preparations of olive or petro'eum oil. Where the colon remained persistently distended high colonic flushings with sterile salt solution might be administered. As the colon bacilli were usually destroyed successfully by the resisting properties of the patient's blood, it followed that anemia during pregnancy must be avoided. In the treatment of colon bacillus pyelitis in pregnancy, rest in bed, a diet of

pasteurized milk, or lactic acid milk, the use of mildly saline waters, flushing of the colon, and the application of dry cold for the pain were usually successful. Further treatment if necessary could be carried out by catheterizing the ureters and locating the pyelitis, and then irrigating through the uretral catheter with non-irritating antiseptics. Should all such measures fail operation was justifiable. The writer had treated successfully three cases, removing the appendix and draining the right kidney, without interrupting the pregnancy. It might be difficult to differentiate a right-sided pyelitis from appendicitis, cholecystitis, rupture, ectopic gestation, or salpingitis. Under such conditions where the patient did not improve exploratory operation was indicated. In a colon bacillus cholecystitis pregnancy did not in any way contraindicate drainage of the gall-bladder. Colon bacillus infection of the bowel should be treated by prompt removal of the appendix if tenderness could be located in that region. Where the infection was not severe and the symptoms were those of abortion or premature labor the leucocyte count should be carefully watched, and, if there were no symptoms of tenderness or distention and the bowel did not become paretic, the patients might be treated medically. The writer had seen numerous cases of this condition in which the symptoms did not justify surgical interference and recovery followed medical treatment. Infection of the uterus and appendages by the colon bacilli gave characteristic symptoms and might be diagnosticated by bacteriological examination of the contents of the uterus. The treatment of this condition did not differ from that of uterine puerperal infection of other origin, except that the tendency to mixed infection and pus formation must be remembered. The fact that the *Bacillus coli communis* formed no antitoxin and that it had so far resisted treatment by vaccines did not encourage one to hope for brilliant results by the use of sera or vaccines. The author cited a number of cases and quoted from various authorities to show that the colon bacilli had been found as the active agent of infection in the uterus, tubes, and ovaries. He did not agree with the suggestion so often made that in these cases of colon bacillus infection pregnancy should be interrupted. It was important that the possibility of infection by this organism be kept in mind in dealing with parturient women.

**Puerperal Thrombophlebitis.**—Dr. William M. Brown of Rochester read this paper in which he presented the proposition that there were many cases of puerperal infection that followed a definite course of phlebitic inflammation and thrombosis which could be cured if they were diagnosed and operated on early and before the clot had progressed too far or involved too many branches. He believed that an early operation properly done would in the large total be less harmful than the uncertainties of hesitation. The author related two cases in which the temperature curve showed the irregularity of the infection which to him was suggestive of venous involvement. In neither case was there any abdominal rigidity or tenderness except a slight soreness on deep palpation on the left side low down, and on bimanual examination a small mass was felt to the left of the uterus and high up. It was firm but not hard. Practically the same conditions were found in both cases. The right side of the pelvis was perfectly normal but the left ovary was large and edematous and passing up from the thickened base of the broad ligament was a thick hard mass of thrombosed veins. In one case there were two separate venous trunks running along together and the thrombosis extended much higher than in the other case. Heavy chromic ligature was passed under the vein well above the end of the clot and tied. Drainage was maintained long enough to insure safety before the wound was allowed to close.

**A Consideration of Some Methods in the Treatment of Puerperal Infections Which Have Given Important Results.**—Dr. Raleigh R. Huggins of Pittsburgh, Pa., presented this communication. He called attention to the fact that there might be an infinite series of gradations from a slight infection arising from laceration to an inflammatory process involving the uterus, tubes, parametrium, lymphatics, and ovaries, and extending beyond these into the blood stream, resulting in systemic infection. The writer reviewed the pathology of infection which justified the conclusion that if the zone of reaction was removed by operative measures the chances of the infection spreading were much greater than if the uterus was left undisturbed. If streptococci of the hemolytic type were present in the uterus they might pass directly through the wall of the uterus in spite of any barriers and without local reaction. Local treatment which was done with the idea of cleaning out the uterus removed what little defense there might be and would only expedite the spread. A disposition to ignore the uterus had been cultivated and the results had been much better than when vigorous measures were employed to empty or irrigate the uterine cavity with various antiseptic solutions. It had been learned that a firmly contracted uterus was of as much value in the prevention of the spread of infection as it was in the prevention of hemorrhage. One hundred and twenty-five cases of infection following abortion after the second month, or delivery, had all been treated in a conservative manner as far as the inside of the uterus was concerned, with the exception that where firm contraction of the uterus was not present or where it could not be secured by the use of strychnine, ergot, or pituitrin, the uterine cavity was firmly packed with iodoform gauze. This had been done for the purpose of securing firm contraction, and if the uterus had not been emptied facilitated the expulsion of the contents. Both morbidity and mortality had been less than formerly when the measures were more active. In the treatment of abortion at or before the second month the uterus was emptied at once without the same regard to the danger of systemic infection. Here the infected area was not large and firm contraction was best secured by freeing the cavity of all débris. Cultures from the uterus would show the nature of the local infection and reveal the presence or absence of bacteria in the blood stream. In this series streptococci had been recovered from the uterus in 50 per cent. of the cases. A hemolytic streptococcus had been present thirty times, but the test for hemolysis was not always made. Blood cultures were positive in thirty cases. There were three deaths; one patient was admitted ten days after the onset of symptoms with a complicating pneumonia; a second case was complicated by a general peritonitis, and the third had a very low resistance as a result of profuse hemorrhage. They had learned that the presence of the most virulent bacteria in the uterus did not mean that the infection would spread, and the infection was less likely to spread if the uterus was well contracted. Unless there was hemorrhage or relaxation of the uterus no local measures were employed. When infection spread beyond the uterus attention should be paid to the lymphatics of the pelvis. The majority of exudates disappeared spontaneously, yet many suppurated, and when this occurred drainage should be instituted as early as the condition was recognized. Hysterectomy was indicated when the infective process spread in the form of multiple abscesses in the uterine walls or when a putrid endometritis caused degeneration of myomatous growths within the uterus. All patients with chronic thrombophlebitis drifting from bad to worse should be operated on. This was true especially when the infection involved the ovarian veins. The author had tried magnesium sulphate intravenously and in many instances the results were most satisfactory. At first it was given in a 1 per cent. solution of saline and not more than thirty grains at a time. Later it was found that much greater quantities could be given with safety if administered slowly. They had never given more than 100 grains, but Dr. Harrar had used 250 grains with no alarming effects. Distilled water had been used instead of saline and there had been fewer chills following the administration. Chills were less likely to occur if the fluid was given at the proper temperature. There had been no accidents from its use and they had given it more than one hundred and fifty times. It had been repeated several times at twenty-four-hour intervals in the same patient. Experiments had not explained its action. It had been of undoubted value when administered in the acute stage of streptococcic toxemia before it had been possible to demonstrate the presence of bacteria in the blood. Its use intravenously in pneumococcic and other forms of streptococcic blood stream infection had not met with the same success and this made one doubtful of its value in this form of infection.

---

SECTION ON PEDIATRICS.

*Tuesday, April 28—First Day.*

Dr. Thomas S. Southworth in the Chair.

**The Influence of Diet on the Growth and Recurrence of Adenoids.**—Dr. Frank Vander Bogert of Schenectady

read this paper in which he first called attention to the undeniable increase in the frequency of adenoids. While all authorities agreed that the lymphatic diathesis was an important etiological factor, it seemed that the lymphatic diathesis itself must be due to an underlying cause; without some underlying constitutional cause it would be hard to account for the congenital cases. Rachitis seemed to play an important part in the etiology of adenoids, and as a more direct and exciting cause, catarrhal affections of the nose and nasopharynx were accused, though it was impossible to say whether the latter were a cause or an effect. The personal experience of the writer led him to believe that even in cases developing in the early months of infancy dietetic errors and gastrointestinal disorders had some bearing. The author argued that as adenoids did not develop in perfectly normal individuals there must be a lack of vitality or a lack of resistance in the parts involved to account for their presence. This lack of resistance to a cold was found in gastroenterics, and the writer's observations had convinced him that much could be done by dietetic measures in the way of inhibiting excessive growth and preventing the recurrence of adenoids. In his experience the severe cases of adenoid growth had been found in children suffering from the more marked types of chronic intestinal disturbances and the tendency to recurrence seemed more common in this type of cases. It was practically only in those whose dietetic errors had led to distinct catarrhal symptoms of the alimentary tract that large adenoid growths were found. Judging from carefully taken histories the determining dietetic factor seemed in many cases to have originated in early infancy. Irregular nursing and early weaning, as well as prolonged nursing, seemed to exercise a marked influence. In later childhood irregular and between meals eating was exceedingly commonly noted in the histories and the excesses in the direction of starches and sweets were most prevalent. Temporary relief usually followed operation but without appropriate after treatment the general ill health often recurred and it was to the intestinal tract that at least a part of the after treatment must be directed. The essayist cited cases illustrating the three points to which he wished to call attention, namely, bad dietetic histories, failure to obtain by operation relief from general symptoms, and improvement under proper dietetic régime in cases in which the symptoms had persisted or growths had recurred.

Dr. William L. Culbert of New York expressed the belief that in many instances nasal infection was the principal factor in the causation of adenoids. It was important to attend to the digestive tract, but the child lived on air as well as on food and it was also important to direct attention to the respiratory tract. Recurrence was bound to follow operation unless there was proper respiratory development. The nose should be cleansed by spraying and the child taught to breathe properly through the nasal passage, so that the air might be properly filtered, moistened, and warmed before its introduction into the lungs. He strongly advocated breathing exercises for the development of the function of the nose and nasopharynx. Dr. vander Bogert called attention to the fact that adenoids returned oftener in young children than in older ones; this was true because they were not able to develop the respiratory apparatus. When they were three or four years of age they could be taught proper methods of breathing. Breathing exercises might in some cases obviate the necessity for an operation. Children should also be instructed in the proper method of blowing the nose. The speaker also called attention to the deleterious results of thumb sucking and "comforters."

Dr. Emil Mayer of New York said he could not accept in its entirety the statement that errors in diet were responsible for the recurrence of adenoids. In the first place congenital adenoids did exist; he had found them in very young infants. The youngest child he had ever seen operated on for adenoids was seven days old, and surely in this short time errors in diet could hardly have had anything to do with the mass in the pharynx. Dr. vander Bogert's theory should be revised thus: A child with adenoids had masses of catarrhal secretion pouring into the pharynx and thence into the stomach, and this prevented the digestive activity and thus disturbances of nutrition were occasioned. In a long life of observation of adenoid operations, in his experience, recurrences were not the rule but the exception. These recurrences might be due to a lymphoid tendency of hereditary nature.

Dr. Carl G. Leo-Wolf of Niagara said that in the case of congenital adenoids one should always think of syphilis, even if one did not go as far as Neufan who stated that adenoids in children under three months of age were always due to syphilis. Recurrence of adenoids would be obviated by washing out of the nasopharynx. If adenoids were due to the lymphatic diathesis they could be prevented by the vegetarian diet, and this had proved beneficial in a number of cases.

**Some Manifestations of Influenza in Young Children.**—Dr. L. Emmett Holt of New York presented this paper. He emphasized the point that in seeking for the influenza bacilli one should use cultures and not smears. Beginning with the winter 1909-1910 and continuing during each succeeding winter, they had examined 1,650 sputum cultures from 1,053 patients in reference to the presence of influenza, pneumococci, streptococci and staphylococci bacilli. The influenza bacillus had been the predominating organism in 32.5 per cent. of the cases in the winter 1909-1910; in 32 per cent. of the cases in 1910-1911; in 33 per cent. in 1911-1912; in 28 per cent. in 1912-1913, and in 42 per cent. of the cases examined during the past winter. The most peculiar feature of these influenza infections in children was the high, fluctuating, irregular temperature which sometimes went to subnormal, and which was accompanied by few clinical symptoms. Frequently in the intervals when the temperature subsided the child did not seem to be ill. There seemed to be no question that some of these cases were mistaken for recurrent whooping cough. The Pfeiffer and the Bordet-Gengou bacilli had many points in common, but the blood picture in influenza and whooping cough differed. In whooping cough there was a high leucocytosis and the same was true of influenza, but in the latter there was also a high lymphocytosis. The condition was highly infectious and the patients should be isolated. They were seldom improved by cold air, though fresh air was desirable. It was an advantage to send the patient south in some instances. Dr. Holt exhibited temperature charts showing the characteristic fluctuating, irregular curve and compared them with the curve in pneumonia. The influenza bacillus might be a complicating factor, making diagnosis puzzling in a number of conditions. To illustrate this Dr. Holt cited a case of typical tuberculous meningitis in which at autopsy the typical lesions of tuberculous meningitis were found but the influenza bacilli were also found in the brain. These temperatures were suggestive of middle ear disease and were puzzling to the aurist. In one such case, after death the influenza bacilli were found in the lungs but not in the ear or the sinuses.

Dr. Linnæus E. La Fetra of New York said that in the study of catarrhal affections in infants and children there was great difficulty in determining the precise cause of infection, because several germs were usually present and one must judge which was the predominating one. Dr. Holt was particularly fortunate in having been able to study such a large series of cases. For a number of years it had seemed probable that a certain type of fever accompanying catarrhal infection in infants and children was due in many cases to the influenza bacillus. It was characterized by wide vacillations in temperature each day, perhaps ranging from 106° to 94° F. The general symptoms were fever and prostration, the fever being the peculiar hectic type suggestive of deep suppuration. The prostration was quite marked but the child's color did not suggest either suppuration or sepsis, and in the intervals when the temperature was low the child seemed surprisingly well. The blood count with many infants having this peculiar temperature and prostration were the only signs found throughout the course of the disease, there being no catarrhal symptoms and no inflammation of the throat or ears. Such cases were very puzzling and were generally attributed to deep-seated pneumonia. Whooping bronchitis was very interesting and it was certainly due in many cases to influenza. It was exceedingly important to remember the influenzal type of fever since the wide range of temperature might suggest mastoid involvement or the presence of sinus thrombosis. Single blood counts should not be relied upon as to the advisability of operation on the mastoid when there was influenzal otitis media. The leucocyte count might be high, up to 15,000, and the polymorphonuclears might constitute 70 or 80 per cent. without there being any involvement of the mastoid or of

the sinus. Only if and when the local signs in the ear canal and bone tenderness were present should the mastoid be operated on. General symptoms of fever, prostration, and high blood count were not a justification for operation. A frequent manifestation of influenza was involvement of the lymph nodes of the neck. One should be cautious about predicting a termination of the fever so long as the enlarged glands were present. Dr. Le Fetra said he had seen three cases of influenza complicated by meningitis during the last five years.

Dr. William H. Park of New York said that in the mucus of the respiratory tract in cases of bronchitis or pneumonia in uncomplicated cases or in those complicating whooping cough and measles, the influenza bacilli were so abundant that the Bordet-Gengou bacilli were not found. It was difficult in many cases to separate clinically the cases due to the influenza bacilli alone, the pneumococci bacilli alone, or mixed cases.

Dr. Herman Schwarz of New York said that Dr. Park had shown that in measles and scarlet fever the presence of the influenza bacilli in the secretions of the throat was more frequent in the winter than in the summer. It was interesting to note that the culture for the middle ear in cases of influenza did not contain the influenza bacilli. The cases complicated by enlarged glands did not show the presence of the influenza bacilli in the suppurative processes of these structures.

Dr. Henry L. K. Shaw of Albany said that smears of the nasal and tracheal secretions in forty infants with catarrhal colds in St. Margaret's Hospital showed the pneumococci. The reason for this was probably as stated in Dr. Holt's paper; they had used smear and not cultures. Dr. Shaw related the case of an infant recently seen by him with meningitis in whose lumbar fluid was found the pure culture of influenza bacilli. An interesting feature of the case was that there were no previous symptoms of influenza in the baby or any member of the family.

Dr. DeWitt H. Sherman of Buffalo asked Dr. Holt whether the prostration was considered a necessary sequella in influenza. He said that during the past winter they had had a great deal of an infection that seemed to be influenza, but contrary to expectation the patients made a prompt and complete recovery.

Dr. L. Emmett Holt of New York said that the majority of these cases showed comparatively little prostration. The temperature was high, but they were not otherwise ill. There was no local lesion. As to finding the organisms in the culture, they were only important when found in abundance. They had not found the organism in the glands; in glandular and retropharyngeal abscesses the influenza bacilli had not been found.

**Active Immunization in Diphtheria.**—Dr. William H. Park of New York spoke on this subject. (See report of New England Pediatric Society, Medical Record, December 6, 1913, page 1052.)

Dr. Frederick M. Meader of Syracuse related his experience with the treatment of diphtheria carriers and drew the following tentative conclusions: 1. Immunization with diphtheria bacilli would stimulate the body to produce amboceptor-like bodies. 2. These amboceptor-like bodies did not appear to destroy diphtheria bacilli if there was a pathological process. 3. The recovery of carriers under normal conditions was not accompanied by an increase in the amboceptor-like bodies. 4. Carriers that were such by reason of diseased tonsils had the diphtheria bacilli in the squamous epithelium, which epithelium was necrotic. 5. Probably persons became carriers because of abnormal mucous membranes. The abnormality might be due to mechanical irritation as by a foreign body, or diseased processes due to microorganisms, or to faulty structure of the part, as bottle-shaped crypts. 6. The best means of treating carriers seemed to be by stimulating the production of a healthy mucous membrane. Careful examination of the throat to detect abnormalities should be made. If necessary the offending part should be removed so that new mucous membrane might be formed. Attention should be paid to the general health of the patient.

**The Importance of Medical Supervision of Older Children.**—Dr. Edward J. Wynkoop of Syracuse presented this paper. He stated that the public had awakened to the need of carefully supervising the period of infancy and at school age medical supervision was provided for the boy and girl, but that period of the child's life from ten to fourteen years had been neglected. During this period leading up to puberty various nervous phenomena might develop which in themselves were unimportant, but which if left untreated might lead to serious results. Rheumatism, with its various manifestations, chorea, and many other diseases were apt to appear at this period. Late hours were a cause of an enormous amount of damage. It seemed almost incomprehensible that the matter of sleep was so disregarded by parents. The nervous child constantly on the go and craving more and more excitement soon had a nervous system that fell an easy prey to almost any vicious habit. At this age the rapidly growing boy or girl needed every bit of nourishment possible to furnish fuel for the rapidly growing structures, and too little time was given to explaining this necessity and in demonstrating what was meant by proper food and correct preparation of the same. Probably there was no condition more common among girls than constipation; its prevention by proper supervision of the diet, exercise, and habits would eliminate one of the greatest evils with which medicine had to contend. It was the exception for children at the period under consideration to be brought to the physician for physical examination and a good wholesome talk on health matters. The child was advised to seek the advice of the dentist at frequent intervals, why not the physician, to see that the heart, lungs, blood, and urine were normal, and that there was no tendency to disease or deformity? Would anyone gainsay the value that this might have on our anemic and constipated girls and our rapidly growing boys? A closer relationship between the physician and these children would give the physician many opportunities to advise the parents in regard to the needs of their children.

Dr. Robert J. Johnson of Syracuse said the Section would be fortunate, indeed, if they had presented to them any paper which in its possibilities for good surpassed this one. Prevention, not when ignorance, neglect, and disease had made the task largely impossible, but in the plastic growing period of youth, when it was easy comparatively to correct and mould into health—this should be our effort. The medical supervision of older children was a matter of education. The parent naturally resented the idea of the child being subjected to a physical examination unless acutely ill, yet many serious ailments of childhood were unrecognized by the parent, no matter how intelligent or watchful. Proper oversight could not be effectively given *en masse;* individual instruction and examination by the physician in the home or in the office alone was lasting, as one thereby gained the child's confidence. The medical school inspector should be a specialist in his line, devoting his entire time to the work, and should be paid accordingly. This plan was meeting with success in certain localities. There should be a closer relation between the parent, the growing child, and the physician. This closer touch would mean better morals, a deeper regard for the known laws of hygiene, and in the end a higher civilization.

**The Causes and Treatment of Eczema in Infancy and Childhood.**—Dr. Rowland G. Freeman of New York read this paper. He declared that eczema being a disease of the skin, might seem in a city like New York to be a disease which should always be treated by the dermatologist. This disease occurring in infancy needed a pediatrician more than a dermatologist, for while the applications to the skin were important, the regulation of the diet and the daily régime were of far more importance. There was a popular idea, in which some physicians shared, that the cure of eczema might be followed by sudden death, and this might well be the case if one attempted to cure eczema of internal origin by external applications only. Acute eczemas frequently developed during the first weeks of life in children fed at breasts which produced much more milk than was required for the nourishment of the child. These cases often gave a fairly typical history. They might be gaining from ten ounces to a pound a week, and having from five to six movements a day which contained curds and mucus. Suddenly the skin of the face and body became red and soon assumed the typical dry scaly appearance of eczema. On weighing the infant before and after feeding it would be found that the child was getting much more food than it was entitled to, while the examination of the breasts would show a milk of a normal or rich quality. These babies were readily cured by reducing the time of nursing so as to limit the baby to the proper amount of milk. Many of the eczemas in older children were more difficult to treat, especially if the child had been

on a normal amount of a well balanced ration. In such cases considerable information might be obtained by a careful analysis of the urine directed particularly to the detention of marked acidity, to the presence of acetone and diacetic acid, or evidence of intestinal intoxication as shown by the presence of indican and phenol. Examination of the stool would furnish indications for the dietetic treatment. Local sources of irritation must be removed, especially, pediculi capitis, plugs of wax in the ears, adenoid obstruction, or the irritation from an adherent foreskin. If there was excessive acidity of the urine it might call for the use of saline laxatives and alkalies, or an intestinal intoxication might indicate a putrefactive process in the intestine which might be relieved by the administration of lacto-bacillary culture. Excess of fat or carbohydrate in the stool should direct attention to the reduction of these elements in the food. In many cases the trouble was too much food; in others a badly balanced ration, and in still others irritating food, such as eggs, oatmeal, stewed fruit, cake, candy, preserved fruit, jam or marmalade. In these cases was found one of the most important uses of caloric feeding. The external treatment must be learned from the dermatologists. In order to get the most prompt results the application must be kept in constant contact with the diseased skin. Lassar's paste made from one part zinc oxide, one part starch, and two parts vaseline, was altogether the most useful application for the skin, especially for the face. It might be rendered somewhat antiseptic by the addition of resorcin or eurosal. For the dry chronic eczematous patches on the body or limbs of babies Dr. Freeman had found one part zinc ointment to seven of Lassar's paste most useful. For the scalp a diluted sulphur ointment was useful.

Dr. Frank vander Bogert of Schenectady reported a case of eczema in a breast-fed infant in which examination of the mother's milk showed a fat percentage of 10 per cent. in one breast, while in the other breast the fat percentage was subnormal. This case was cured in one week by prohibiting the use of the high fat breast and regulating the mother's diet and exercise. Two other cases were cited in which the use of citrate of sodium with the food was effective in clearing up the eczema.

Dr. George W. Crary of New York believed that it was possible to put too much emphasis on the internal treatment in exclusion of the external. The external element in the disease should be considered as well as the internal. It was not advisable to say that any one article of food was bad and should be prohibited; whatever disagreed with the child laid the skin open to attack as well as other organs of the body. Overfeeding was a very important etiological factor and here the skin trouble might be looked on as an effort at elimination to dispose of the over-feeding. Seborrhea in the child's attendants might be a factor in the production of eczema, and he had seen the condition cured in a child by attention to those about it. Zinc ointment should be used with care; one got better results with Lassar's paste.

Dr. L. Duncan Bulkley of New York said that he endorsed all that Dr. Freeman had said in regard to the internal causes of eczema, and the absolute necessity of regulating the diet and attending to the secretions of the bowels and kidneys, in infants as well as in adults. For the general eruption on the body nothing was more efficacious than the following: Carbolic acid, one-half dram; calamine, prepared, one dram; zinc oxide, two drams; glycerine, three drams; rose water, four ounces. This sopped on freely served the best purpose in generalized eczema of the body and extremities. Lotions were preferable to ointments.

*Wednesday, April 29—Second Day.*

**The Effect of Sugars on the Gastric Secretions of Children.**—Dr. DeWitt H. Sherman of Buffalo presented this communication which embodied the results of gastric analyses showing the effect of the three sugars, milk, cane, and malt, on the gastric secretions. Fifteen babies were used and each baby was tested on each of the three sugars. The sugars were all in six per cent. solution, in a similar barley water mixture. As in other series of tests the gastric contents were withdrawn one hour from the middle of the taking of the meal. The amount of the three sugars ingested averaged exactly the same. The amount recovered varied some. The amount ingested in each case was 144 c.c.; the amount recovered averaged 23.40 c.c. for milk sugar, 34.40 c.c. for cane sugar, and 33.40 c.c. for the malt, using Mead's dextrimaltose. Whether they could infer from this that the milk sugar passed more quickly they were unprepared to say. They doubted it, for did the milk sugar solution stimulate to greater activity the motor function of the stomach, one would also expect it to stimulate to greater activity the excretory function. This it did not do. They were naturally pleased to see how closely their second series compared with the first series of analyses made three years ago. The only difference in the two series lay in the combined hydrochloric acid. The average of the two series showed free hydrochloric acid, 2.20 c.c.; combined hydrochloric acid, 4.75 c.c.; total acidity, 8.85 c.c. They found that the cane or granulated sugar stimulated gastric solution a little more than the milk sugar solution, and that the malt sugar solution in the form of dextro-maltose was more than twice as stimulating as the milk sugar solution. This last fact might be of more importance to remember in infants with hypersensitive stomachs. The infants tested averaged about seven months. The very youngest ran an average a little higher than the standard and the older ones ran an average a little lower.

Dr. T. Wood Clarke of Utica said this paper was a valuable contribution to their knowledge of infant feeding. The infants who vomited hard curds were usually cases of hyperacidity. It had been found that the addition of lime water to the milk increased the gastric acidity and the firmness of the curds. Sodium citrate on the other hand reduced the hydrochloric acid content and prevented curd formation. Practically this had given him very good results until recently when he had not obtained the expected results from the citrated milk. Dr. Sherman had explained this. It was because he had been using more malt sugar than formerly. Apparently the malt sugar by stimulating hydrochloric acid secretion made it necessary to increase the amount of citrate used in the milk.

Dr. DeWitt H. Sherman of Buffalo stated that the discussion had demonstrated that the rapidity of the passage of the sugars and the size of the curds was in direct proportion to the acidity. They had also learned that lime water was a gastric stimulant. The speaker said he did not often give alkalies, but if he did do so it was in the form of a citrate in the food or a small amount of alkali between meals.

**Antityphoid Vaccination in Children.**—Major F. F. Russell, U. S. A. Medical Corps, Washington, D. C., presented this communication. He stated that antityphoid vaccination had been introduced into the army in 1909, and at that time they had vaccinated a few children. They had been vaccinating more and more each year since. Typhoid fever was a disease of young persons; of 1,000 deaths from typhoid fever collected in the registration area of the United States one-third occurred in persons under twenty years of age. Antityphoid vaccination was very satisfactory in children because they stood it better than adults and there were few reactions. They had collected statistics from all parts of the United States of the children in the army posts and the families of officers, which included data regarding both the general and the local reaction. Less than 2 per cent. of the children showed a temperature of 103° F. or more. As a rule they did not have to remain home from school or indoors after vaccination. For these reasons vaccination among young people was increasing rapidly. They never took the risk of vaccinating a sick child. A trivial indisposition, however, was not a contraindication to vaccination, but one must use discretion in such cases and also be governed by the immediate danger of contracting typhoid. Among the children vaccinated no harmful effects had been noted. Revaccination should be performed more frequently in children than in adults. The dose was regulated according to the weight of the child. It was better to give a little more rather than a little less in proportion to the weight. If the child gained rapidly in weight it might be advised to repeat the vaccination. The duration of immunity was thought to be about three years; as yet there had been no falling off of immunity in the men in the army. In the antityphoid vaccination it was a good plan to follow the method used in smallpox and vaccinate once in infancy, once in childhood, once in youth, and once in adult life. This would probably give good protection. The results of antityphoid vaccination in the army were most convincing as to the value of this measure. In the year 1913, in the entire army

of 90,000 men, there were only three cases of typhoid fever and no fatalities. These three men had not been protected, two being new recruits who came down with the disease before the vaccination was completed, and the other had never been vaccinated. The elimination of typhoid fever from the army greatly lessened the morbidity so that there was a great saving of time. In the present state of our knowledge no school or institution should run the risk of an epidemic of typhoid fever when it could be prevented without risk. The injection should be given subcutaneously and never deep into the muscles. It was desirable to have a slow absorption. With a deep injection one was more liable to have a severe reaction and this would arouse an altogether unnecessary opposition to the measure. In the army the second injection was given after an interval of ten days, while in civil life the interval was seven days. Saturday was chosen so that if there was a reaction the patient could lay off on Sunday. A fear had been expressed that antityphoid vaccination might light up a latent tuberculosis, but the statistics in regard to the incidence of tuberculosis in the army since the introduction of antityphoid vaccination showed this fear to be entirely unfounded. In the annals of medicine there was only one campaign that could be compared with this one and that was the practical extermination of smallpox by vaccination.

Dr. Morris L. Ogan of New York related the experience of the New York Health Department with antityphoid vaccination. Since the beginning of 1913 some 2,000 persons had been injected with complete immunity. It was well-known that typhoid fever was a disease of youth and childhood. A comparison of the statistics of the Health Department with those of Osler showed that in their experience typhoid fever had occurred oftener between the ages of fifteen and twenty years than in Osler's series. The statistics of the Health Department showed that the disease was at least as liable to attack children as adults. In a series of 1,700 non-immunized children 2.8 per cent. contracted the disease, while in a series of 5,000 adults 2.1 per cent. became infected; thus it seemed that children contracted the disease easier than adults. Physicians had been advising against antityphoid vaccination and gave as their reason that children did not often contract the disease. This idea should be combated. Of 318 exposed children who were vaccinated but four contracted the disease, and these were mild cases without any deaths. In the actual presence of typhoid fever vaccination was not only justifiable but advisable. As to the severity of the reactions, they had not been able to follow up their subjects as carefully as could be done in private practice; frequently they only saw the case when a visit was made for further immunization. About 73 per cent. of the reactions were very mild. They had found the reactions to be more severe during the first six years of life than during the next six year period. This might have been because they had given a slight overdose, as they had given more than the average dose in proportion to the weight of the child. They had had severe reactions in only five cases and in one of these the child was coming down with the disease. In only one instance did the temperature reach 103° F. Their experience was extremely favorable and they had found with others that children bore antityphoid vaccination better than adults.

Dr. Godfrey Pisek of New York said that this paper was very important just at this time when so many parents were asking as to the advisability of antityphoid vaccination for their children. Each member of this Section should constitute himself a committee of one in urging the adoption of this measure. All children attending boarding school or traveling, or exposed to infection should be vaccinated. Dr. Russell's point in regard to making a subcutaneous injection and not a deep injection should be strongly emphasized. The opposition of many practitioners to antityphoid vaccination was very discouraging and it could only be accounted for by the fact that they had never heard Major Russell.

Dr. Walter Lester Carr of New York said that his experience had been chiefly with boys in boarding school and he had used a dosage relatively greater than that mentioned; in strong boys he frequently gave full dosage. He advised general antityphoid vaccination in children at boarding school, traveling, or in any manner exposed to infection. Physicians were more frequently diagnosing typhoid fever in childhood and this might account for the relatively greater number of cases reported to the New York Board of Health.

Major F. F. Russell of Washington, D. C., said he was glad that Dr. Ogan spoke of the vaccination of contacts. They vaccinated against all contacts and had seen no bad affects. In order to avoid severe reactions, instead of giving the full dose and repeating at the end of ten days, one might give half the dose and repeat at the end of five or six days.

Dr. Lillian H. South of Bowling Green, Ky., said that in her work as State Bacteriologist of Kentucky she had distributed 15,000 full immunizing doses of antityphoid vaccine. Owing to floods they had had several epidemics and in one town of one thousand population five hundred were down with the disease. Their inspectors were all immunized. They had built the "Kentucky sanitary toilet" and this had helped to stamp out the disease. The prevalence of typhoid had been due to the bad sanitary condition in rural districts and this sanitary toilet had been the great factor in eliminating the disease. It consisted of a miniature septic tank, and the only attention it required was about one bucket of water once a week. In giving the immunizing dose of vaccine they injected it under the skin of the abdomen. If there was a reaction they postponed the administration of the second dose for fifteen days. A small preliminary dose might be given to see how the organism would react. In their work they realized that vaccination to be effective must be accompanied by instruction in other sanitary precautions. The sanitary toilet referred to was not only effective in conquering typhoid fever but was equally effective in eliminating dysentery and hookworm.

Infant Welfare Work in New York State.—Dr. Henry L. K. Shaw of Albany gave this talk which was accompanied by a lantern slide demonstration. He stated that in New York State outside the City of New York there were only thirty-two milk stations in twelve localities; in only three places were these stations open all year and in only two were they supported by the municipality.

In New York City during the year 1913 the death rate of infants under one year of age was 101 per 1,000 births, while in the remainder of the State it was 120. This could not in any possible way be assumed to be accidental, but was due to various causes. The statistics of New York City showed that the drop in the death rate was coincident with the establishment of the milk stations. A comparison of the mortality rates of the cities of the different classes showed that this rate was least in the cities of the first class, where the most infant welfare work was being done. The death rate was highest in cities of from 10,000 to 15,000 population, then as the size of the towns decreased the death rate among infants decreased, until in rural districts there was a rate of 103 deaths per 1,000 births in the year 1912. It had been somewhat higher than this during the year 1913.

The mortality for the first month of life was from 30 to 40 per cent. of the total mortality of infants under one year of age. This was probably because outside of New York City they had not reached the supervision of the first month of life or the antenatal work. The antenatal work of the New York Milk Committee had reduced the mortality for the first month of life 18 per cent., and 95 per cent. of the supervised cases were breast fed. The cities of the second class were badly in need of housing laws which would do away with the present deplorable insanitary conditions. In Utica a school room had been used for a welfare station during the summer. This was mentioned to throw out a hint as to the use to which the school house might be put during vacation. Dr. Shaw said that as the State Health Department was initiating a campaign throughout the State to lessen the infant mortality he wished to tell how a milk station could be equipped for less than $100. There was such a model station in the Welfare Exhibit. Though the milk stations throughout the State were supported largely through philanthropy the State Board of Health kept a supervision over them requiring them to send in a weekly report. Dr. Shaw also suggested that the day nurseries be turned into infant welfare stations.

Dr. T. Wood Clarke of Utica said that the smaller cities of the State needed an awakening on the subject of infant hygiene and they were going to get it. He related the history of the work in Utica since its inauguration two years ago. In that city the death rate among infants in 1911, before the welfare work was begun, was 158 per 1,000 births; in 1912, with one welfare station in operation, the death rate had been 143, and in 1913, with two welfare stations in operation,

the death rate was 138. It seemed worthy of note that immediately on closing the station in September the death rate rose.

Dr. Joseph C. Palmer of Syracuse told of the infant welfare work that was being done in his city. He believed that whatever the plan of work adopted the essential feature of the work should be educational. He urged antenatal instruction for the mothers, believed that the stations should be kept open during the entire year, and that they should never tire of teaching the old sermon over and over again on cleanliness, fresh air, bathing, proper food, care of milk and utensils, and exclusion of flies.

Dr. Charles Herrman of New York said that at the beginning the physicians might be willing to conduct the work without recompense, but late competent pediatricians would have to be paid for their time and trouble. The distribution of milk in small bottles, each sufficient for one feeding, or even in quart bottles, added greatly to the expense of the station and was not absolutely necessary. The control of the attendance at the station depended on the physician and especially on the visiting nurse.

**The Health Program of the Physical Training Department of the Board of Education, New York City.**—Dr. G. Ward Crampton made this address and had some of the children under his care give a demonstration of the exercises used in the schools. He declared that the style of teaching hygiene up to two or three years ago had been a farce, based on the assumption that by teaching a child all about anatomy and physiology you would have a basis upon which to give instruction in practical hygiene. Now they started out in a much more direct way by giving practical object lessons in personal hygiene. The old idea that for four or five hours daily the child should sit quietly, that he was a receptacle to be filled with extract of textbook, was all wrong. Such immobility was unnatural. In the attempt to find the proper method of procedure they followed the thesis that they should provide such exercises as the child would ordinarily do under normal conditions. Normal physical play was necessary to mental, moral physical, and social development. They had developed class gymnastics on the functional basis. They wanted from the exercise a stimulation which would give an increased heart beat and change the stasis of the blood. They aimed at exercises that developed mental activity and gave an education in accuracy, alertness, precision, and inhibition. They used also an entirely different kind of exercises which were given at a different time and in a different way, and these were the hygienic exercises. The good posture exercises illustrated this point. Bad posture was a ptosis and they aimed at its correction. Some of the exercises advocated for boys were light gymnastics, mimic discus throwing, fencing, etc. For the girls there was folk dancing, basket ball, hockey, and walking. Dr. Crampton said that girls did not need the same kind of training physically as the boys. He felt sure that the training they were getting promised well for the future of the race.

Dr. George Dow Scott of New York asked Dr. Crampton whether he used rope jumping for the girls. In his experience in training boys for the football squad he had found this form of exercise admirable in cultivating the quick start.

Dr. C. Ward Crampton of New York replied that he had not been using rope skipping very much, but would use it more in the future. He expressed himself as opposed to the excessive development of muscles. The individual of the present day did not need large muscles; what they aimed to secure was a well-balanced organic development.

Dr. Joseph C. Palmer of Syracuse entered a plea for the more intimate association of the Physical Training Departments and the Departments of Medical Inspection of School Children. They were interdependent and should cooperate in every way. Children with various defects should have exercises suited to their special needs. Cases of scoliosis and kyphosis should be most carefully studied and should receive training in classes and groups with care to avoid any violent strain. The speaker had visited a class of this kind conducted by Dr. Werndorff in the Lorenz Clinic where forty or fifty Austrian girls came twice a week for exercises and to receive stretchings and kneadings suited to their conditions. They should create a public interest that would furnish a swimming pool and a gymnasium in every school. They should do all in their power to extend the physical training and medical inspection to the rural districts. An investigation by the National Council of Education and the American Medical Association had shown that city children were from 10 to 20 per cent. healthier than country children. In districts chosen at random it was shown that 25 per cent. of city children suffered from poorly nourished bodies, while 31 per cent. of country children were thus handicapped. Heart trouble was twice as frequent among country as among city children, and lung disease three times as frequent. It was no longer city life against country life but city oversight against rural indifference and neglect. Perhaps by recognizing these facts and rehearsing them some little aid might be given in improving the conditions of both city and country children.

Dr. C. Ward Crampton, closing the discussion, said that in reply to the question about competitive exercise, he wished to say that he had no use for athletes but much use for athletics. The athlete had only one use and that was to arouse the interest and enthusiasm of boys in athletics. The boys in the public schools of New York did not compete against one another but against a standard. When a boy reached a certain standard he received a certain kind of medal and when he reached a higher standard a different kind of medal, etc. They were using much less apparatus in the schools now than was used six years ago. There were special classes for crippled children and special exercises and plays; the girls had exercises with the emphasis on the abdominal muscles especially directed against ptosis.

**Record Charts for the New Born.**—Dr. Walter Lester Carr exhibited charts which he had found suited to his needs in keeping the histories and directing the management of his patients. The essentials which he regarded as of greatest importance were in reference to the care of the eyes of the newborn infant and the method of dressing the cord. The second chart was used in fixing the time of nursing and assisting the nurse or mother in establishing a routine.

Dr. Charles Herrman of New York said that these charts were important in view of the great mortality during the first month of life, and the care during the first two weeks was a large factor in determining this mortality. The care during the first month was much more important than the care after that time. By keeping such a chart one was not so apt to overlook anything that it might be desirable to know later.

Dr. Walter Lester Carr of New York said he wished again to emphasize the points in regard to the care of the eyes and the cord. The latter was important because infection in a distant part of the body might be dependent on cord infection. Proper attention during the first few days of life was very important in determining the later history of the child.

*(To be continued.)*

**Congenital Heart Disease; Probably Pulmonary Stenosis with Incomplete Ventricular Septum.**—W. Essex Wynter reports the case of a man aged 26 who suffered from pains in both elbows and knees at the end of September, 1913, this being the only occasion on which he could recall anything of the nature of a rheumatic attack. On account of the loud cardiac murmur he was kept in bed for several weeks, and finally sent to the hospital. The apex beat was just within the nipple line, and pulsation, with dullness on percussion, extended one inch to the right of the sternum. A loud systolic murmur could be heard over the precordia, the point of maximum intensity being in the fourth space near the sternum. It was so loud that it could be heard for some distance radiating from this point, but was best conducted toward the left clavicle in the course of the pulmonary artery. It was inaudible in the carotids and posteriorly. The second sounds were distinct, but not increased, and there was no diastolic murmur. The pulse was normal in character, neither small nor collapsing, and regular. Blood-pressure, 170 mm. of mercury. There was no enlargement of the liver, no edema, nor any cyanosis, except during rare attacks of cardiac disturbance, and there was no clubbing of the digits. The patient had always suffered from shortness of breath on exertion; was never able to play games, and could not perform any arduous work. Blood count: Red cells, 6,512,000; white cells, 6,400; hemoglobin, 100 per cent.; index, .08. The *x*-ray screen disclosed an enlargement of the right ventricle and a limited bulging of the conus arteriosus to the left.—*Proceedings of the Royal Society of Medicine.*

### THE VALUE OF POLYCYTHEMIA FOR THE DIAGNOSIS OF DUODENAL ULCER, BASED UPON SIXTEEN OPERATIVELY DEMONSTRATED CASES.

By G. A. FRIEDMAN, M.D.,

NEW YORK.

ATTENDING PHYSICIAN IN DIGESTIVE DISEASES, VANDERBILT CLINIC.

In two papers recently published I[1-2] have stated that the blood of patients suffering from non-bleeding duodenal ulcer differs from the blood of patients ailing with gastric ulcer. Further studies indicated that while in gastric ulcer and in chronic appendicitis moderate anemia is the rule and polycythemia the exception, in duodenal ulcer just the reverse occurs; polycythemia is frequent and anemia rare. As the discussion of the morphology of the blood in gastric ulcer and in appendicitis has been left for another paper, it is only necessary to mention here that Smithies[3] in an analysis of one hundred and forty cases of gastric ulcer from the Mayo clinic stated that in the average gastric ulcer a mild grade of secondary anemia is present.

There is not a single symptom or sign pathognomonic for duodenal ulcer. As in many patients the organic lesion (duodenal or gastric) is frequently associated with functional disturbance, it is in some cases hard to separate the nervous symptoms from the sole cause of trouble. If one is successful in doing this and duodenal ulcer is suspected, the differentiation between the latter and gastric ulcer and especially appendicitis is often difficult. The history of a patient with interpretation of gastric analysis and feces was of no value for diagnosis of uncomplicated duodenal ulcer until eleven years ago, as according to Mikulicz the condition was never correctly diagnosed before operation until that time.

In regard to the value of laboratory findings, from gastric analysis Mikulicz's[4] statement I believe holds good at the present time. But owing to the works of American and English surgeons and especially of Moynihan[5] the history of the patient became the predominant aid for diagnosis.

Moynihan's symptom-complex is as follows: Hunger pain, from which patient obtains relief immediately after ingestion of food; late pain, a pain experienced several hours after meal, from three to six; and night pain, by which patient is waked up and has to take milk and crackers for relief. If all of the above symptoms are complained of the diagnosis of duodenal ulcer can be made correctly according to Moynihan in 95-100 per cent. of the cases. Moynihan does not pay attention to the localization of pain, which in ulcer of the duodenum is mostly to the right of the epigastrium. Laboratory findings are not much considered by him in general, as the presence of occult blood was demonstrated only in 30 per cent. of his cases.

One must admit, as seen from Table 1, that although not all of his stated symptoms are met so frequently as he leads us to believe, hunger pain is a very valuable symptom in the diagnosis.

Notwithstanding the fact that hunger pain is occasionally complained of by patients ailing with gastric ulcer and appendicitis, the frequency of this symptom in ulcer of the duodenum is very evident.

For drawing attention to hunger pain in connection with duodenal ulcer Moynihan deserves great credit.

A far superior aid to the diagnosis is the correct interpretation of radiological findings. I must admit that I have never been convinced of changes in the duodenal cap, as being of value for diagnosis. But what is true is that an ulcer or a scar from healed ulceration causes irritation of the nervous apparatus and this irritation leads to excessive peristalsis. Truly, there are no rules without exceptions. Hyperkinesis of the intestines without the presence of duodenal ulcer may be found occasionally in neurotics. Such individuals, who show on *x*-ray examination excessive peristalsis and on physical examination other nervous manifestations, as loss of pharyngeal reflexes, relative eosinophilia, have been called by Eppinger and Hess,[6] "vagotonics," as these authors became dissatisfied with the common name of gastric or intestinal neurosis. But they also state that "vagotonia" may be associated in the same patient with gastric ulcer.

I had two personal cases of operatively demonstrated ulcer at the lesser curvature of the stomach in which there were no nervous symptoms or signs and still on *x*-ray examination excessive peristalsis was demonstrated. However nothing was found in the duodenum. In one of my patients in whom at operation carcinoma of the head of the pancreas was found by Dr. Gerster, the *x*-ray findings of hypermotility pointed to duodenal ulcer. This patient was not icteric and his history was rather suggestive of ulcer.

Last, but not least, should be mentioned the occasional findings of hypermotility in chronic appendicitis.

But all these facts do not lessen the value of *x*-ray findings for the diagnosis.

Let us not forget the relationship between clinical signs and symptoms of appendicitis and duodenal ulcer. Many of us have probably more than once diagnosed duodenal ulcer, where appendicitis was found at operation, although the reverse occurs less frequently. The reason is that the symptoms and physical signs are often alike in both conditions. A diseased appendix may cause duodenal irritation, which may lead to excessive peristalsis, as the ulcer or scar itself. There is therefore no

reason to reject the opinion that an ulcer at the lesser curvature may cause an irritative condition in the duodenum, as to simulate the ulceration caused by the ulcer itself.

Speaking for myself I must say, as seen from Table II, that radiological findings have given me the greatest satisfaction in the diagnosis.

But, as every little helps, I offer to the profession a new diagnostic aid—polycythemia, which, when confirmed by a large number of cases, may turn out to be even of greater value than *x*-ray examinations, as many a patient cannot stand the expenses of radiological work. The diagnosis of duodenal ulcer was made in most of our cases before we learned about *x*-ray interpretation.

Material. In the practice of a physician who is not a surgeon, it takes years to obtain a large material of operatively demonstrated cases, for the following reasons: Many ulcers do not require surgical interference, especially where symptoms disappear time after time upon dietetic and medicinal treatment. Although one can speak of the precancerous stage in gastric ulcers there hardly exists anything like it in duodenal ulcer, as the development of malignant growth in the usual seat of ulcer is extremely rare in the duodenum.

Some of our patients refused operation, not only through fear of the knife, as for any other operation, but also because they had learned from their friends, who had been operated upon for ulcers (gastric or duodenal), that the operation did not benefit them. And we physicians, to whom through kindness of the surgeons the postoperative patients are referred back, can frequently sympathize with our preoperative patients.

The surgeon nowadays skilfully performs gastroenterostomy, pylorectomy, and so on, but the medical man often sees the sufferings of the patient later, especially in those in whom the ulcerative process is associated with a considerable functional element or in persons past middle age.

I am always in the habit of explaining in my own way to the would-be sceptics, provided I do find a strict indication for operation. As many of my patients belong to the poor my explanation must be simply illustrated. I say: "Look, here, Mr. X., your fellow countryman arrived from the old country many years after you did. He became rich while you are still poor. Why is it? Your friend has quickly learned the language; he adapted himself rapidly to the customs of the land, and you did not." And so with the operation. The operation creates a new condition in the stomach. In some individuals the stomach adapts itself to new conditions, in some it does not.

However, as long as surgery remains, in the present state of our knowledge the only palliative for a large number of cases, the material should be chosen for the surgeon with the greatest care. The chief indication for operation in patients with duodenal ulcer is severe pain, which does not respond to any medical treatment. The indication for surgical interference in intestinal hemorrhages from ulcer is disputable. All of our patients who came to operation were previously under all kinds of treatment and only such were referred to the surgeon in whom pain could not be checked by the usual dietetic and medicinal treatment.

Our material consists of eleven additional cases, eight males and three females. Five with operative evidence have already been published, making a total of sixteen for the year 1913.

As the additional cases present in one way or in another interesting features, abstracts of histories are given. For statistical purposes in reference to the frequency of polycythemia the five already reported cases, marked with stars in Table VII, have been added.

Case I.—M. K., aged forty-three, tailor, referred by Dr. Rayevsky from Liberty Sanatorium, June 11, 1913. History given by Dr. Rayevsky: Patient suffers from constant pain in epigastric region for several years. Operation performed (appendix removed). Adhesions were found extending from gall-bladder to stomach. On the stomach wall something was found which resembled an ulcer. The adhesions were released, stomach explored. Patient left hospital three weeks after operation, apparently cured. His tuberculosis developed later. The abdominal pains reappeared two months after he had left the hospital. History taken June 11: Patient complains of severe abdominal cramps from three to five hours after meals. He has to wake up at night and to apply a hot waterbag to the belly in order to obtain relief from cramps. He is never relieved from pain after ingestion of food. Patient has never vomited, nor has he noticed blood in his stools. Appetite very good. No loss of flesh. Bowels regular. Complains of nervousness, cold hands, and cold feet. He uses neither liquor nor tobacco. Past history: Never had any diseases. Family history negative. Physical examination: Looks dried out; lungs show signs of incipent tuberculosis of both apices; heart normal; abdomen, border of liver, and kidneys not palpable; spleen not enlarged; great tenderness in epigastric region, and somewhat above navel to left, where rectus muscle is slightly rigid; kneejerks greatly exaggerated. Operative findings (July 1, 1913): Numerous adhesions between first portion of duodenum and gall-bladder; broad cicatrix in first portion of duodenum; stomach normal; no gallstones found; gastroenterostomy performed. Patient, as I learned from his physician six months later, was perfectly well in regard to his abdominal symptoms.

Case II.—W. D., aged forty-three, cigarmaker, entered the Beth David Hospital, August 20, 1913. Five years ago patient began to have sharp, cutting pain in right lumbar region, which radiated to left of abdomen, chest and back. The pain used to last from one-half to two hours. Pain never came on late after meals and never at night. He was always relieved after food. For last two years pain is continuous. During his illness he was on several occasions free from pains for one month. He vomited only twice since his present illness started. Never hematemesis, nor melena. Has to pass urine twice at night. He had never had any complaints of indigestion. Appetite very good. Bowels regular. No loss in weight. Complains of a feeling of heaviness in the precordium and nervousness. Past history: Had diphtheria at age of six years. Tonsillar abscess twice. Five years ago was operated upon for hemorrhoids. Denies lues. Uses tobacco moderately; liquors not in excess. Family history: Mother died from gallstones. Physical examination: Looks dried out; corneal anesthesia; complete loss of pharyngeal reflexes; slight tenderness around navel to right side; no muscular rigidity. Operative findings: Extensive induration found at the pylorus, extending to the lesser curvature, and down into the duodenum. Pylorectomy decided upon (September 15). Patient discharged well October 15.

Case III.—R. B., aged fifty, watchman; was first seen November 2, 1913. Patient has been ailing with indigestion for fifteen years. Since last year symptoms became aggravated. Sharp pain in the pit of stomach from one to one and one-half hour after ingestion of food. Pain is so intense that it doubles him up. Pain lasts for several hours, and he is never relieved after food; on the contrary, pain is frequently more severe immediately after meals. Has pain at night. Four weeks ago he vomited first since his illness has begun, but feels like vomiting whenever he has pain. Three weeks ago he had noticed blood in his stools. Sour eructations. Heartburn, for which he uses frequently bicarbonate of soda. Appetite poor. Constipated occasionally. Has lost in weight. Never icterus. No nervous symptoms. Past history: Pneumonia thirty years ago; no venereal diseases; smokes nine cigarettes a day; uses no liquor. Family history: Father died from Asiatic cholera in Russia; one sister died from gastric tumor, another died suddenly after having been ill for many years with attacks of abdominal pain and

indigestion. Physical examination: Looks rather anemic; signs of pulmonary emphysema; slight murmur at the mitral valve; great tenderness in epigastric region, more to right, and somewhat above navel; slight muscular rigidity in this region; no tender spots to left of spine, nor tender spots characteristic of gallstone disease. Operative findings: Mass of dense adhesions found all around stomach, binding it to gall-bladder, under surface of liver, colon, and intestines; adhesions separated and then a hard indurated ulcer discovered posteriorly in the first portion of the duodenum; pylorus found to be patent; presence of stones noted in gall-bladder; posterior gastrojejunostomy performed; two stones removed; bile fluid is normal in appearance. November 7, 1913, patient died from pneumonia.

Case IV.—G. K., aged thirty-four, teacher, was first seen at the Vanderbilt Clinic, November 13, 1913. Patient has complained of gnawing abdominal pain for five years. Pain starts in the epigastric region and radiates to back, sides, but especially to right hypochondrium and back. Pain comes on occasionally from two to five hours after meals, but most of the time independently upon ingestion of food. Pain is always relieved after drinking milk. Has pain at night, applies frequently hot-water bag to the abdomen. Attacks of pain became more frequent lately. He feels relieved from pain during day, when in recumbent position and after rest. He was free from abdominal pain and from all symptoms at one time for five months. Never vomited, nor has he noticed blood in his stools. Patient complains of heartburn, especially after eggs, and occasionally of nausea. Appetite very good. Has never been constipated, and therefore as far as his memory goes has never used any cathartics or enemas. No loss in weight. Complains of nervousness. Past history: Fourteen years ago had malaria, never icterus; denies lues; five years ago his physician in Russia suspected gastric ulcer and attended to him accordingly; smokes fifteen cigarettes a day; used liquor in excess until his present illness began. Family history: Mother died from blood poisoning after childbirth; brother died from typhoid fever. Physical examination: Healthy looking man. There is great tenderness in epigastric region, more to right. Weight, 168 pounds. Blood pressure, 115. Operative findings: Indurated ulcer in first portion of duodenum posteriorly; pylorus, patent; stomach, normal; no stones in gall-bladder; gastroenterostomy. Patient discharged well.

Case V.—H. S., aged fifty-two, teacher, was seen first November 10, 1913. Paatient has had indigestion twenty-three years. Attacks of gnawing and sharp pain in the abdomen, and across. Lately paroxysms of pain are becoming more frequent and more intense (every ten days). He is relieved from pain immediately after food. Has never had any pain at night. Pain is more intense four to five hours after meals. Feels like vomiting, but actual vomiting occurred only once, two months ago. Never melena. Has frequently heartburn. Appetite is capricious; lately anorexia. Lost in weight for past few months eight pounds. Constipated. No nervous symptoms. Past history: Lues denied; never had any serious diseases; never icterus; smokes ten or fifteen cigarettes a day; uses no liquor. Physical examination: Looks robust; tenderness in epigastric region, right hypochondrium, and right parasternal line, somewhat above navel; muscular rigidity in this region; blood pressure, 140. Operative findings: Ulcer at anterior wall of duodenum found; stomach normal; gall-bladder normal. Gastroenterostomy. November 26, 1913, patient well.

Case VI.—H. I., aged twenty-eight, housewife, was first seen March 10, 1913. Patient has complained of indefinite abdominal pain for ten years. Two and one-half years ago was operated upon on account of pain for appendicitis. She was not relieved for a single day after appendectomy was done. She felt practically worse than before. Patient has to wake up at night on account of pain. Lately pain lasts all day long, and feels relieved from one to two hours after meals. In the first years of her illness pain used to come on four hours after meals, but since the operation pain is rather continuous except shortly after ingestion of food. After drinking hot water she felt at the beginning of her illness as if the water would come in contact with a wound in the stomach. Injections of morphine given by her physician do not give her much relief. Never vomited, never melena, never icterus. Appetite very good, but afraid to eat, especially her supper. Has lost very much in weight. Constipated. No nervous symptoms. Physical examination: Great tenderness around navel to right, marked muscular rigidity; otherwise negative. Operative findings: Gallstones found in gall-bladder, adhesions between gall-bladder and first portion of duodenum; scar at first portion; stomach normal. Cholecystectomy, May 1, 1913.

Case VII.—G. J., aged twenty-three, working at flowers, was seen first November 27, 1912. Patient complains of a choking sensation in the throat. Since several months she has pain all over the body, but pain is more intense in right lower abdomen, especially in walking. Insomnia, cold hands and cold feet. Sour taste in the mouth. Food does not leave the stomach at all. Rumbling of gases in the abdomen. Has lately abdominal cramps at night, relieved after passing flatus. Occasionally indefinite abdominal pain in the abdomen several hours after luncheon and after supper. No hunger pain. Never vomiting, never bloody stools. Has lost somewhat in weight. Bowels slightly constipated. She was seen by a number of physicians and nearly every one considered her as a neurotic only. Past history: Had typhoid fever at age of twelve; nine weeks ago was operated on for appendicitis. Appendix was found to be diseased. She had chills and fever soon after she left the hospital. Family history: Negative. Is a healthy looking girl. Face rather flushed. Loss of pharyngeal reflexes. Right floating kidney. Hyperesthetic zones in different parts of the body. Highly exaggerated knee-jerks. There was on many examinations only slight tenderness in the region of navel, more to right. Operative findings: Broad adhesions between gall-bladder and first portion of duodenum; gall-bladder thickened, but no stones; stomach normal. Gastroenterostomy, December 27, 1913.

Case VIII.—M., aged twenty-one, operator, was seen first June 12, 1913. Patient was never troubled with indigestion or pain until six months ago. Since that time she complains of pain in abdomen and chest. Pain comes on from five minutes to two hours after meals. Pain is sharp and localized around navel and pit of stomach, and radiates to the back. He was not free from pain for a single day since illness began. Pain is most intense after stooping or coughing, and is never relieved after ingestion of food. No vomiting or melena. Sour eructations. Appetite poor. Has lost in flesh. Obstinate constipation (uses magnesia or enemas for bowels). Very nervous. Cries occasionally, when free from pain, without any reason. Past history: Was operated upon for glands in the neck; typhoid fever twelve years ago (ten weeks in bed); menstruation regular but painful. Family history: Negative. Physical examination: Rather pale looking; loss of pharyngeal reflexes; spastic abdomen; great tenderness in epigastric and in appendicular regions. Patient was under Lenhartz diet for two weeks, and later until September 9 under soft diet and the usual medicinal treatment for ulcer and nervousness. She did not obtain any relief from treatment. Operative findings: Duodenal ulcer adherent to the gall-bladder; no stones; stomach normal. Gastroenterostomy, November 29, 1913. Patient was free from abdominal pain two months later.

Case IX.—L. S., aged fifty, locksmith, entered Beth David Hospital, August 27, 1913. Patient had four months ago on one day diarrhea (four movements), with blood of chocolate color, and fainted four times. He had no cramps or any abdominal pain at that nor at any time before the incident. Only two weeks later he began to complain of sharp cutting pain in the right and left hypochondriac regions. Simultaneously he had also pain in the back, coming on two to three hours after dinner, and lasting until 2 A. M. No hunger pain. Appetite good. Has lost ten pounds in weight. Bowel slightly constipated. Uses no tobacco nor alcohol. Past history: Negative. Family history: Negative. Physical examination: Looks anemic, but fairly well nourished; loss of pharyngeal reflexes; lungs, heart, normal; abdomen, lax, tympanitic; tenderness in epigastric, right, and left hypochondriac and in appendicular regions (practically tender all over abdomen). Patient was under Lenhartz diet for two weeks and until October 11 under the usual ulcer therapy. Discharged October 12 considerably improved. Reentered the hospital, November 5, on account of severe abdominal pain. Operative findings: Soft ulcer in first portion of duodenum; pylorus patent; stomach normal. Posterior gastroenterostomy, November 10, 1913.

Case X.—Z. P., aged fifty-two, restaurant keeper, was first seen November 29, 1913. Patient has been apparently well until one week ago, when he began to have pain in the pit of the stomach and chest. Drinks much milk in order to obtain relief from pain. Pain comes on fifteen to twenty minutes after food. Has abdominal pain at night. Never vomiting, nor melena. Anorexia since nine days. Has lost in flesh. Constipated. Past history: Three years ago he had a similar attack of pain, which lasted for several weeks; otherwise no diseases; denies lues; smokes six pipes a day; uses liquors moderately. Family history: Negative. Physical examination: Abdomen tympanitic; lower liver dullness cannot be made out on account of tympanites; great tenderness at navel, to right, and slight tenderness in appendicular region; blood pressure 120. Patient was seen once more and escaped from observation. About one month later, on December 27, Dr. Luria asked me to inform him about my findings, as the patient entered his service at the Jewish Hospital, Brooklyn. From Dr. Luria I have learned that the patient vomited in the hospital several times, and had chills and fever. Operative findings: Perforation in first portion of duodenum. Near the perforated area a fishbone was found. Liver showed necrotic areas. December 27, 1913, gastroenterostomy done. Patient died.

Case XI.—K. A., aged forty-five, traveling salesman, was first seen September 27, 1913. Patient has been well until several months ago, when he began to complain of slight difficulty in swallowing solids. He had never had abdominal pain, never vomited, nor had noticed tarry stools. Appetite good. Never any dyspeptic symptoms. Bowels regular. Has lost considerably in flesh. Past history: Negative. . Family history: Negative. Physical examination: No tenderness anywhere in the abdomen. An obstruction of the esophagus was found at a distance of 12½ inches from the incisors. On esophagoscopic examination, which was made by me later in the hospital, a cancerous looking growth could be demonstrated in the esophagus at the mentioned distance from the teeth. Patient was referred to the surgical side for gastrostomy, which was supposed to precede radical operation. Operative findings: Stomach normal; soft ulcer of first portion of duodenum found; stomach opened. Unsuccessful attempt made to pass stomach tube through esophagus in reverse direction. Impossible obstruction encountered a few inches from cardia. Large probe passed and unsuccessful attempt made to pass tube alongside. Several months later the radical operation could not be made, as the cancerous mass of the esophagus was adherent to the aorta.

I am indebted for the reports of operative findings to the following doctors: A. A. Berg (Cases 2, 3, 6, 9, 11), Charles Peck (Cases 4 and 5), Charles Dowd (Case 1), A. G. Gerster (Case 8), G. D. Stewart (Case 7), and W. Linder of Brooklyn (Case 10).

*Discussion of Cases.*—Case 11 is most interesting. As seen from Table V the presence of occult blood was found twice on routine examination of the stools. The cause for the positive guaiac tests was not clear at all. After introducing many times bougies of different caliber and after esophagoscopic examination not a drop of blood could be detected on the instruments. However, at the operation a soft ulcer was discovered in the duodenum. The finding of an ulcer in this patient was a surprise, as he did not present a single sign or symptom pointing to this condition. He came originally to operation for carcinoma of the esophagus. This case therefore proves once more the latency of duodenal ulcer and also the immunity at least of the first portion of the duodenum to malignant growth, as cancer had developed, but not in a locality where a predisposition had been created by an ulcerative process. It is a well-known fact that the soil of the duodenum, with the exception of the papilla of Vater, is not favorable to cancer. The cause of polyglobulia in this patient was possibly starvation, as I had found it in two other patients, suffering from esophageal carcinoma. But on the other hand, the latter patients had considerable difficulty in swallowing, and of course the polyglobulia in them was clear, while this patient had practically slight disturbance in deglutition he took during his stay in the hospital enough eggs and milk, and other foodstuffs in semisolid form. Starvation polycythemia was not evident in this case.

The diagnosis in Case I was difficult. The patient had been operated upon about three months before he was seen first for appendicitis. From the medical man who referred him to me I did not obtain any information as to whether or not the appendix was really diseased. From the report of the appendectomy operation it is evident that the surgeon manipulated in the neighborhood of the duodenum (adhesions were mentioned from gall-bladder to stomach, and so on). As second operation has revealed a broad scar in the duodenum, is it hardly conceivable that in a period of two months an ulcer developed which led to scar formation? Therefore, one can assume that the ulcer or scar was overlooked at the first operation. Elsewhere I have pointed out that an ulcer may not be seen at operation and later be discovered at autopsy. The diagnosis would have been easy if not for the confusing report of the previous appendicitis operation. The findings of polycythemia in the blood in three counts, the average of which is given in Table VII, was the chief support for the diagnosis. The *x*-ray findings in this instance could not have been so valuable, as the patient presented many nervous symptoms.

There was not a single hitherto known factor explaining the high count of red cells. Patient had a very good appetite and for this reason starvation polyglobulia could be ruled out. Vomiting, as in the majority of patients with duodenal ulcer, was not complained of, and therefore the polyglobulia was not due to concentration of blood. Higher counts are sometimes met with in gastric dilatation. There was no stagnation of food on fasting stomach and on *x*-ray examination the stomach was found about 3 inches above navel.

Case II.—This patient presented also many nervous symptoms. Objectively corneal anesthesia and loss of pharyngeal reflexes were found. Except hunger pain, which could be associated in this case with neurosis, patient did not give a "Moynihan's" history. The *x*-ray findings, as seen in the table, were negative.

It was therefore difficult to persuade the surgeon to operate upon this patient. The preoperative diagnosis was duodenal ulcer. At operation an extensive induration was found in both organs, stomach, and duodenum. The pylorus was found to be patent. The question in which of the two the ulcer started remains open. As polycythemia was found on many examinations, I believe that the beginning of the ulcer was possibly in the duodenum.

Case III indicates the association of duodenal ulcer with gallstones. As there was no history of gallstone disease and rather a history of gastric ulcer, the formation of concrements in the gallbladder was probably secondary. The adhesions between duodenum and gall-bladder caused probably a pulling upon it. The emptying power of the gallbladder became reduced. Hence stasis of bile was possible and as a consequence formation of stones.

Cases IV and V did not present any difficulty

to the diagnosis. In case V it is worthy to note the long duration of illness—twenty-three years. Cases IV and VI were the only two in which a full "Moynihan's" history was obtained. Note again in Case VI the association of duodenal ulcer (scar) with gallstones, and a previous appendectomy as in Case I. Patient did not feel much relieved many months after cholecystectomy. I believe that she would have been better off if gastroenterostomy had been performed.

The patient in Case VII was a young girl, upon whom appendectomy was done nine weeks before she was first seen by me. She gave a most typical history of a neurosis. The girl was under my observation on and off about one year, and in the intervals of her absence she would visit other physicians and surgeons occasionally, only with my consent. It would not be an exaggeration on my part to state that she was seen by a dozen of the best consultants in town. No one, except Dr. Gerster, to whom I referred her for advice, would agree to an organic element in this patient. Her blood was examined several times. Anemia was found only on one occasion, on the second day of her menstrual flow. The diagnosis was duodenal ulcer. At operation, which was performed by Dr. Stewart (St. Vincent's Hospital) broad adhesions were found between first portion of duodenum and gall-bladder. No stones. Stomach normal. Gastroenterostomy was done. An ulcer too small to be seen must be granted.

Case VIII was another instance of duodenal ulcer in a young girl with many nervous symptoms. The history of the patient rather pointed to gastric ulcer. The *x*-ray findings favored duodenal ulcer. Blood indicated anemia. The preoperative diagnosis was gastric ulcer.

A correct diagnosis could have been made in this case if history and blood findings had not been overestimated and radiological findings underestimated.

Case IX was somewhat similar to Case II in regard to latency of duodenal ulcer. The intestinal hemorrhages and fainting spells occurred in the first case suddenly, without any premonitory sign or symptom; only several weeks later patient started to complain of pain. Ulcer therapy could not check his pain. Operation was advised. However, gastroenterostomy did not benefit him, as several months after operation the attacks of pain were more intense than before. This patient did not complain of nervous symptoms, although on physical examination loss of pharyngeal reflexes was demonstrated. His age, sixth decade, did not favor a good postoperative prognosis. As it was stated, the stomach does not seem readily to adapt itself to new conditions in older people.

In Case X the patient gave a history of having been ill one week, but admitted after cross-examination that he had a similar attack three years ago. It is possible, therefore, that the fishbone favored the perforation of an old ulcer. However, Dr. Linder, who operated upon this patient, believes that the sole cause of trouble was the fishbone incident, as the ulcer did not have the characteristics of an old callous ulcer.

Table I indicates that the full Moynihan's symptom-complex was present in 20 per cent. of the cases; hunger pain in 50 per cent.; late pain in 60 per cent.; night pain in 80 per cent.; hunger pain and late pain in 10 per cent.; hunger pain and night pain in 10 per cent.; night pain and late pain in 30 per cent. Presence of symptoms in regard to frequency: Night pain and late pain.

TABLE I

| No. | Hunger Pain | Night Pain | Late Pain |
|---|---|---|---|
| 1 | 0 | + | + |
| 2 | + | 0 | 0 |
| 3 | 0 | + | 0 |
| 4 | + | + | + |
| 5 | + | 0 | + |
| 6 | + | + | + |
| 7 | 0 | + | + |
| 8 | 0 | + | 0 |
| 9 | 0 | + | + |
| 10 | + | + | 0 |

Table II indicates that of eight cases examined satisfactory results were obtained in six—75 per cent. of cases examined with *x*-rays.

TABLE II

| No. | | Reported |
|---|---|---|
| 1 | Hypermotility of intestines | Dr. Hirsh |
| 2 | Normal findings | ..... |
| 3 | Hypermotility | ..... |
| 4 | .... | Dr. Leaming |
| 5 | | ..... |
| 7 | | Dr. L. Weiss |
| 8 | | ..... |
| 10 | Normal findings | Dr. Luria |

As in all cases at operation the pylorus was found to be patent, the findings of food retention in Cases 2, 3, 9 and 10 do point to a condition of pylorospasm (40 per cent.).

In 40 per cent. of the cases the patency of pylorus was demonstrated before operation by the color of contents; bile tinged. Gastrosuccorhea was absent in most cases.

TABLE III.—GASTRIC ANALYSIS ON FASTING STOMACH

| No. | Amount in C.c | Color | Visible Stagnation | Microscopical Stagnation |
|---|---|---|---|---|
| 1 | 13 | Normal | Absent | Absent |
| 2 | 30 | .. | ..... | A few starch granules, fat globules and cellulose |
| 3 | 50 | . | Present | Many sarcinæ and starch granules |
| 4 | 0.5 | Bile tinged | Absent | Absent |
| 5 | 25 | Blood tinged | | ..... |
| 6 | 0 | ..... | | ..... |
| 7 | 16 | Bile tinged | | |
| 8 | 0.5 | | | |
| 9 | 50 | Normal | Present | Sarcinæ and starch granules |
| 10 | 40 | Bile tinged | Absent | A few muscle fibers and cellulose |

From table IV is evident that of nine cases examined hyperchlorhydria was present in eight, hyperacidity in one. Average acidity for hydrochloric acid, 46; total acidity, 77.

TABLE IV.—GASTRIC ANALYSIS AFTER EWALD TEST-BREAKFAST

| No. | Amount in c.c. | Volume of Solids | Volume of Fluids | Acidity |
|---|---|---|---|---|
| 1 | 120 | 90 | 30 | 64/100 |
| 2 | 240 | 120 | 120 | 40, 62 |
| 3 | 50 | 40 | 10 | 48, 82 |
| 4 | 0 | 0 | 0 | 0 |
| After 45 min. | 40 | 30 | 10 | 50/74 |
| 5 | 150 | 90 | 60 | 30/80 |
| 6 | 0 | 0 | 0 | 0 |
| After 30 min. | 40 | 10 | 30 | 34/92 |
| 7 | 130 | 100 | 30 | 34/92 |
| 8 | 50 | 50 | 0 | 14 42 |
| 9 | 210 | 70 | 140 | 65 81 |

In two cases the emptying power of the stomach was found to be normal (50 c.c.), in five reduced motility, and in two hypermotility, as no food was obtained in the usual time and smaller than normal amounts after aspirating before one hour. The

volume of solids was found to be larger than the volume of fluids in five cases; in Case II equal amounts were obtained; in eight cases there were only solids; in the remainder the volume of fluids was larger.

TABLE V

| | Feces for Occult Blood | Urine |
|---|---|---|
| 1. | – | – |
| 2. | –, –, – | – |
| 3. | + | Indican in excess |
| 4. | –, –, – | Indican in excess |
| 5. | – | – |
| 6. | – | – |
| 7. | –, –, – | – |
| 9. | +, +, +. | – |
| 11 | +, +. | – |

Of nine cases, as seen from Table V, examined for occult blood in the feces, the guaiac test was positive in three, or in 33 per cent. This figure does not differ much from the 30 per cent. given by Moynihan for a large material. The table therefore tends to show that statistics from a small material may be also of value. The results of urine examination do not require any comment.

TABLE VI—TRYPSIN UNITS IN THE FECES

No. 1. 50,000; 3. 25,000; 4. 25,000; 5. 5,000; 6. 25,000

The findings in this table are very interesting. The feces of five patients examined after the method of Gross-Fuld quantitatively for trypsin, showed high values from 5,000 per cent.—50,000 units against normal 500. As in gastric ulcer, I have found lower than normal values, these findings in duodenal ulcer tend to show possibly hypersecretion of the pancreatic gland due to irritation from the duodenum.

Table VII indicates that the average hemoglobin of fifteen cases of non-hemorrhagic ulcer was 90 per cent. The average number of red cells, 5,921,000, or close to six millions. Polyglobulia, as seen from table, was found in thirteen out of sixteen cases, or in 81 per cent. White blood cells: Leucopenia was found in one, leucocytosis in two cases; in perforated ulcer, and in Case II, where duodenal ulcer and gastric ulcer were found. In the remainder normal counts were found.

TABLE VII.

| No. | Percentage of Hemoglobin (Sahli) | R. B. C. | W. B. C. |
|---|---|---|---|
| 1 | 95 | 6,700,000 | 8,740 |
| 2 | 90 | 6,576,000 | 14,960 |
| 3 | 82 | 5,660,000 | 7,600 |
| 4 | 112 | 6,510,000 | 9,000 |
| 5 | 100 | 5,730,000 | 8,800 |
| 6 | 80 | 5,580,000 | 9,100 |
| 7 | 90 | 6,000,000 | 8,920 |
| 8 | 85 | 4,300,000 | 4,500 |
| 9 | 55 | 4,473,000 | 7,600 |
| 10 | 94 | 5,130,000 | 21,000 |
| 11 | 86 | 5,800,000 | 6,000 |
| *12 | 92 | 5,600,000 | 9,000 |
| *13 | 100 | 6,400,000 | 8,060 |
| *14 | 120 | 5,700,000 | 8,060 |
| *15 | 70 | 6,630,000 | 9,940 |
| *16 | 90 | 6,500,000 | 9,800 |

Polymorphonuclear, moderate increase in Cases IX and X; small lymphocytes, decrease in Cases V and IX; small mononuclear, increase in cases V, VIII, and IX; large lymphocytes, increase in two cases where ulcer was complicated by gallstones; eosinophiles, relative eosinophila (4 per cent.) in Case VIII; transitional, an increase in three cases, III, V, and VI.

From the various points made by the author in this and in the two other papers on the same subject, he feels justified in bringing forth the following conclusion in regard to the diagnosis of duodenal ulcer:

The physical and chemical data obtained by means of analysis of gastric and even duodenal contents are of secondary importance. They are very variable and, of course, depend as much and more on the functional condition of the stomach than upon that of the duodenum. Good evidence of that is found in the fact that the fairly frequent diagnoses of duodenal ulcer are events of most recent years, notwithstanding the fact that a good idea of gastric function has been known over a generation.

That the history interpreted from the viewpoint of recently discovered facts is of value is best seen from the work of Moynihan, whose operative experience is probably exceeded by no one. His observations have proved that a great part of what were earlier looked upon as neuroses of the stomach and intestines—marked by hypersecretion, gastralgias, abdominal pain elsewhere, etc.—is really due to a definite physical lesion, that is to ulceration of the duodenum. In our opinion, however, he lays too much stress upon history alone. It is true that a good Moynihan complex can usually be elicited in cases of duodenal ulcer, but it is also true that a similar complex is present in cases where no ulcer has been found, and what is more important, duodenal ulceration may exist without giving any very typical symptoms. This statement is of course almost an axiom in medical knowledge. Pathognomonic symptoms, exclusive of all other conditions, and always present, are described in textbooks, in this or that disease, but they alone cannot always be depended upon. The periodic paroxysms of malaria the initial chill, fever, and cough of pneumonia, the abdominal pain and local tenderness of appendicitis are frequently enough observed, yet numerous instances of these conditions fail to show these symptoms. This is even more true in abdominal conditions, where any one of the so many organs or tissues may be physically and functionally at fault, and be responsible for very similar symptoms.

*X*-ray findings are of great value. That they are not exclusive is shown by the great difference of opinion among *x*-ray workers themselves, or, in-

deed, the very existence of hypermotility, etc., in duodenal ulceration has recently been seriously questioned. The fact is that the observations in duodenal disease have been only very recent, and while much is to be expected in the future from this method of diagnosis, at the present time it is of limited though distinct value. The author has endeavored to show that polycythemia is almost a constant accompaniment of duodenal ulcer. The occasional case of gastric ulceration or of other abdominal diseases accompanied by this finding in the author's experience, has given clear indications for the proper diagnosis. The exceptional blood findings will be considered by the author in connection with the study of the blood in gastric ulceration.

The polycythemia of duodenal ulceration remains after an operation. In many cases it has been the only distinctive feature, and has enabled the author to make diagnosis in spite of atypical history and indefinite *x*-ray findings.

This symptom is one that is easily enough determined, certainly so in hospital cases and in private practice as well, for of course a microscope and a hemocytometer should be common equipment of the modern physician. In calling attention to this symptom the author believes that he has facilitated the diagnosis of this important condition, and he is very anxious to have his findings gone over by other men having the proper facilities and material at hand. In the meantime, he can state from both his hospital and private practice experience that no symptom has been found as helpful in the diagnosis of duodenal ulcer as the symptomatic polycythemia discovered by him. Since his two papers have appeared he has had reports from several surgeons regarding the correctness of his statement. Dr. Gerster, Dr. Peck, Dr. Stewart, and Dr. Goodman have operated upon their own patients with duodenal ulcer in whom polycythemia was found.

## NOTE ON MECHANICAL SUPPORT FOR THE FEET IN LOCOMOTOR ATAXIA.*

BY WILLIAM J. M. A. MALONEY, M.D., F.R.S. EDIN.,
NEW YORK,
ATTENDING NEUROLOGIST, CENTRAL AND NEUROLOGICAL HOSPITAL,
AND
VICTOR E. SORAPURE, M.D., F.R.C.S. EDIN.,
NEW YORK,
VISITING PHYSICIAN, CENTRAL AND NEUROLOGICAL HOSPITAL.

WHEN standing, the ataxic tabetic rotates his feet outwards in a horizontal plane, around a vertical axis, which passes through the ankle joint, to such an extent that the distance between the great toes may be several times that which separates the heels. These abducted feet are sometimes overpronated, and in such cases both the anteroposterior and transverse arches usually yield. Such a foot affords a wretchedly inadequate support. The only stable element in it is the os calcis. The foot moves as a flail attached to the ankle and in front of the os calcis is a flabby conglomeration of bones. The muscles of such a foot are lengthened, and hypotonic. The ligaments are stretched perhaps beyond functional utility. In some cases we have examined, an increase of an inch in length and of an inch in breadth occurred when the body weight was placed upon the foot. We might as well expect the tabetic to walk easily on stilts as expect him to walk easily upon these abducted, pronated, formless feet. In his necessity, the tabetic makes a simian use of his toes, for the joint sense in his feet is usually lost to a greater degree than either common sensibility or sensitiveness to scratching. Indeed, common sensibility in the tabetic foot moy be wholly normal and the perception of scratching may be increased. The ataxic, using these senses to compensate for his lost joint sense, clings to the ground with his toes. During this toe action, which is to a certain extent a reflex expression of fear, the middle joints are arched up against the box of the shoe. The ataxic, moreover, often dorsiflexes his foot and toes as a prelude to the movement of flexion at the hip joint.

Sometimes the abducted feet are supinated, the patient walking on the os calcis and base of the fifth metatarsal. In such feet the clutching with the toes is even more marked than in the pronated feet; and although both arches suffer the displacement of the tarsal bones is less constant.

The clutching of the ground with the toes and the excessive dorsiflexion of the foot cause blisters and callous formation on the tips of the toes, where they rub against the sole of the shoe, and over the dorsal aspect of the middle joints of the second and third toes, which come in contact with the box of the shoe.

Ataxia may be alleviated or even cured by appropriate motor education. If blindness occurs in an ataxic tabetic, the ataxia may improve. From hour to hour, ataxia varies with the calmness and the excitement, the fatigue and the freshness, the despondency and the cheerfulness, the confidence and the fear, of the patient. These temporary psychic states cannot possibly alter the structural defect which is the fundamental basis of the ataxia, but they undoubtedly enhance or minimize the influence of that defect upon the function of coordination. Psychic processes are thus all-powerful in the ataxia of tabes. Upon the psychic element, motor education depends. The first step in treating ataxia is therefore to take such measures as will minimize the mental influences which aggravate incoordination. Fear, fatigue, pain, depression, and excitement are the chief of these incoordinating influences; and the greatest of these is fear. The lack of support which his feet afford to the swaying tabetic creates in him, not merely uncertainty as to the outcome of every step, but even a lively fear. The instability and fear result in prodigal expenditure of muscular and nervous energy for balancing purposes, and contribute thus to fatigue. Fear and fatigue increase ataxia, and ataxia increases the fear and fatigue. So the troubles of the ambulant

* Read before the Orthopedic Section, New York Academy of Medicine, April 17, 1914.

ataxic multiply. In the twenty-four or forty-eight hours, which elapse between the lessons in coordinate movement, the physician should not allow the patient to stagger a whit more than is unavoidable. Staggering, uncertainty, fear and fatigue can be relieved by appropriately bracing the foot and by carefully planning the shoe. The correction of the mechanical defects of the tabetic foot is an essential preliminary to the motor education of the ataxic. If the fear and fatigue are alleviated, the ataxia diminishes.

When the feet are separated so that each external malleolus is in the plane of a line dropped vertically from the great trochanter, and the long axis of each foot is directed forward so that the feet are parallel, the feet are in the position which confers the greatest amount of stability in standing. In this position, the weight bearing on each foot is distributed across the longitudinal and transverse arches, and is directly transmitted to the ground by a tripod, consisting first of the internal tubercle of the os calcis; second, of the sesamoid bones and the head of the first metatarsal; and third, of the base of the fifth metatarsal.

Our efforts were directed to bracing the tabetic foot in such a manner that in this proper position, the full weight would be borne on the natural tripod in standing and in walking. In order to do this precisely, it was necessary, in addition to the usual procedure of recognizing a diminution in the longitudinal arch, and correcting this along the lines indicated by a cast of the foot taken in a position of rest, that we should obtain a cast of the foot in the act of bearing the full weight of the body. A comparison of this cast with that taken of the foot at rest shows exactly the points on which the weight is falling, the degree to which the natural arches have given way, and the amount of spread in all directions, which has resulted from the overstretching of the ligaments, and muscles.

To obtain the cast of the foot in action, we proceed as follows: Two tin plate boxes, fourteen inches long, and seven inches wide, with removable sides two inches high, are half filled with dental wax, which has a melting point of 110° F. The boxes are so constructed that they accommodate any size of foot, and they may be fixed parallel to one another, at a desired distance, by means of rigid connecting rods. The boxes are placed in hot water, which is allowed to heat to about 116° F., until all the wax is thoroughly softened. Then the wax is carefully kneaded, into a smooth layer of uniform thickness, covering completely the bottom of the box. The patient is shown how to stand with the feet parallel, and separated by a distance equal to the width at the hips. Then he practises placing one foot, say, his right, squarely upon the ground, meanwhile resting his weight upon the physician; next placing his left upon the ground parallel with the right; and then, supported by the physician only enough to prevent swaying, allowing his weight to be borne wholly upon his feet. After two or three trials, this maneuver is easily accomplished. The two boxes are lifted out of the hot water, braced together at the desired distance, and placed in front of the patient. The patient, leaning upon the physician in the manner in which he has been instructed, places first his right foot squarely upon the wax in the right box, and his left foot squarely upon the wax in the left box. Then he allows all his weight to rest upon his feet, and in doing so he is still supported by the physician sufficiently to prevent swaying. In about two minutes, the temperature of the wax in the box falls below the melting point, the wax solidifies, and the patient, once more leaning his whole weight upon the physician, then removes his feet from the boxes. In each box there now remains, deeply impressed in the solid wax, the imprint of the patient's foot as it was when his weight was fully upon it. Into this mold, fluid plaster-of-Paris is poured and allowed to set. Then by placing the boxes again in water above 110° F., the wax softens, and the plaster casts can be lifted out.

If the temperature of the water be allowed to rise too high, and then to cool too suddenly, the wax becomes hard and brittle. It can be restored to its original plastic state by being again heated, and very slowly allowed to cool. For heating purposes, we use the ordinary water delivered from the hot water faucet, and regulate the temperature with the aid of a bath thermometer. The only precautions necessary in choosing the wax are, first, that the wax be solid at body temperature; and, second, that its melting point be within a few degrees of the body temperature, so that a patient may not require to step into wax which is uncomfortably hot.

Plaster casts are now taken of the foot at rest, in the usual way—the leg crossed upon the opposite knee and supported in the position of least constraint, while the cast is being taken.

We are now provided with a plaster cast of the foot in action and a plaster cast of the foot at rest. With these two casts as guides, we build a third. In building this third cast, our effort is to utilize the normal pressure points in the foot and to restore as far as we can the normal bony arrangement of the foot, the pressure tripod. For this purpose, we use a replica of the cast of the foot at rest; add plaster to it at points where we wish to avoid pressure, and scrape away plaster at points where we wish to allow pressure. This third cast is the model of the foot upon which the brace maker fashions the plate. Instead of using a replica, the cast of the foot at rest may itself be used, but this gives a less accurate result.

The cast of the foot in action shows usually that the faulty position assumed throws the weight on the posterior and outer limb of the tripod. Sometimes, all the weight is borne on the heel; sometimes, on the heel and the internal limb of the tripod; and sometimes on the heel and outer limb of the tripod. In a condition such as the last the weight falling on the os calcis and the base of the fifth metatarsal and the foot supinated—the following are the main points which guide us in constructing the model for the brace maker. The posterior part of the longitudinal arch between the tubercle of the os calcis and the base of the fifth metatarsal is increased sufficiently to throw the foot inwards, and by diminishing the convexity of the heel across the tubercle of the os calcis, the foot is thrown forward, both planes converging on the inner limb of the tripod, until the weight falls squarely on each. Our aim is to pronate the foot without pressing on the inner side more than is needed to guide the supinated foot into the proper degree of pronation. The model is made more wide than the cast at rest, but less so than that in action, so as to limit the spread and yet not compress the tissue unduly. The lengthening of the foot is, of course, diminished by the longitudinal arch support. The spread of the transverse arch is also

diminished by increasing the concavity between the two anterior limbs of the tripod, and extending the brace completely across the space.

The type of brace used is a modification of the Whitman brace—the inner lip being curved below the level of the scaphoid. The outer flange is lower and does not extend so far forward; and the support of the transverse arch extends outwards beneath the four inner toes. When the spread is very great, the inner lip is extended forward to include the first metatarsophalangeal joint, surrounding it completely on the inner side.

No two pairs are exactly alike, each being built on its own model constructed from the casts of the foot at rest and in action.

The brace is light, accurately applied, and efficient. It supports the foot in action. This support is obtained as the result of study of the foot in action, which has shown us the distribution of the pressure upon the foot. Braced by this plate, the foot is no longer a treacherous, structureless prop, but sustains pressure on the normal pressure points, and affords reliable support from every part of its surface.

Maloney endeavored further to increase the foot support by means of a high shoe or boot, especially strengthened on the outer side of the ankle, to increase the support at the ankle and prevent the foot turning in. This shoe had a low heel, which was wedge shaped, the base of the wedge being on the ground, and this heel was continued along the outer side of the shoe. A welt as broad as the patient would permit projected around the sole, and a steel plate was placed in the sole to prevent bending. When this shoe was on the ground, it rested with its whole bearing surface, and the patient got support from every part of this extended surface, simultaneously. To overcome the tendency to grip with the toes, Maloney raised the anterior part of the sole so as to hyper-extend the toes. But this shoe was heavy. The shoe we have now designed is made for us by Mr. Max Deutsch of New York. A straight last is used. The sole projects three-eighths of an inch all around the upper. A hickory wood filler extends from the heel through the shank to the front of the sole, rendering it rigid and unbending. The heel, wedge-shaped, with the base of the wedge on the ground, is seven-eighths of an inch high, has its inner and outermost layers of leather, and the two intermediate layers of cork, enveloped in leather. On the inner surface, the heel extends forward as far as the astragalus; on the outer surface, it is continued forward to about the middle of the cuboid. A special feature is made of the snugness of the fit in the longitudinal arch. The box is high. The upper is made of calf leather. Around the ankle, between the lining and the upper, is a small reinforcing leather brace. A thick, soft tongue enables the shoe to be tightly laced. The total weight of a shoe (size 8, on an A last) is just less than fourteen ounces.

The special features of this shoe are, first, its rigidity; from the moment the foot is put flatly upon the ground, all movement ceases, there is no more oscillation, the foot has an unbending support; second, it is lighter than ordinary shoes, hence the tabetic can walk more with less fatigue; third, the increased ground area of the heel and of the sole augment the foothold; and, fourth, the ankle support prevents the ankle from giving. A patient, thus shod and braced, can use his whole foot instead of his heel, as a support. The foot in front of the os calcis, instead of being an unknown quantity to him, is now a rigid support. In feet so braced, local and remote pains diminish, and disappear. Shooting pains in the legs, we think, decrease both in severity and in frequency. Apparently these pains can be, to a certain extent, reflexly initiated by local irritation in the foot, and the removal of that local irritation diminishes them. Blisters and callous formation disappear. The patient now does not oscillate every time the foot is put down. He walks on a secure, rigid base. He is more stable. He feels more stable. He fears less, and as fear begets ataxia, and ataxia begets fear, his increased reassurance greatly improves his gait. The patient, thus supported, is soon weaned from the straddle-legged attitude which in tabetics renders coordinate walking so difficult. He is launched successfully upon the way to the cure of his ataxia.

This method of treating the foot is essentially temporary. By means of exercises, we increase the tone of the hypotonic muscles until the muscles themselves are capable of maintaining the bones in the correct position. Our efforts in mechanically supporting the foot are directed solely towards maintaining the foot in a correct position, and supporting it there until such time as the muscular support may be sufficiently developed to fulfill this function unaided.

## PROPHYLAXIS OF LARYNGEAL TUBERCULOSIS.*

By A. R. SOLENBERGER, M.D.,
COLORADO SPRINGS, COLO.

There are few diseases in which the modus operandi is so well understood as in pulmonary tuberculosis, and perhaps none which have created such general interest. But it is to be regretted that the same interest has not been manifest in its most frequent complication, which we know not only adds largely to the mortality, but also increases infinitely the suffering of the patient and the dangers of contagion. If it is true (and I suspect it still is) that this indifference is due to the belief that little can be done to avoid this complication, and still less when it has occurred; that all has been done when efforts were made to improve the general condition; then the laryngologist has an urgent duty to perform; for he is, I believe, now in a position to dispel this error.

I think, therefore, I need offer no apology for the choice of this subject at this time, the less, too, because of the conviction I have that prophylactic work on the part of the laryngologist has not been at all commensurate with the means now in his hands. Even if the laryngologist can justly plead the lack of opportunity, that he does not usually see the cases at the logical time for the most effective prophylactic work, even so his duty is none the less clear; for it is then that his co-operative relation as a teacher to the internist, should become more aggressive.

As above noted, the general tuberculous process is exceptionally well understood. To understand how this process invades the larynx we need but observe the structural and functional relation which

*Read before the Western Section of the American Otological, Rhinological, and Laryngological Society, Denver, Col., 1912.

this organ sustains to other centers of infection; for there are so few cases on record of apparently primary infection of the larynx that we may proceed with the etiological part of our study on the hypothesis of the secondary nature of the infection.

Of course it would be helpful to know just how this secondary implantation of the germ takes place. The weight of evidence seems now to be that it is most frequently submucous[1], that even when the greyish yellow spots or colony of spots are seen the tiny tubercle is still under the mucosa. It is really seen *through* the transparent mucosa. If it is seen *on* the mucosa the tubercle has already broken down, or, if a group is seen the slight ulceration is the result of their coalescence. We know also that the germ may come from without and from within; through the atmosphere direct; from the bacillus-laden sputum; also through the lymph channels, and perhaps through the blood. These, at least, are the avenues of infection which most interest the laryngologist.

As noted we do not see the infectious germ in transit. We will always see what will, perhaps, ever appear to be certain gaps. We see only its footprints; but, like life itself, the tuberculous process has its continuity, and so in the case of the tuberculous larynx we may, I think, plainly see the disease circle and the causative vicious circle. We may, therefore, logically begin our study of the prophylaxis of laryngeal tuberculosis with the consideration of those conditions which predispose to this complication. This, I admit, would lead us to recognize many of the causes which predispose to general tuberculosis. But let us see how they bear on laryngeal tuberculosis alone.

It will suit our purpose to begin at the end of our subject for we will thus enter at once upon the real practical problem of laryngeal tuberculosis as it unfortunately confronts the laryngologist to-day. When a case of laryngeal tuberculosis comes into the hands of the laryngologist the latter usually finds the following conditions: phthisis, without physical signs in the lungs possibly, but usually more or less active chronic inflammations general throughout the head; loss of, or perverted secretions of the three kinds of glands in the nose and throat; and destruction for the most part of the ciliated epithelia. One or all of these conditions are present in every case.

Diseased faucial tonsils, diseased lingual, and pharyngeal tonsils; enlarged cervical glands, and diseased bronchial glands—all these are very frequently found. Less frequent, but not at all uncommon, are chronic inflammations of the nasal sinuses; ulcers in the nasal fossæ; nasal septal deformities and enlarged, not to say diseased, lymphatic tissues in the nose, all more or less obstructive to ventilation of the air cavities of the head, and often sufficient to destroy the equilibrium of nasal respiration and, in not a few cases, to cause mouth breathing.

Now these associate conditions (not to speak of the lungs) not only constitute ever active predisposing causes of laryngeal tuberculosis, but are a veritable handicap in the treatment of the laryngeal lesion; for they are now, in turn, also a real complication of the laryngeal lesion and make its prognosis much more grave. Of these predisposing causes in the order of their perniciousness I would place all those pathological conditions which cause mouth breathing, creating a direct impact of air upon the larynx. Recent observations show ever more convincingly a large number of consumptives who are mouth breathers. It has been noted that such are not only liable to laryngeal complications but also to involvement of the bronchial glands.[2] Next, I would place chronic inflammation of the nasal accessory cavities when these cavities constitute pus reservoirs. Chronic follicular inflammation of the lingual tonsils (not so rare as we were wont to suppose), because of its intimate structural relation with the epiglottis, frequently, I am convinced, passes from a predisposing to an exciting cause of laryngeal infection; and so does the diseased pharyngeal tonsil when it exists; though, perhaps, in a lesser degree.

The diseased faucial tonsil, however, because of its general frequency and also its intimate anatomical relation to the larynx, must be given a unique place among the predisposing causes. They, too, I am convinced, frequently become the real purveyors of the bacillus to the larynx.[3] To see just how they come to have this dual causal relation would necessitate a complete review of what we now know of the causative relation of the diseased cervical glands to the tonsil and to pulmonary tuberculosis. Briefly, however, we may find the very probable answer by inquiry as to the cause of the infection of the cervical lymphatic glands. It is now well established that a large number of these diseased glands are tuberculous. Schlenker[4] and Kreukman,[4] I think, are right in their conclusions that the infection of these glands is caused by a thrombosis of the efferent lymph vessels of the lungs or to a similar thrombosis of the efferent lymph channels of the tonsils. These investigators frequently found these thrombi. But we need not entirely count on their existence in every case. We need only know that the lymph glands by the very nature of their structure and function, fall an easy prey to infectious germs. If the thrombi are present they will naturally act in a retrograde way of infection upon the tonsils, larynx, and, indeed, upon all the segments of the Waldeyer ring which are rich in loops of lymph vessels. Thus the gap of infection between these centers and the larynx seems to fill up: we see the infected lymphatic thrombi above it and the infected lymphatic thrombi below it. We see certain areas in the larynx rich in lymphatic tissue and we see that these areas are those which are the earliest and most frequently infected. As above stated, we know the nature of the lymph structure. It has a weak organization, in consequence of its weak innervation; it has an extreme liability to stagnation of its fluids, and of all the tissues of the body it furnishes the soil most susceptible to infection. Indeed, evidence, both chemical and laboratory, is constantly accumulating in proof of the frequent infection of the various segments of the Waldeyer ring which infection frequently seems primary or exists before any physical signs can be detected in the chest.[5] Viewed then, as *predisposing* causes, we see the gap filling in completely. The vicious circle, also, is complete.

And thus in our prophylaxis work, if it is to be efficient, we should proceed on the supposition that when any of these segments become diseased they may become at least transmitters of the bacillus to the larynx.

*Remedial Prophylaxis.*—In our remedial prophylactic measures we think at once of its twofold nature in point of time: First, before the larynx is involved. Second, after the involvement. To the

laryngologist there need hardly come any lesson with respect to the part that surgery must play. He is now fairly busy in clearing up the diseased segments of the upper half of the circle. To him, however, still belongs the duty of insistently teaching the internist to diagnose earlier these predisposing conditions so that the remedy may be applied before they have become causal disease transmitters.

But one duty of infinitely more importance comes before this. I believe if there were time that nowhere more than here could so logically, so scientificially, be made a plea for prophylactic work in childhood. I have in mind not only laryngeal tuberculosis but general tuberculosis with all the predisposing causal conditions which lead up to it. I have in mind the lymphatic system only; the beneficent rôle it plays in health, the pernicious part it plays in disease and when it becomes diseased itself. I have for a long time been convinced, and my conviction has grown, with the growth of our knowledge of the far-reaching function of the lymphatic system, that the external lymph glands, no less than the internal, have an important function to perform.* Our prophylactic measures should, more largely than they are now, be directed toward the creation and maintenance or a robust lymphatic system in both childhood and adolescence. I believe we will in the future make greater efforts to combat those influences which weaken the lymphatic system and restore it to health when diseased. This may be the work of the long to-morrow, but it is wisdom to begin now to heed the warning, which we ever see, in the way nature has of doing things. We will not infinitely prosper if we disturb too much the balance of nature even in the least of her workings. But until the long to-morrow comes it is always good science to surgically remove tissue which has lost its function, which at best can only be a hindrance to other tissue which is fitter to survive.

But how can this be done safely in the presence of active infection of an organ which has such intimate structural relations with other infected organs —without danger of dissemination? Surely here are surgical procedures which require the highest judgment and discrimination. Nowhere does one thing balance so delicately another. Perhaps nowhere does experience count for more.

But, if the laryngologist is on the alert he will usually find a time in the general condition of the patient when, by well selected surgical methods he can safely, for instance, eradicate diseased tonsils, restore equilibrium of nasal respiration by correcting nasal septal deformities; or drain a pus reservoir in a nasal accessory cavity. I have for a number of years applied radical measures to these serious handicaps, not only before the presence of laryngeal lesions, but during their presence, with results that have been uniformly gratifying; that is, I have not seen any spread of the disease on this account. Obviously all surgery should be held in abeyance when there are any signs of approaching laryngeal involvement, and when there is an incipient involvement. The specific feeders to such processes should be treated temporarily, medicinally; nor would I resort to surgery when trying to resolve an infiltration, or when trying to secure the fibrosis of a tumor, and, of course, not when there is what is understood to be an active tuberculosis of the lungs.

As to surgical methods and procedures my experience is in agreement with that of Mermod, that whenever the galvanocautery can be used it is much the safest. Lactic acid, if applied, must be more or less continuous and is thus, on the whole, more painful than the permanent burn of the cautery. We all know with what frequency and success Mermod' has used the galvanocautery in the larynx. That I have not seen any extension of the infection where I have used cold instruments may be due largely to the systematic use of iodine, both before and after the operation, and painting the parts with a strong solution of lugol in the after treatment; also using dusting powders with 20 per cent. to 40 per cent. iodine containers, diluted with anesthetic powders in the case of tonsillectomies. Routine gargles of iodine, with or without hydrogen peroxide, in all throat operations, I believe to be very effective.

The next consideration in our prophylactic study would naturally be that of the early signs of laryngeal involvement. Of first importance is the question: are there any early signs which are useful to the general practitioner without the use of the laryngoscope? Unfortunately we must say there are very few. So it bears repeating that if ever the time is to come when the most efficient prevention work shall be done the phthisiologist must train himself to the *diagnostic* use of the laryngoscope. The great mass of the tuberculous will be always too far removed from the laryngologist to secure an early diagnosis. Not even those now resident in the ever increasing number of sanatoria are receiving this attention; except, perhaps, those located in the larger cities. It is self-evident, also, that the physicians in charge of those sanatoria which cannot meet the cost of a resident or visiting laryngologist should also be skilled in the prophylactic work in incipient cases.

But what are the approaching or incipient signs? They are of some value to the physician who has to rely only on the symptoms elicited from the patient. He will see them in the mere weakening of the voice; in vocal fatigue on talking; in hoarseness, a sense of dryness in the throat; troublesome localized tickling; a lump-like tickling on swallowing; pain, a feeling of languor and debility, and increased dry cough. He should also see them in the symptom complex of every attack of acute laryngitis. These signs no doubt often herald the approach of the disease and should always be an indication for speedy laryngoscopic examination. But they are also signs of actual involvement. Sometimes nearly all these external signs are absent in the process of involvement even to the point of disintegration. We also know that the invasion of the tubercle bacillus is frequently insidious.

Can this plea, then, be too insistent for the early and constant use of the laryngoscope wherever and whenever the subjective signs appear? And I am not speaking now of the numerous cases where the laryngoscope may be the first to detect the presence of general tuberculosis. Such cases are now becoming more and more a matter of record. Probably the most convincing proof of this is found in the investigations of Hughes of Melbourne.* Hughes saw a score of cases which came to him for slight throat symptoms. He saw "raised ridges or elevations" that always occurred at the same spot, viz., "in the center of the sulcus, between and below the arytenoids." About one-half of these cases did not show any physical signs of tuberculosis at the time but developed them later. Then he looked further and found a much smaller infiltration in

two cases which proved to him to be an earlier one; for he saw them develop into the "raised ridges." The tuberculin test was positive and tuberculosis developed later in these cases. From these findings and others Hughes, very naturally, raised the suggestive hypothesis whether laryngeal tuberculosis, after all, may not frequently be the earliest manifestation of general tuberculosis. Whatever we may think of Hughes' hypothesis the methods of his findings will, I think, lead to much closer and earlier observations and would greatly help the work of prophylaxis.*

In passing now to the laryngoscopic signs or those of actual involvement, we would look for the earliest ones in that part of the larynx where, as above noted, the lymphatic tissue is most in evidence in the mucosa of the interarytenoid fold, in the mucosa of the posterior third of the vocal processes in the mucosa of the arytenoids themselves; in the mucosa of the rim and underside of the epiglottis. We do not now rely on pallor, except when it is seen on the palate; even then it is more likely to be only a part of the general anemia, hence is pathognomonic of an advanced condition. Localized hyperemia is much more pathognomonic and at one time, in the early stages, it frequently is for a time diffuse, and it is only when this clears up that the infectious focus is seen. But more frequently the inflammatory process is circumscribed *ab initio*, depending, I think, upon whether there was a previous chronic laryngitis and also whether the lesion is purely tuberculous. Of course it cannot be expected that the phthisiologist thus trained in the use of the laryngoscope should make differential diagnoses. This would be entering upon the most advance work of the laryngologist. Fortunately, this is seldom necessary for a basis of practical prophylactic work. If he sees an inflammation in the larynx, localized or localizing; unilateral or becoming so; limited to one cord or one arytenoid; and if in the more advanced lesions the infiltrated areas are found in the "elect" tissues, and if they show the well known conventional appearance—if he sees these in a tuberculous patient he may safely pronounce his findings tubercular.

It will not be necessary to describe further the topography nor yet, the geography, of these incipient lesions. To the laryngologist they are alphabetic; but the phthisiologist should learn to see these pictures clearly. Many laryngologists have in recent years most clearly and faithfully portrayed both their nature and their appearance, and none more truthfully than Lockhart[9] in his recent book, Levy[10] in a series of brochures, and Minor,[11] in his paper read before the recent Congress of Tuberculosis at Washington.

What I would emphasize here is the rationality, the practicability, and the absolute need of including in the field of prophylactic work, also all the more advanced lesion of swellings, infiltrations, and tumofactions; for despite the fond hope that the cooperation of the laryngologist and phthisiologist will be very largely effective in securing the diagnosis and treatment of predisposing and earlier lesions, these second stage lesions will still constitute much the largest field of prophylaxis. Only those who have the immediate care of the tuberculous can fully appreciate how fortuitous a circumstance is the resolution or fibrosis of a laryngeal tuberculous tumor, for they only know what a dire circumstance is its disintegration. I am aware that the pessimism of the general profession would include also these so-called second stage involvements as well as the stage of ulceration.

We cannot hold strictly to any classification when we consider the prognosis; for there are too many modifying and extenuating factors, both local and constitutional, entering into each individual case. Locally, for instance, the broken down lymphatic tissue in the posterior commissure is more amenable to treatment than a nest of bacilli still encapsulated in the joint of the arytenoid. Some deep ulcers heal more benignly than superficial ones. The prognosis of a third stage lesion on the vocal processes or on the inner aspect of the arytenoids is always better than one farther out toward buccal and atmospheric exposures.

Briefly, we can lay down here only this principle which should guide us in our prophylactic treatment: locally, to so disinfect the tuberculous nidus; to so nourish it; to so stimulate phagocytosis as in each host the guest needs; which can usually be fairly well clinically estimated by the degree of heat and cold or the degree of activity present. One modifying corollary should be attached to this, which, if disregarded, would more than wholly negative any benefit from local remedial measures: viz., that the disinfection, the stimulation, etc., should never reach the point of *irritation;* otherwise the old dictum "nole me tengere" had better remain in force. I would add a secondary corollary, which is more in the nature of a definitive of the second stage lesion, viz., that very rarely should a wound be made in these lesions; the exception should be made only in the use of the medicated or hot needle in cases where the tumors will not resolve or fibrose in capsule by external measures. This, of course, leads up to the necessity of a pathological definition of the second stage lesion.

In conclusion I would emphasize what I trust has been faithfully reflected, but in what I fear has been an all too general plea for prophylaxis of laryngeal tuberculosis, the one matter of primary importance, viz., that the laryngologist should take a position vastly more insistent and aggressive as a teacher of prophylaxis. His pupils should be not only the phthisiologist and the pediatrist but the general practitioner; indeed, all who assume the responsibility of the care of the tuberculous patient —to secure the most intelligent and effective cooperation in prophylaxis.

The laryngologist has written quite enough, but it may be necessary to more frequently extend his teaching to the medical forum.

*Since the presentation of this paper, Hughes has made further investigations and has reported his findings in the *Australian Medical Journal*, March, 1913. He found so many cases presenting these involvements, some showing definite, and some very slight and others, no signs of pulmonary affection, that he now makes a summary submission: (1) That slight but definite change in the larynx is found in every case of pulmonary tuberculosis. (2) That it is constantly present in cases applying for treatment of purely throat symptoms and then he gives his differential diagnosis of tubercular and chronic laryngitis.

## CHRONIC PROSTATITIS.*

By ADAM KEMBLE, M.D.,

WASHINGTON, D. C.

INSTRUCTOR IN GENITOURINARY SURGERY, THE GEORGE WASHINGTON UNIVERSITY.

It was no less distinguished surgeon than Freyer of London who in his admirable textbook on "Surgical Diseases of the Urinary Organs" said: "The disgusting practice of massage of the prostate, advocated by some surgeons in America and on the Continent, should never be had recourse to. It is useless and has grave objections attached to its employment." It is the purpose of this paper to invite to the members of the society a renewed interest in this often overlooked disease, chronic prostatitis, and to detail some of the brilliant results obtained by this "disgusting and dangerous practice," prostatic massage. No practice which affords relief to distressing symptoms can possibly be disgusting and I am still looking for immediate or remote dangers from this important addition to therapeutic measures.

The name, chronic prostatitis, implies its own definition but is also usually understood to include chronic catarrhal processes in the seminal vesicles and ampullæ of the vasa deferentia. The most potent etiological factor is gonorrheal infection. This is the probable cause in a majority of cases. A study of 50 cases in my practice has shown a history of gonorrhea in 32 or 64 per cent. and no history of gonorrhea in 18 or 36 per cent. This is, I believe, closely in accord with the observations of others. A further study of my cases has convinced me of the growing importance of other factors, notably, masturbation and long continued sexual excitement without intercourse. A study of the gonorrheal cases impresses me that in many of them a chronic catarrhal process had been existent before the invasion by the gonococcus and that in these cases gonorrhea runs a more protracted and severe course. Other causes of less importance are injury, descending infection, and excessive intercourse.

A recent communication by Hichens and Brown of the Mulford laboratories has given us our most exact information on the bacteriology of chronic prostatitis. The decreasing importance of the gonococcus and colon bacillus and the prominence of the various staphylococci, streptococci, and bacilli of the diphtheroid type are strikingly illustrated by their work. It is undoubtedly true that the prostatic mucous membrane is an excellent host for a great variety of organisms.

The essential tissues of the prostate are the glandular and the muscular tissues, the stroma, nerves, blood-vessels, and lymphatics. The stroma and muscular elements arise from the capsule and ramify around the gland acini. The glandular arrangement has all the complexity of the acinous and tubular types. It is only natural that infections of the posterior urethra must invade the prostatic ducts and this practically always occurs. The infection may travel to any or all parts of the gland and give rise to various degrees of inflammation. Young, Geraghty, and Stevens have described the tissue changes as involving both the parenchymatous and periacinous elements, the periacinous infiltration appearing to be most prominent. The gland acini may in some cases be dilated and filled with desquamated epithelium and leucocytes, in other cases only vestiges of the gland elements remain, the predominant tissue here being of a fibrous nature. The muscular elements are thinned out from pressure by the dilated gland sacs. Grossly the gland may appear normal in size and appearance or show enlargement and irregularities. Palpation may reveal areas of induration or softening. Associated with these changes are found various degrees of inflammation in the seminal vesicles and ampullæ of the vasa deferentia. The normal secretion of the prostate consists principally of lecithin and this in chronic prostatitis is largely or wholly replaced by pus.

The nerve elements in the prostate command the greatest attention. Sensory fibers reach the prostate from the tenth and eleventh dorsal, the five lumbar, and the first, second, and third sacral nerves. The secretory fibers come from the sacral plexus of the sympathetic. Large ganglionic areas are found underneath the capsule. The reason for this remarkable and abundant nerve supply is not understood. Undoubtedly it concerns in large degree the sexual function and plays an important part in the various sexual disturbances of the male. Certain it is that inflammatory disturbances in the prostate gland may cause most remarkable symptoms.

The symptoms of chronic prostatitis are usually classified as urinary, sexual, and referred, following the designation of Young, Geraghty, and Stevens. While most cases may be grouped under these headings I have frequently encountered cases which had no other complaint than a urethral discharge, and others which had no signs or symptoms whatever of chronic prostatitis and which on rectal examination and examination of the expressed secretion showed marked inflammation of the gland. The sexual symptoms are usually closely identified with disease of the colliculus or verumontanum. Space will not permit a discussion of this interesting and important condition.

In detailing the symptoms of chronic prostatitis the author asks the reader's indulgence in an analysis of 50 cases gathered from his practice. Although the number of symptoms appears large it will be noticed that there is a similarity in distribution and character and one soon learns to suspect the existence of this disease when a new symptom presents itself. An example of this occurred recently:

Case I.—J. H. O., aged 25. Had gonorrhea five years ago and eight months ago. Complained of intense itching of the skin over hips and thighs. The history suggested chronic prostatitis, the patient also inquiring about his urethral condition. The prostate revealed a marked degree of chronic inflammation. In-

*Read before the George Washington University Medical Society, January 17, 1914.

durated areas were scattered throughout the gland and strong adhesive bands bound the prostate and vesicles to the pelvic wall. The secretion was full of pus. The gland was massaged thoroughly at the first visit and the patient instructed to apply no local treatment to the skin. The itching entirely disappeared in a few hours and has not returned.

What has been of great interest to me are the symptoms for which the patients sought relief. Of the 50 cases referred to above, 2 had no signs or symptoms whatever and were discovered on routine examination. One had severe pain at the perioneoscrotal junction, 1 had a feeling of heaviness and weight in the perineum, 4 complained of irritable urethra, 2 of suprapubic pain, 4 of pain in the back identical to lumbago, 1 pain in both inguinal regions, one pain and soreness in bladder, 1 irritation of the neck of the bladder, 1 itching of skin over hips and thighs, 2 pains in the lower limbs, 2 pains in the testicles, 2 had difficulty in starting the urine stream, 3 frequency of urination, 3 failure of erections, 2 precocious ejaculations, 1 seminal losses, 1 prostatorrhea, 1 loss of sexual pleasure at intercourse, 14 had a urethral discharge of varying degree and 1 had insomnia.

Summarizing the symptoms noted in the histories of these 50 cases there occurred: complete loss of sexual power once, night emissions seven times, failure of erections five times, precocious ejaculations ten times, poor erections four times, painful erections once, painful ejaculations once, hypersexuality once, sluggish emissions once, prostatorrhea three times, coldness of the external genitalia once, frequency of urination eight times, slowness and difficulty in starting the urine stream four times, dribbling at end of urination five times, irritability and burning during and after urination six times, occasional incontinence once, urgency once, hematuria once, history of hematuria once, urethral discharge twenty times, perineal pain four times, sensitive penis twice, suprapubic pain six times, pain in lower limbs seven times, scrotal pain three times, testicular pain four times, sensitive testicles once, history of attack resembling renal colic three times, uneasy sensations in the perineum twice, one-sided lumbar pain twice, herpes preputialis once, headache once, headache during ejaculation once, pruritis ani four times, suicidal despondency once, insomnia twice, loss in weight once, neurasthenic symptoms four times.

It will be noticed that these symptoms are almost constantly referred to the lower segment of the body. Calling attention again to the extraordinary nerve supply of the prostate it will become apparent why we have such a wide distribution of these pains. Fibers come to the prostate from segments in the cord corresponding to the nerve supply of the body from the diaphragm to the feet. Sensory stimuli proceeding from the prostate undoubtedly suffer misinterpretation, the impressions being received by nerve cells corresponding to areas in the body other than the prostate. You are all familiar with the psychic error which occurs in anginapectoris where sensory stimuli proceeding from an overtaxed heart cause extreme pain in the hand and arm and shoulder. Here the impressions are picked up by nerve cells corresponding to these parts. This is fundamentally what takes place in the referred symptoms of chronic prostatitis. It has been my observation that inflammation in the seminal vesicles and indurations in the upper poles of the prostate are most inclined to be associated with pain in the back and the renal colic type of symptom. Young of Baltimore has reported itching of the soles of the feet. A deep and enduring sciatica should at once call for an examination of the prostate.

There is an obstructive type of chronic prostatitis with definite obstruction to urination which is in no way analogous to the senile hyperthrophy of the aged. This type presents definite contraction of the vesical orifice, small contracted bladder, residual urine and other symptoms of urinary obstruction. Two such cases under my care gave histories of long and severe attacks of posterior urethritis.

The diagnosis rests on palpation of the prostate per rectum and examination of the expressed secretion. The patient urinates in three glasses after which a gloved finger is inserted into the rectum and the prostate systematically examined. The size, contour, irregularities in outline, indurations and presence of adhesions are all noted. The finger is passed up over the vesicles and ampullæ of the vasa and notes made of the conditions found. I have been in the habit of diagraming accurately the conditions found. The prostate is then thoroughly massaged and the expressed secretion which hangs from the meatus caught on a slide and examined microscopically. The presence of lecithin, motile or nonmotile spermatozoa and pus cells is noted. The degree of inflammation can often be gauged by the amount of pus present and the comparative amount of lecithin. More than five or six pus cells present in a field using the sixth inch lens and No. 2 eye piece indicate prostatic inflammation. Frequently it happens that the first examination discovers no pus and a massage two or three days later brings an abundant amount. Here the pus has been located in the peripheral gland acini and did not get into the excretory ducts during the first massage. Very large amounts of lecithin indicate little pus and vice versa. In cases with a gonorrheal history application of the complement fixation test will quickly reveal the presence of the gonococcus. It is no longer necessary to be in doubt about the presence of the gonococcus. Increasing use of this test convinces me more of its value. Inflammations of the verumontanum are readily diagnosed with aid of the urethroscope. I have been struck with the frequency of diseases of this organ and make it a routine to urethroscope all patients at some time during the course of the treatment. The presence of stricture should be ruled out as it is useless to attempt treatment of the prostate when this complication is present.

Massage of the prostate is the bulwark of treatment. No other measure we have can approach it in efficiency. The prostate is so constructed that inflammatory products within the gland acini and tubules drain very poorly and these products accumulate, dilate the acini, injure the muscular tone, and make pressure on the various nerve ganglia situated in the gland. Massage is the great assistance we can offer nature in the correction of this defect. Under massage we can hope also for an increased blood supply and a beneficial action on the muscular elements. Attention must be particularly directed toward indurated areas which should receive the greater part of the treatment. Immediately after the

massage the urethra and bladder must be irrigated with some mild antiseptic solution preferably potassium permanganate 1-6000. Occasionally when the urethra is irritable I apply 15 per cent Argyrol to the prostatic urethra through an Ulzmann syringe. The treatments are repeated on an average of every four days. Several cases have been greatly benefited by the application of 2 per cent. carbolic-lanolin ointment to the prostatic urethra immediately after massage. Through the straight urethroscope appropriate applications are made to the verumontanum when examination has revealed evidence of disease in this organ. The benefits of massage are usually observed early in the treatment. On the clearing up of the condition it will be observed that the pus cells grow less in number and the lecithin bodies return or increase. Occasionally in the type with urinary symptoms the Kollman dilator has been of great service. Dilatations up to 35 or even 40 on the French scale can be borne without much discomfort. I have frequently observed that a massage several days after a dilatation is rewarded by an abundant amount of secretion in cases that showed a sparse amount before.

Results of treatment: Of the 50 cases reported above the results of treatment to date are as follows: Number cured, 27; number improved, 9; number unimproved, 3; number discontinued treatment, 5; number improved and still under treatment, 5; number unimproved and still under treatment, 2. I have not estimated the average length of time required for treatment but would judge it at about two or three months. Several cases have shown marked chronicity and several with a decided tendency to relapses.

The following cases are illustrative of different types of the disease:

Type with pain in the back:

Case II.—Physician, age 23. Consulted me in April, 1913. No history of gonorrhea. Never masturbated but frequently became violently sexually excited. He never, however, allowed himself sexual gratification. About two years ago he sprained his back lifting a heavy weight. Since that time he has complained of intermittent attacks of dull aching pain in lower part of back. Attacks come on at short intervals and last from a day to several weeks. Is not troubled while exercising but attacks come on while quiet in his home. More recently the pain has been unendurable and incapacitates him for work or study. He has been advised by several physicians during the past year but has had no relief. Examination of the prostate revealed a moderate degree of chronic prostatitis with small areas of induration in the upper poles. The secretion contained a moderate number of pus cells, many lecithin bodies and no spermatozoa. Relief by massage was very prompt. In less than a month he was free from all pain and discomfort and it has not returned after a lapse of eight months.

Type—Urinary and referred.

Case III.—E. H. S., age 77. Very robust and vigorous old man. No history of gonorrhea. Consulted me in May, 1913. Three months ago complained of pain and soreness in bladder, with frequency of urination day and night, slowness in starting the urine stream, painful urination and occasional pains in the scrotal and pubic regions. Has been getting progressively worse. Examination: Voided a small amount of clear urine. The catheter passes easily, finding 40 c.c. residual urine. The prostate was difficult to reach but showed no palpable signs of chronic prostatitis. The secretion contained a large amount of pus, many lecithin bodies and many actively motile spermatozoa Massages were instituted immediately and carried out over a period of several weeks. During this time he received several dilatations with the Kollman dilator. All pains and urinary symptoms had disappeared at the end of this time and the catheter found an empty bladder. The patient voided a good stream and could propel it a distance of four or five feet. Cystoscopy of this patient revealed no intra-vesical enlargement of the prostate. He recently reported to me that he is perfectly well.

Type—Verumontanum, unusual.

Case IV.—Physician, aged 40. Consulted me in April, 1913. Gonorrhea with left-sided epididymitis fifteen years ago. No recurrences or sequelæ. Masturbation in boyhood well up to two years ago. Thinks his present trouble started with a slight cold in the bladder which lasted three or four days. Noticed that he had lost all pleasure and satisfaction with sexual intercourse although erections and ejaculations were normal. Took a course of prostatic massages about eighteen months ago but received no benefit whatever. I regarded this as a pure verumontanum case before examination. A very light degree of prostatic inflammation was discovered. The urethroscope elicited the most extreme pain, this patient having the most sensitive urethra I have ever encountered. The verumontanum was found to be enlarged, congested and edematous and bled profusely. It was cauterized with the silver nitrate stick. Four weeks later the same treatment was applied. Three weeks after this he reported himself as perfectly well, and very recently reported the same.

The Cecil.

## BACTERIA AND BACTERIAL PROLIFERATIONS IN DAIRY PRODUCTS, RELATED PROBLEMS, AND THEIR SOLUTION.

By J. M. W. KITCHEN, M.D.,

East Orange, N. J.

After reading Dr. Charles E. North's article in the Medical Record of November 22 last, I have been speculating as to what proportion of the medical profession has a definite, up-to-date idea of bacteriology as related to the present general character of dairy products. "A frank confession is good for the soul." Although I have been engaged in experimental dairying for thirty years, and thought I had a working knowledge of this matter, I confess that on December 1, 1912, I had a very inadequate idea of the serious nature of the situation as it now seems clear, does exist. Since that date I have been giving my best investigative study to the subject, and with the editor's permission will give my view of the situation, much of which view is based upon a collation of the research publications of the past several years by the national government and other investigators. Dr. North's article opens up a subject which should be further elucidated.

In order to bring out the points I want to make I will have to repeat some matter that Dr. North well presented in his article. The investigations of the national government and others during several years past, have thrown much light on what before was obscure and dark. The government has arrived at conclusions and made recommendations, but has not made clear how those recommendations can be carried out.

The teachings of the past quarter of a century in regard to the desirability of cleanliness in milk production are now generally well accepted, but there is much more that must be still accepted, in advance of the mere ideas of cleanliness and medical supervision of production; and there are some very difficult problems connected with this desirable advance, as to which there has been very little public discussion.

Some time after Pasteur's work became known, investigators began to suspect that the something that was apparently wrong with milk was probably due to bacterial infections. I have not been

able to determine if there were any specially definite ideas held at that time, and it is a question if there is not still a great deal of indefiniteness of view still held in this connection. Witness the monoworship of the bacterial count, which has practically no relation to pathogenic quality in milk. At that time began the campaign for clean milk, with a coincident development of the certified, high-cost milk dairies, approved by the medical milk commissions.

This activity has been of undoubted benefit to the public through the development of higher ideal standards; but directly, has not greatly protectively benefited over 99 per cent. of consumers. Of course no one questions the value of cleanliness in milk; but the fact is obvious that ideal conditions for securing cleanliness are practicaly impossible of attainment in connection with producing the greatest bulk of the dairy products consumed. The result is that pasteurization is more and more looked upon as an essential sanitary performance. Just how much pasteurization is now practised by dealers for the purpose of destroying disease germs, and how much for the purpose of preventing the souring of milk through the destruction of lactic acid bacteria, is difficult to say. The latter object started the practice. So far as I am able to judge, dealers at the present time sell to the public what the public demands, while the demands of the public are determined by a colossal, widespread ignorance, indifference, and even prejudice as to what constitutes sanitary safety in dairy products. Apparently no one is adequately educating the consuming public; and yet the solution of the problem depends almost entirely upon educating the public. The real basic problem at the bottom of this matter is, how is it possible to educate the public?

During several years past, thousands of folios of printed matter have been published relating to various branches of this subject; but very little of that matter has gone into the hands of those most needing information. Furthermore, this printed matter is in such form that it cannot be understood by the general reader. Without question millions of lives have been sacrificed from lack of knowledge on this subject, and millions more will be sacrificed.

Here is the situation as it exists to-day: Probably two million cows in the United States are tuberculous, and there is much pathogenic infection of milk, cream, and butter. Notwithstanding that such conditions exist, very little physical inspection or tuberclin testing of cattle is done. Some cows do not react to tuberculin and may pass myriads of tuberculous germs through the intestine and even through healthy udders, which germs may infect the milk of the whole dairy, without anticipation or perception. Inspecting and testing officials are few in number, and some of these officials are incompetent and even criminally negligent of their duties. Politics is not unknown in this branch of service. New York City I understand has only one inspector for every thousand dairies.

The action of municipal, State, and national government is absurdly inadequate to meet the situation. The experimental stations and breeding associations are steadily advocating the high-power cow, whose high productivity, which is really a condition of galactorrhea, is, through weakening effect, one reason for the increase in the prevalence of bovine tuberculosis. The danger from typhoid infections, from contaminated dairy water supplies, and from other infections, including diphtheria, scarlet fever, influenza, septic sore throat, etc., is an almost continual menace due to working attendants, flies, dust, imperfectly sterilized bottles, and filthy purveyors. Such dangers are on the increase with the increase of population. As the cities grow in size, and the supplies are received from greater distances, the time of holding between production and consumption increases. We know that bacteria proliferate at temperatures much below those at which lactic acid bacteria flourish, and wherever bacteria proliferate they excrete effete matter that may be toxic. Certainly we know of very poisonous ptomaines being produced in very cold milk and there are proliferations occurring producing excretionary matters that give no sign to sight, smell, or taste. Just what amount of damaging excretions the various varieties that gain entrance to milk may produce, is of course impossible to say; but it is at least reasonable to suspect that such materials accumulating in milk may have had an important etiological influence in inducing infant disease and mortality. In nature, the time intervening between mammary production and infantile digestion is very short, and although it is considered that for several hours after bovine milk is produced, an antiseptic or at least deterrent action against bacterial growths exists in it, and which is probably due to a transfusion of the germicidal constituents of the cow's blood; still there is but very little of the market milk consumed by infants that does not undergo a long stage of waiting before consumption. Hence, as a mere matter of precaution, it would seem to be a very important matter to consumers that the treatment of the milk during the *entire* time it is held should be such that all bacterial growths should be prevented in the milk.

It is probable that the preservative element in new milk that disappears within from six to twelve hours, or more quickly if heated, but not so quickly if cooled, may have some digestive influence; but the fact has to be considered that it is not practical to preserve that element beyond a very limited time. It is, however, very easily possible to practically stop all bacterial action in market milk if the milk is cooled to a sufficient temperature before the so-called antiseptic quality of the milk disappears. The almost universal practice in handling milk is only to refrigerate it to 55° or 60° F. before shipping to market, and then holding it during transportation at the moderate temperatures secured by icing, which does not refrigerate sufficiently. It would seem that a very important improvement in milk and butter transporting methods will be the early deep mechanical refrigeration of milk at the shipping station.

This should be at or close to a temperature of 29° F., and such low degrees of refrigeration should be maintained during transit by the use of mechanical refrigeration developed on the milk train. A further refrigerative treatment at the delivery station in insulated sheds should be practised. The milk should also be conveyed to the distributing plants in insulated vehicles. This general idea could be further elaborated in connection with the distributive handling of milk, cream, and butter. All dairy products should be sufficiently aerated to free them from objectionable flavors and odors. Inasmuch as this may require considerable time the process should be performed in a germ-free atmosphere of a nonfermentative temperature either

above or below the temperature required to support germinal proliferative action.

This is particularly necessary in the winter season when owing to lack of free ventilation the odors given off from the bovine hide, impregnating the atmosphere of the cow stable, is breathed in and otherwise transmitted through the general animal fluids of the cow to the milk being produced. I have no positive proof that such excretory matters are damaging other than through perceptive smell and taste, but I believe such volatile matters are objectionable. In face of the fact that all the cleanliness in the world may not prevent damages due to unforeseen or unanticipated sources of infection, there seems to be no question but that all milk and butter that is open to suspicion of being dangerous should be pasteurized. Milk, preferably, should be pasteurized in the bottle after sealing. A good many medical men still hold to the idea of raw milk for artificially fed babies, and so hold, although the bulk of authorities of eminence now say not to use raw milk, and cite clinical experiences of unquestionable value to defend their position, and notwithstanding that the government's experimentation tends to show that no change in taste or in chemical composition occurs in milk that is pasteurized at moderate temperatures under the holding method.

I feel sure from my own experiments that one cannot make as superior a quality of butter edibly from heated cream as from the raw article. Furthermore, an expert can detect some slight change of taste in milk and butter that have been pasteurized if part of the milk or cream has been brought into immediate contact with very hot heating surfaces. The idea that heating milk destroys some vital quality in it, has apparently no foundation in fact. All that the heat can do besides destroying the living bacteria would be to eliminate the enzymes produced by bacterial growths, and which are not normal constituents of milk, they being products that are formed *after* the milk has been produced. No important evidence appears to be existing that the nutritive value of milk is damaged by any ordinary degree of heating, or is rendered less valuable in any particular that cannot be counteracted by the addition of fruit juice or other food constituents.

It seems that there is a question, though one of small moment, as to whether the young of the human race should be exposed to the infection of bovine tuberculosis with a view of cutting out those unfit to survive, and of accustoming those individuals to the influences of mutable forms of the parasite later in life. It may be noted that some people have queer views, but most people will probably agree that there are very few cases indeed, in which the medical adviser would be warranted in subjecting his infant charges to the dangers of milk infections that may occur at any stage in the handling of milk. I fully agree with the preponderance of medical authority of eminence, who teach that *all* milk should be pasteurized, and that it should be pasteurized in the final container before its sealing.

All should agree also that butter that is not produced from the milk of absolutely healthy cattle should be pasteurized, and that preferably it should be pasteurized by the commercial handler under intelligent municipal oversight at, or near to, the point of distribution. The question of how the consuming public is to be educated to demand safe products is a very difficult one to answer, inasmuch as the consuming public, besides being ignorant, objects to the slight increase of cost that is essential in securing that safety. Dealers supply what patrons demand, while the ignorance, indifference, and even prejudice of the consuming public is appallingly great.

The municipal adoption of high ideal standards will be helpful, especially in smaller communities under municipal educational efforts such as have been adopted in Montclair, N. J.; but such municipal action is difficult to secure in opposition to vested trade interests in the hands of those who are ignorant, selfish, and even criminally negligent of duty to patrons.

Apparently the most helpful possibility lies in the organization of new purveying companies whose patronage and commercial prosperity would depend on an educational propaganda carried out in securing commercial advancement. In smaller communities, such new enterprises might well take the shape of consumers united dairy companies. In larger communities new companies could be started, at first by the aid of humanitarian effort; or possibly, by inconspicuous dealers who would wish to advance through adopting the highest ideals. In all events, the adoption of right municipal standards should be backed up by the existence of establishments prepared to carry out standard ideal requirements. In all such cases, the application of new capital is required, as well as applied intelligence, and it may be assumed that the problem is solved whenever an up-to-date commercial enterprise is successfully launched in any community that is honestly based on the principle of "safety to the consumer." In every such instance competing concerns will have to fall in line, or else lose their business. To gain an initial momentum, this reform apparently must be backed by combined commercialism and humanitarianism.

The following questions may be pertinent to this matter:

1. In view of the fact that some of the milk supply is more or less infected with bovine bacilli, has it been good practice to stuff our tuberculous patients with raw milk that may have contained the same germs that have already invaded the patients?

2. If a heavy dose of ptomaine poison resulting from food fermentations may result in weeks of weakening diarrhea in an adult, why may not a continual repetition of small doses of bacterial excretory matters given in milk to infants, be a cause of the intestinal derangements which have killed so many babies?

It seems obvious that whatever will prevent the formation and accumulation of bacterial excretions in food is of sanitary advantage. Bacteria may be necessary in securing the dissolution of solid food matters in the alimentary tract, but it is at least a question whether their aid is necessary.

It is very certain that babies' milk at least should be very clean milk. It is reasonable to think that the sale of very dirty milk should be prohibited, no matter how well it may have been handled by the dealer. Stated concisely, the solution of the great milk question depends on educating the consumer to understand what constitutes safety in dairy supplies and in securing willingness to pay about a cent a quart extra to secure safety and high edible excellence.

# THE X-RAY TREATMENT OF MYOMA.

By EDGAR BIRDSALL, M.D.,

GLENS FALLS, N. Y.

ROENTGENOLOGIST, GLENS FALLS HOSPITAL.

THE *x*-ray treatment of myoma can no longer be looked upon with skepticism by the well-informed physician. Over a thousand cases thus treated have been reported in the literature and at the last International Medical Congress one entire session of the Gynecological Section was devoted to its discussion. The enthusiasm displayed by the gynecologists was even greater than that of the roentgenologists.

The ovary is more susceptible to the action of the *x*-rays than any other tissue in the body with the exception of the testicle. This has been amply proven by experiments on rabbits and on human beings. When the ovary is exposed to the *x*-rays the ripe and ripening follicles are first affected, next the prefollicular cells and last the interstitial tissue. If the application is not carried too far, the follicle undergoes regeneration, that is, the atrophy is overcome and a restoration of function results. If treatment is continued a permanent atrophy occurs. Coincident with this is a gradual lessening of the menstrual flow until amenorrhea occurs. This amenorrhea may or may not be permanent, depending on the intensity of the irradiation and the age of the patient. The nearer the patient is to the menopause, the more rapidly and effectually will the amenorrhea be produced, as at this period the ovaries offer much less resistance to the rays. In women under the age of 40 the *x*-ray treatment is not the form that should be selected.

It is thus clearly shown that the menstrual flow depends on the activities of the ovaries, and as the tumor also diminishes in size even though it receives no direct irradiation this reduction must be a result of the decreased congestion and nutrition. But the rays also have a direct effect on the tumor tissue.

The first change noted is a decrease in the amount of the menstrual flow, which also becomes lighter in color. The atrophy of the tumor is the last thing noted. There is no decided change in size before complete amenorrhea has been produced. These atrophic changes will continue for months following the cessation of treatment, until the tumor can no longer be palpated. The entire disappearance of the tumor has been noted in about 75 per cent. of the cases reported. Symptoms, such as hot flashes, fleeting perspirations, etc., that are associated with the normal menopause, also occur, but as a rule, only in the cases in which the amenorrhea has been rapidly produced. Pain, if present, and produced by hypersensitive ovaries, will be immediately relieved, but if caused by the pressure of the tumor, it will of necessity not be relieved until the tumor has sufficiently decreased in size. Hence, when pressure symptoms are alarming Roentgen treatment should not be used. Climacteric hemorrhages, when not malignant, are beneficially influenced by Roentgen treatment.

*Indications and Contraindications.*—Subserous, submucous, and pedunculated fibroids should be treated surgically. Cases associated with marked anemia, nephritis, diabetes, organic heart disease, or exophthalmic goiter should be given Roentgen treatment. The treatment is contraindicated in patients under the age of 40 and in those cases in which serious pressure symptoms are present. Fibroids that have undergone malignant degeneration or become gangrenous should not receive Roentgen treatment.

The question of subsequent malignant degeneration of the fibroid has been raised. The answer to date is that no such sequela has as yet been reported. The percentage of cases undergoing malignant change with no treatment at all is but from 1 to 2 per cent., thus giving another good reason for the selection of the Roentgen treatment. An argument raised against Roentgen treatment is that it is more expensive than operation. This may possibly be true but is more than counterbalanced by the fact that it is free from danger. The treatment covers a period of from three to six months, according to the technique employed. This is another argument used against the method, but when one considers that complete convalescence from the surgical operation cannot be looked for under three months, and that with the Roentgen method the patient is at no time prevented from attending to her usual duties, the argument cannot be sustained by the facts.

The following statistics recently compiled by Dr. Arthur Holding of New York City, which he took from the available literature on the subject, amply demonstrate the success of this method of treatment.

| | | |
|---|---|---|
| Number of cases treated..... | 794 | |
| Number of cases still under treatment .....60 | | |
| Number of cases which continued treatment .....27 | | |
| Number of cases lost track of..40—127 | | |
| Number of cases treated in which results are known.... | 667 | |
| Number of cases cured..... | 376 | 56 per cent. |
| Number of cases improved.... | 208 | 31 per cent. |
| Number of cases unimproved.. | 74 | 11 per cent. |
| Number of cases lapsed..... | 7 | 1 per cent. |
| Number of cases dead..... | 2 | .03 per cent. |

CASE I.—Miss L. J., age 35. Had been treated for myoma for the previous four years (1902-1906). The treatment consisted of galvanism, one pole in the vagina and the other over the fundus. Ergotin in 1 grain doses, three times a day was also administered. At the end of ten days the ergotin was discontinued for ten days and again resumed. The patient complained of severe backache, bearing down pains in abdomen, indigestion, and vertigo. Menorrhagia was very profuse at the menstrual periods and continued during the interim. Patient was weak and unable to attend to her duties as a cook. An examination revealed an intramural fibroid about ten inches in diameter. An immediate operation was advised and refused. *X*-ray treatments were then suggested though at that time little was known concerning the therapeutic action of the rays in this condition. Treatments were given twice weekly. An *x*-ray erythema was twice produced which caused considerable delay. The menorrhagia showed a decided improvement, the hemorrhages being less profuse and of shorter duration. At the end of six months the menstrual periods were normal. She was able to resume her duties. The tumor still measured about ten inches in diameter. At the end of another six months amenorrhea had been produced and the tumor was about four inches in diameter. Owing to the condition of the skin, treatments were discontinued. I did not see the patient then for five years, when she came to consult me on another matter. At my request an examination was made and no evidence of the tumor could be found. The technique employed in this case was crude but was the best we knew at that time. This in part accounts for the length of time required to produce a complete amenorrhea. The age of the patient was also a factor.

CASE II.—Miss C., age 40. Complained of profuse

and prolonged menstruation, extreme physical weakness, palpitation of the heart, sense of weight and pressure in the abdomen, backache, and, what she termed, bloating. The heart action was weak and the pulse was rapid. There was no organic heart lesion. A mass in the abdomen extending half way to umbilicus was easily palpated. This proved, on further examination, to be an intramural fibroid. X-ray treatments were advised. In this case, the abdomen was divided into three fields for exposure, one field over each ovary and one over the uterus. Each field received a separate exposure during the same treatment, the two fields not under treatment being covered with lead foil to prevent their receiving a double dosage. A tube of medium penetration (about 6 Benoist) was employed. The quantity of rays absorbed at each treatment was measured with a radiometer. A filter of heavy sole leather was used to protect the skin. A dose sufficient to produce a slight redness of the skin was given to each area, though not all at one exposure. The treatment was then discontinued for four weeks until all danger of a reaction had passed. Four series of this nature were given. At the end of this time menstruation had ceased. The tumor was two-thirds its original size. No further treatments were given. The tumor continued to decrease in size for the next six months at which time it was so small that the patient was not conscious of its presence. At the present time she is well and attending to her duties as a cateress.

Case III.—Mrs. M., age 45, married, four children, all living. Last child born three months previous. At time of labor the attending physician suspected twin pregnancy. This proved to be incorrect, as an examination after the delivery of the child revealed a large fibroid. The same technique was employed as in Case II. Amenorrhea was produced at the end of the third series. The patient was approaching the menopause, which probably accounts for the shorter time required in this case. The reduction in the size of the tumor was not marked and a fourth series was given. Four weeks later, at which time she had been told to return, the tumor was about one-half its original size. Treatments were then discontinued and the patient returned to her home in a neighboring city. No later examination has been made but she writes me that she is feeling fine.

# VOICE AND MANNERS IN MEDICAL PRACTICE.

By T. D. CROTHERS, M.D.,

HARTFORD, CONNECTICUT.

The president of a great university, when asked why it was that some of his teachers showed such irregularities of thought and manner, replied, "cultured men are abundant, but gentlemen with cultured manners, trained voices, and common sense are very rare." To a certain extent, this is true among physicians. Common sense and gentility are acquired after a while, but voice culture is wanting. Both the legal and clerical professions show the same weakness. Attempts to cultivate the voice are considered superfluous and of no value, and manners are a question of the individuality of the person, and of minor importance.

This is a delusion and a stupid idea that is startling to the last degree. Professional men of all others should recognize and cultivate voice and manners, the same as a musician. It is possible to possess all the finest musical instruments made, and through want of technic be utterly unable to bring out the sounds and melodies. It is possible to possess a range of knowledge in science that is encyclopedic and exhaustive, and yet be utterly unable to express it, or make it available for others. The voice and manners are the technic, to a very large degree, of a successful physician. Numerous illustrations confirm this. One is that of a very learned physician whose scientific knowledge embraced several languages, and whose memory and judgment were excellent; yet he was a failure as a practitioner. He repelled his patrons. He antagonized people who consulted him. His manners were bad, his voice was wretched and discordant, and his whole life was a struggle with debts and efforts to secure a living. His friends said he lacked personal magnetism. This was true, but there were so many other things he lacked that it was doubtful if any one was the sole cause of his failure. Another doctor in the same town was credited with being a great surgeon. He had coarse, ungainly manners, a scowling face, and a harsh, discordant voice. While he was a sensible man, and undoubtedly a good mechanical surgeon, he lacked every essential to make him attractive to his patients. As a teacher in a medical college he was cold, formal, and supposed to be very learned, but he was unpopular with the students.

How often one notes the popular doctors of the city or village or town, the doctors who are praised by their patrons everywhere, and command the respect of all classes, who are scientifically very mediocre men. The inquiry is, how is it that they have such a large patronage and are regarded as such high authorities? One man of this class had a very musical, trained voice. His mother had been an actress in early life, and she insisted that her son should have exact ways of expression and pronunciation, and with them natural and attractive manners, and this culture had continued all through life and was one of the largest assets in his professional work. He was a man of good sense and quick to profit by the experience of others, and he knew how to express himself in the most excellent and pleasing way. This very power of expression brought conviction and confidence. Illustrations similar to the above will be found almost everywhere. In practical life they explain the difference between failure and success in many cases.

A young man who spent five years in the great medical centers of Europe came back with coarse mannerisms and harsh, abrupt tones. He had imbibed the very worst manners and coarseness of expression of his teachers. This was his downfall. He was disappointed at his failure to win and became an inebriate. He was a very highly trained man, but the very essentials to make his training effective were wanting. The thoughts and impulses of the mind and its comprehension of the things of life should be expressed in the very best way possible, and the voice should be trained for this service. It is a grave question whether training of the voice and manners should not precede the acquisition of knowledge. Everyday experience shows that knowledge is useless unless it can be conveyed in the most effective manner to others. The greatest musical composition in the world, if presented on broken, discordant instruments, would utterly fail; but when rendered on good instruments, with skill in technic, it would be very pleasing and delightful.

The human voice is capable of as high a development as the intellect. The human voice out of tune, broken and jarring, is unfit to set the facts and the

conclusions of science in any proper way. There is no organ in the human body so full of possibilities, through training and culture, as the human voice, and yet it is practically neglected, and often made more discordant by a great variety of weaknesses, of which smoking is one. Hundreds of persons graduate every year, from the best schools and colleges with a high degree of intellectual learning, and with voices untrained, whose manners and expressions have been entirely ignored. They talk in broken, discordant notes, in bronchial tones and nasal inflections that are jarring and unpleasant, combined with awkward facial expressions, stilted manners, untrained control of the body, and often a very low sense of the art of dress and personal appearance. They literally follow the medieval theories that the voice, like the stomach and other organs, needs no care or training, but will take care of itself. How often graduates from literary colleges exhibit this weakness and want of culture! How often in medical societies quite learned men read papers, showing the worst possible neglect of the voice, or the common-sense manners and powers of expression! The annual meetings of the American Medical Association furnishes many good illustrations, both in the public exercises and the sectional meetings. It is rare to hear any one who has any conception of the power of voice and expression. In everyday life the quack, with his polished manners and trained voice, makes a profound impression, while the highly trained doctor without this is unnoticed. There is nothing more important in medical colleges, and the training of medical students, than voice culture. In many respects it is one of the most valuable modes of training possible for future success.

A musical voice, free from discords and harsh notes, with proper inflections and harmonious tones, gives power and strength to the expression of the simplest thought. If to this is added manners, expressions, and poses that are natural and free, there is a certain superiority that is recognized by all. This is seen so often in the sickroom, where a doctor with a musical voice is so warmly welcomed. How often his soft tones and clear methods of expression bring renewed courage and strength to the patient. Like the harmonious tones of music, they strike responsive cords in the brain and nervous system. How often children recognize the tones of the physician and are attracted to him! In other cases they are repelled. How often the discordant, nasal voices, the lack of expression and grotesque facial twitchings and the general absence of sympathetic culture are positive obstacles in the treatment of disease! Physicians wonder at their failures, and while they are not employed by families who are satisfied by weaker medical counsel, they never realize that their voice and manners are their greatest obstacles. Occasionally a physician recognizes this fact.

A physician at a banquet said, "I cannot smoke. It would destroy my power of speech. I must not use alcohol because it will injure the tone and manner of expression, and the harp that I depend upon to bring out the melodies of thought, counsel, and advice will be marred and broken." How often physicians exhibit catarrhal affections in the nasal tones and feeble voice! How often physicians are unable to express themselves in an impressive way because they are out of tune! They have done those things which will destroy the very powers which are necessary to command attention and help others. Physicians should exercise extraordinary care to keep the voice clear and resonant and prevent congestion which centers in the nasal passages and vocal cords. They should cultivate the most natural polished manners, so that the persons who appeal to them for help can be impressed by something more than the drugs they give or the operations they perform. Physicians should represent the highest types of culture; culture that is real, apparent and genuine, not superficial and transient. They should exhibit voice culture and body training in its fullest sense. These are the most essential things in the sickroom, and in company with invalids and weaklings who are ever looking for strength.

In one of the large eastern cities many years ago there was a physician of unusual vigor mentally, and a man of considerable genius, a teacher. He had coarse manners, a bronchial voice, and used explosive exclamatory expressions. It was said of him that he destroyed more students than any other man. Students who copied his manner and tone, as those of an ideal hero, suffered in all after life from the diminished respect and want of confidence of their patrons. Many of them grew discouraged, went out of business, became pessimists, and condemned the profession when the fault was in themselves. On the other hand, I have seen ideal teachers in medical colleges who unconsciously inspired their audience and cultivated them along higher lines than had been done by any of the facts that they were mentioning. Their tone of voice and manners made an impression far more enduring than the facts they were teaching. In my experience covering nearly half a century with the borderliners I have noted, among the active causes of failures in professional life, a lack of voice culture and training. Lawyers, clergymen and doctors all fail to secure the influence with the people with whom they come in contact because of inability to express their thoughts in an impressive way. Had the voice been trained the same as the eye and the intellect, had the exterior qualities been trained to express like the voice the best and the clearest facts they would all have been successes.

A noted revivalist who screamed and yelled his thoughts in the most vociferous way, disgusting some and frightening others, wondered why he did not make a more profound impression. The real fault was his gormandizing habits and his discordant bronchial and nasal tones. The melodious voice of Henry Clay always charmed his audience everywhere. Wherever he went people flocked to hear him, while the heavy bass tones of Daniel Webster failed to attract, and actually drove people away. They preferred to read what he had to say, but wanted personally to hear Clay's pleasing voice.

Asylum and hospital physicians furnish innumerable instances of the power of the voice to alter the course of disease and to change the atmosphere of the patient's mind in the most helpful way. We all recognize the power of the mind over the body in many wonderful and unknown ways, but it will be new to most readers that the voice, if properly cultivated and trained, would be equally powerful and effective in producing what is practically unknown now. Books have been written showing that music has a peculiar power in diminishing the irritation and nervous disorders of individuals, and that many times it is a veritable remedy, but so far no one has pointed out the power of the human

voice to do far more than any mechanical instrument and vibratory sounds.

Every medical student should be taught voice culture and general manners; how to conserve the voice and develop it so that it will express thought in its most powerful form. Professional training in the future will give far more attention to the voice, and its practical character will be recognized in every circle.

## Medicolegal Notes.

**Malpractice—Contributory Negligence.**—In an action for malpractice in the course of removing a spur from the plaintiff's nose, the plaintiff's evidence was held to reasonably support his theory that the defendants negligently failed to remove a cotton tampon from his nose, thereby causing the injury. It was held that the question of whether the defendants were guilty of such negligence as constituted malpractice was for the jury and not for the court. The fact that the plaintiff did not return for further treatment as soon as he discovered that he was not getting along as he should did not bar his right to recover, even though it were probable that had he promptly returned the defendants would have discovered and remedied the results of the negligence. It is true that if a patient employs a physician to treat him for a malady and receives careful and skillful treatment at his office, but fails to return to the office for further treatment before he is discharged by the physician, and in consequence suffers an injury, he is not entitled to recover against the physician for such injury. It is also true that a physician's liability ceases the moment his patient dismisses or discharges him, if his treatment of the case has been proper until that time. But these principles have no application where the physician's treatment of the case has been improper.—Williams vs. Wurdemann, Washington Supreme Court, 128 Pac. 639.

**Care of Destitute Sick: County's Liability to Physician.**—Under the provisions of section 14, chapter 67, Nebraska Compiled Statutes, 1911, if any person, not coming within the definition of a pauper, shall fall sick within any county of the State, not having money or property to pay his or her board, nursing and medical aid, it is the duty of the overseers of the poor of the precinct where such person shall be to furnish such assistance as they shall deem necessary. This gives the overseer full authority to provide the necessary medical aid to such sick person. Where a physician is employed by an overseer of the poor to give medical aid to a destitute person who has fallen sick, and the service required is performed, the fact that the overseer has not made a written report of his doings thereon to the county board cannot defeat the liability of the county for the services rendered under such employment.—Meyers v. Furnas County, Nebraska Supreme Court, 140 N. W. 633.

**Value of Medical Services for Jury.**—In an action by a surgeon to recover $187.50 for his services in performing a surgical operation on the defendant's foot the defendant admitted the performance by the plaintiff of the services, but denied they were of the value alleged. The plaintiff and his assistant testified that the value of the services rendered and medicines furnished was $187.50. There was no evidence for the defendant to contradict this, and the court directed a verdict for the plaintiff for the full amount of his claim. It was held on appeal that, notwithstanding the fact that the plaintiff's evidence was undisputed, the question was still for the jury. "It is said by [the plaintiff] that the case is an exceptional one; that plaintiff is a specialist at Milwaukee, Wis.; and that the jury could know nothing of the value of such services. We would not be justified in changing the rule because the case is exceptional, if it be such. Cases may arise where the appearance of the witness, his reasons given as a basis for his opinion, the character of the injury or disease, the length of time taken to perform the operation, and like matters, would justify the jury in not finding the exact amount stated by the witness. All the facts and circumstances, together with the opinion, should be placed before the jurors, who must be permitted to exercise a judgment founded on the common knowledge of mankind. Experts may give their opinions, but they may not usurp the functions of the jury." But the testimony of the experts may not be arbitrarily rejected by the jury. Without expressing an opinion as to the reasonableness of the charges, the court reversed the judgment and remanded the case for submission to a jury. —Fowle v. Parsons, Iowa Supreme Court, 141 N. W. 1049.

**Representations—Malpractice—Examination Before Trial.**—In an action for compensation for an operation upon defendant's wife, and for the medical services of two others, a physician and surgeon, who had assigned their claims to the plaintiff, the defenses were that the plaintiff had represented that the patient would recover within two weeks, which was untrue, that the plaintiff was not a surgeon, and that the defendant's wife had died, and also want of good judgment and reasonable care on the plaintiff's part. It was held that, as the alleged misrepresentations could not be regarded as representations of fact, the defendant was not entitled to examine the plaintiff before trial on that issue, but was entitled to examine him on the issue of malpractice.—Storer v. Harris, New York Appellate Division, 141 N. Y. Supp. 897.

**Medical Books as Evidence.**—A physician testifying as a medical expert in a personal injury case did not base any of his opinions upon medical works, but confined his testimony to his experience. It was held improper to cross-examine him by asking him if he agreed with the writings of any medical author, unless he had first testified that he had read such author and regarded his works as of sufficient merit upon which to base his opinion. Medical works, by the great weight of authority, are not admissible as independent proof of the opinions therein expressed. "While the reasons given are not altogether satisfactory," the court said, "nor wholly unanswerable and conclusive, yet they have survived the lapse of time, and neither the encroachments thereupon nor the criticisms thereof have lessened their value." In U. P. Ry. Co. v. Yates, C. C. A., 79 Fed. 584, Thayer, Circuit Judge, said, "One objection to such testimony is that it is not delivered under oath, a second objection is that the opposite party is thereby deprived of the benefit of a cross-examination; and a third, and perhaps more important reason for rejecting such testimony is that the science of medicine is not an exact science." The court in the present case added two more reasons. Without the introduction of the entire work, the exact views of the author and his reasons for the same cannot be definitely ascertained from mere extracts, and if one book be admitted, or any extracts therefrom, another should be admitted on the other side, and there would be no end to the record that would follow in such cases. "Furthermore, considering the technical terms that are frequently used by medical authors, which often conceal rather than disclose the meaning, the ordinary juror would not be very much enlightened by the introduction of such testimony." Even in states where there is a statute providing that historical works and books of science or art are presumptive evidence of facts of general notoriety or interest, the courts have refused the admission of medical books. In Ashworth v. Kittridge, 66 Mass., 193, it is said: "Medical science has its own nomenclature, its technical terms and words of art, and also common words used in a peculiar manner, distinct from their received meaning in the general use of the language. From these and other causes, a person not versed in medical literature, though having a good knowledge of the English language, would be in danger, without an interpreter, of misapprehending the true meaning of the author; whereas a medical witness would not only give the fact of his opinion and the grounds on which it is offered, with the sanction of his oath, but would also state and explain it in language intelligible to men of common experience." Professor Wigmore has said that "scientists have none of the temptations in their writings to prevaricate and to conceal which surround the expert testifying for a particular purpose." The court said that the answer to this might be that if their writings were universally admitted, as the testimony of an expert now is, and if it be true that experts do "prevaricate for a particular purpose," then, as a scientist is nothing more than an expert, he may be, once his writings are universally held to be admissible in evidence, surrounded with just as many and as great temptations as Professor Wigmore intimates that experts are now, to prevaricate and conceal. Scientific writers, might, it was said, become as numerous and as varied as experts, and their writings could be made to fit either side in certain litigations.—Denver City Tramway Co. v. Sawley, Colorado Court of Appeals, 129 Pac. 258.

## THE NATURE OF ACHONDROPLASIA

THE achondroplastic dwarfs whose stunted and deformed bodies are not unfamiliar objects on the streets, in the museums, and on the stage, have given rise to considerable speculation as to the cause of their peculiar anatomical formation. These dwarfs have been known from earliest antiquity. The God "Ptah" of the ancient Egyptians showed the typical stunting of micromelia, and "Bes," their god of sexual intercourse, was modeled after the dwarf, whose genitalia of apparently exaggerated proportions suggested a fitting prototype for this idol. The Pharaohs were evidently the first monarchs to place a premium upon dwarfs as court fools, a practice which had a rational basis in the unusual degree of intelligence exhibited by these individuals.

Scientific interest in these short-limbed, stocky, and deformed curiosities of nature was aroused when Parrot in 1876 recognized them as constituting a distinct clinical group. The pathology of this condition was first worked out in 1892 by Kaufmann, who distinguished three varieties, which he named chondromalacia fetalis, chondrodystrophia hypoplastica, and chondrodystrophia hyperplastica. All of these forms are congenital, although the lesions may not be apparent until some time after birth. The disease was described as essentially one of cartilage, with a resulting impairment of bony formation. Bones that develop in membrane are apparently not affected. In chondromalacia fetalis the fetus is almost always born dead, with soft pliable limbs. This is the class of cases that has hitherto been termed "fetal rickets," but which bears absolutely no relation to rickets. This class represents, likewise, the majority of the cases, for practically very few of the cases of chondrodystrophy survive birth. In the hypoplastic variety the chief characteristic is the arrested growth of the diaphysis, which is likewise variously deformed; there is an absence of normal compact bone, whose place is taken by a spongy bone with irregular Haversian systems and with varying thickness throughout the shaft. The epiphyses are irregular in their shape and in the period of their ossification. In the hyperplastic variety there is an enormous overgrowth of the epiphyses. The joints are variously distorted. In some of the cases of chondrodystrophy there is practically no distortion of the skeleton, whose principal lesion is the arrested development of the long bones; in other cases there are pronounced deformities, consisting of bowlegs, coxa vara, scoliosis, kyphosis, lordosis, etc.

The most important and the most intensive study of achondroplasia that has as yet been made is that which is contributed by Murk Jansen,* the orthopedic surgeon of Leiden, Holland. He points out that the shortness of the extremities is not the result of any crookedness or bending of the bones, as in rickets or osteomalacia; or of multiple fractures, as in osteogenesis imperfecta. It is not due to absence of the proximal parts, as in phocomelia or congenital deficiency of the femur; nor of the distal parts, as in congenital amputations and in hemimelia. The shortness affects the proximal more than the distal parts of the extremities and is called rhizomelic micromelia. Jansen notes also that the condition reminds one of the proportions of the normal fetus, in which, also, the extremities are short in comparison with the other parts. The pelvis likewise lags behind in development, being small in proportion to the rest of the body. In the vertebral column it is noted that the size of the vertebral bodies gradually diminishes from neck to sacrum. The chest is shortened and is too small for the proper accommodation of the vital organs. As the result of the accurate observation and measurement of dwarf skeletons, the author came to the conclusion that in them the degree of retardation of growth of the various parts of the skeleton is determined by the time of their primary formation. Achondroplasia is a symmetrical, disproportionate dwarf-growth. The skeleton is more affected than other parts of the body. The bones formed in cartilage are affected to a degree which is determined by the time of their scleroblastemic formation: the oldest formation being affected least, the latest most. The slightest forms are those in which even the extremities are but little checked in growth.

The mechanical malformation characteristic of achondroplasia suggests to Jansen the idea that the embryo, between the third and eighth weeks of its intrauterine life has been bent, infolded or "coiled up" like an anchor-rope. The source of the deforming forces is found by exclusion in the amnion. The amnion is known to cause indentations on the body of the fetus, fractures of its limbs, and actual amputations of the latter. But neither amniotic bands nor the magma reticulare can produce that equal pressure against the head and tail of the embryo which is responsible for the stunting and malformations of achondroplasia. Hydramnion and smallness of the amnion are the next two alternative causes. Hydramnion is excluded by the facts that the rapid growth or distention of the amnion might soon put an end to the abnormally high pressure and give the embryo an opportunity of re-

*"Achondroplasia—Its Nature and Its Cause." A study of the stunting of growth in embryonic cell-groups caused by amnion-pressure in the different stages of the development of the skelton (anencephaly, achrondroplasia, cacomelia). By Dr. Murk Jansen, lecturer on orthopedic surgery, University of Leiden, Holland. London: Baillière, Tindall & Cox, 1912.

suming the normal attitude before injury has been inflicted; and that when the abnormal increase of liquid in the amniotic sac begins only after the amnion has been lifted from the surface of the embryo, the abnormal axial pressure need not be exercised. It is concluded, therefore, that too small an amnion is able to compress the fetus. This smallness of amnion is the result of an insufficiency of its growth in relation to that of the embryo. Smallness of amnion produces other phenomena of pathological embryology besides those of achondroplasia; sometimes the vertebral column is curved and the development of the brain is disturbed; sometimes the injury is restricted to the extremities and allied deformities result. Clubfoot may be the sole manifestation. In four of seven clubfooted children there was a marked brachycephaly agreeing with that of achondroplasia. Amnion pressure, if exerted during the first and second weeks, is able to cause a wrinkling of the embryonic axis, with destruction of ecto- and mesodermal elements (anencephaly). If the abnormal pressure is operative from the third to the sixth weeks it gives rise to infolding of the embryonic axis and stunting of growth (achondroplasia). If the abnormal pressure arises from the sixth to the eighth week it causes cacomelia in which bones are lacking (hemiectromelia, oligodactyly) and other deformities, or cacomelia with the normal number of bones, as in clubfoot.

Jansen's theory is based upon careful embryological and clinical studies, and is apparently the most ingenious that has yet been advanced to explain the origin of achondroplasia and other congenital malformations.

## STREPTOCOCCUS TRANSMUTATIONS.

THE transmutation of bacteria is certainly not nearly as fanciful a subject as the transmutation of metals but it has proved as attractive to bacteriologists for many years and until recently has been nearly as unsuccessful. In view of the probable evolutionary development of the microorganisms, such transmutations have generally been considered possible, but the difficulties in their production and determination have been great. It has been possible by means of prolonged animal passage to change the tubercle bacillus from the bovine type into the human and back again, but that is comparatively a small change. Several investigators have claimed to have effected transmutations among the members in the streptococcus group, but the changes thus produced have been largely subtractive, such as the removal of the power to form capsules or hemolyze blood, rather than additive, and cannot be considered in any way conclusive. Practically no satisfactory work has been done upon altered immunity reactions which constitute the only true biological test.

Recently, however, success in this direction has been attained. E. C. Rosenow (*Jour. Infect. Dis.*, 1914, xiv, 1) has been able to convert hemolytic streptococci into *S. viridans*, typical pneumococci, and *S. mucosus*, and to change these about almost at will. The exact details of his methods are too long to repeat, but he employed animal passage, growth on ascites-dextrose-agar, both in air and in an atmosphere of pure oxygen, growth on blood-agar in symbiosis with *B. subtilis*, and growth for a prolonged time on rather dry blood-peptone-agar. The change effected was apparently complete so far as bacteriological methods enabled him to determine it. Rosenow says, "The transformation of some of the strains has been found to be complete by every test known. Thus the morphology, the presence of capsule, the fermentative powers, the solubility or insolubility in bile and in sodium chloride solution, the behavior toward the respective broth culture filtrates (Marmorek's test), the specific immunity response, as manifested by the production of opsonin and agglutination by antipneumococcus and antistreptococcus serum, and the more or less specific pathogenic powers have been studied. Strains that correspond to hemolytic streptococci have been converted into typical pneumococci as determined by all the above tests and vice versa."

At first sight this might appear rather discouraging. No sooner do we convince ourselves that microorganisms have each a specific action and are constantly associated with certain diseases than an author tells us that these bacteria are not constant, but change one into another. It must be remembered, however, that in each instance the organism retains its characteristics under all ordinary conditions and that our present knowledge of the bacterial association with disease will be widened rather than altered. The streptococcus group is one of immense importance. Among its members are found the etiological factors of endocarditis in all its forms, lobar pneumonia, septicemia, certain kinds of sore throat, erysipelas, rheumatism, and many other conditions as well as numerous complications of diseases caused by other bacteria. Rosenow is of the opinion that these transformations may take place in the body and that "focal infections are no longer to be looked upon as merely a place of entrance of bacteria, but as a place where conditions are favorable for them to acquire the properties which give them a wide range of affinities for various structures." Especially in the frequent association of rheumatism, tonsillitis, and endocarditis he sees in the tonsil "a place where the organisms acquire the peculiar properties necessary to produce the disease known as rheumatism."

Rosenow's interesting results have, of course, not yet been confirmed, but his various recent reports on the subject are of such a nature as to force their acceptance and confirmation may confidently be expected. Clearly this constitutes an exceedingly important contribution to scientific medicine and one that should aid materially in the solution of many pressing clinical problems.

## COMMON SENSE IN PUBLIC-HEALTH ADMINISTRATION.

THE exercise of common sense is an essential factor in the successful issue of any undertaking, and is especially so in public health affairs. Brilliant

conceptions unless in their carrying out common sense is employed are lamentable failures. Attention is drawn to this fact in Reprint No. 173 from the Public Health Reports, published March 20, 1914, by W. C. Rucker, Assistant Surgeon-General U. S. Public Health Service, who states as a prelude to his remarks that the amazing fact of epidemiology is its extreme simplicity. That is to say, when the cause of a disease is accurately known and the factors concerned in its dissemination have been determined the measures to be taken to prevent or eradicate the disease are relatively simple. In proportion to our lack of knowledge regarding the cause and transmission of a disease, the more complicated are our theories as to its epidemiology.

Accordingly, public health administration in order to be of practical value must be conducted along logical lines, that is, common sense lines. Carrying this argument to its ultimate issue, results of practical value cannot be obtained if the men in whose hands are placed the management are not themselves thoroughly competent. Which is to say that inadequately trained public health administrators are comparatively useless and may even do more harm than good. Rucker points out that a great wave of enthusiasm for public health reform is now sweeping over this country, and in consequence much legislation is proposed which is contrary to common sense.

It is well to remember, however, that a little learning is a dangerous thing, and while it is quite necessary that the man in the street should be interested in questions that concern the public health, it must be left to the trained men to draft laws leading to reform. It is sufficient that sanitarians should popularize the tenets of preventive medicine and inculcate in the rising generation the principles and practice of personal hygiene. On the other hand it is harmful that a mass of undigested and impractical measures should be placed on the statute books to serve as boomerangs to the public and health officers.

The present agitation over track pollution by interstate carriers is cited by Rucker as a case in point. Enough is not yet known exactly as to the amount of disease spread by this means, and until we have obtained this exact knowledge it would be futile and foolish to exact laws with a view to preventing spread of disease by this agency. Public health laws enacted with the best intentions by States and municipalities are criticised in a kindly and discerning manner by Rucker, who also deprecates the arbitrary enforcement of the exact letter of the law instead of its application with common sense to meet the situation. Such a procedure frequently defeats the purpose for which the law was created.

The author concludes by saying that common sense in public health administration comprehends the employment of well trained, full time health officers, at adequate salaries, the appropriation of sufficient funds to enable such officials to administer the laws, and the enactment of specific legislation having as its foundation the basis of fact and practicability.

### The Pollution of Tidal Waters.

In "Public Health Reports" for April 10, 1914, Hugh S. Cumming, Surgeon, U. S. Public Health Service, publishes an address on the pollution of tidal waters, read by him before the Maryland Conservative Association at its first annual meeting held in Baltimore, Feb. 25, 1914. Summarizing, Cumming points out that there is found in tidal waters (1) Comparatively concentrated areas of pollution; (2) Decreased destruction by oxidation; (3) Increased nuisance from putrefaction in consequence, and (4) Not much difference in viability of disease germs. As for the bearing of sewage pollution on health, Fuller is quoted as saying that there are two principal nuisances which are conspicuously due to sewage. The first is caused by the conditions that are offensive to the sight and smell. The second class of nuisance is associated with the disease germs contained in sewage and which are transmitted to neighboring communities through the water of the stream into which the sewage empties or through shellfish. The menace of polluted tidal waters so far as shellfish are concerned is a grave one, although the danger from this source has been considerably exaggerated. As for the regulation of pollution of tidal waters Cumming directs attention to the fact that by an Act of Congress the Public Health Service was authorized to study the diseases of man and conditions influencing their propagation and spread, including sanitation and sewage and the pollution direct or indirect, of the navigable waters of the United States. Under this act the Public Health Service is now planning a systematic study of the more important industrial wastes, of their effect upon navigable waters, and of remedial measures. Undoubtedly a careful study should be made of the effect of polluted water on shellfish and the investigations about to be undertaken by the Public Health Service should solve the problem. The United States has long lagged behind Europe with regard to supervision of water supplies, and it is high time that the blot should be removed from her sanitary escutcheon.

---

### The Chemotherapy of Infectious Diseases.

The good results obtained in the treatment of various protozoal diseases by the use of salvarsan, have led to the employment of this agent in a number of diseases whose infectious agent is unknown or in those caused by bacteria. Klemperer and others have recently reported that scarlet fever is favorably influenced by salvarsan. The latest investigation along this line is that recorded by Orlovius in the *Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, Vol. 2, No. 2. He treated his cases of puerperal sepsis by means of intravenous injections of neosalvarsan. In about half of these cases he observed a prompt improvement resulting from this method of treatment. The drug was employed only in those cases in which a bacteriemia was demonstrated. If there were local purulent foci or metastases the treatment was ineffective. It is necessary to inject the neosalvarsan under the strictest aseptic precautions as early as possible or just after the onset of the fever, and before local complications such as parametritis, thrombophlebitis, etc., have arisen. The author's cases were those of infections by streptococci and staphylococci and by colon bacilli. In the cases in which neosalvarsan was injected at an early stage

there was noted one-half hour after the injection a chill which was followed by an immediate rise in temperature. This would drop to normal the following day, on the evening of which it would rise slightly. It would then drop to normal again, and would remain at this level provided that no new bacterial invasion of the blood occurred. In the latter event a second injection of neosalvarsan was required.

### Penile "Menstruation"

Rare cases of apparent menstruation through the penis—escape of blood for two or three days with succeeding leucorrhea—however suggestive of menstruation in the female, cannot be hastily assumed to be a form of hermaphroditism. At a recent meeting of the Verein Deutscher Aerzte in Prague (*Münchener medizinische Wochenschrift*, April 7), Lucksche was able to exhibit the genitals, internal and external, of a man who in life, since his eighteenth year had "menstruated" until his death at 25 of phthisis. The patient, of male habitus, showed certain secondary sexual characteristics approximating the female type; while some parts of the genitals showed a tendency to atrophy. But every portion of the male genital system was present, while there were no rudimentary female organs. It was decided that such a subject was no hermaphrodite, and that the periodical escape of blood from the urethra could possess nothing in common with menstruation from a uterus. The patient's periodical loss of blood was evidently an independent phenomenon, devoid of any sexual stimulus.

## News of the Week.

**New Dispensary.**—Plans have been filed with the Building Department for a four-story dispensary building to be erected at the northeast corner of Gouverneur Slip and Front street, New York. It will be known as the Gouverneur Dispensary and will be maintained by the city. The cost is estimated at $200,000.

**Wood Alcohol Law.**—Dr. Charles Baskerville of the College of the City of New York has prepared a model for a uniform State and municipal law governing the sale and use of wood alcohol, as follows: "No person shall sell, deal in, supply or give away, any article of food or drink or any medicinal or toilet preparation intended for human use internally or externally which contains any wood alcohol, otherwise known as methyl alcohol, either crude or refined, under or by whatever name or trade mark the same may be called or known. Traffic in the drug is legal if the container in which the same is sold shall have affixed thereto a label containing the following words: 'Poison—Wood Alcohol. It is unlawful to use this fluid in any article of food or drink or medicinal or toilet preparation, for human use internal or external.'"

**Long-lived Missourians.**—The Bureau of Vital Statistics of the State of Missouri has recently reported that during the year 1913 there occurred in the State the deaths of thirty-four men, all of them one hundred years of age or over, and that 393 persons died between the ages of ninety and ninety-nine years.

**Child Labor Law.**—An effort to amend the Massachusetts State law regulating child labor, so that children between fourteen and sixteen who had passed a physical test might be employed in textile industries, was defeated in the legislature on May 6. The bill was favored by representatives of the textile centers, who contended that the present law forbidding the employment of children under sixteen years of age was too severe.

**Yellow Fever in Brazil.**—A yellow fever epidemic at Bahia, Brazil, was reported to Washington on April 29. It is said that lack of funds handicaps the work of preventing the spread of the disease.

**Smallpox in City.**—Another case of smallpox in the city was reported to the Department of Health of New York on May 5, making the fifteenth case since the first of the year. Commissioner Goldwater has issued a strong appeal for a general vaccination.

**City Death Rate.**—The death rate in New York City for the week ending May 2, 1914, was 14.89 per 1,000 of population, the total number of deaths being 1,593, as compared with a rate of 14.88 and a total of 1,532 deaths for the corresponding week of last year. This shows an absolute increase of 61 deaths, and an increase of 0.01 in the rate, which is equivalent to a relative increase of one death. The causes showing an increased mortality were measles, scarlet fever, whooping cough, typhoid fever, diarrheal diseases under five years, and pulmonary tuberculosis. The mortality of infants under one year was approximately the same, while that between one and five years was considerably below the mortality for the corresponding week of 1913. A considerably increased mortality was recorded for the age period of over sixty-five. For the first eighteen weeks of 1914 it was 15.43 per 1,000 of population as against a rate of 15.63 during the same period of 1913.

**Hospital Dedicated.**—St. Anthony's Hospital, Richmond Hill, Long Island, was dedicated by Bishop McDonnell of Brooklyn on May 5. The hospital will be open for public inspection on May 30 and 31.

**The Egbert Le Fevre Deanship Fund.**—The widow of Dr. Le Fevre, late Dean of the University and Bellevue Hospital Medical School, has given to the University the sum of $10,000, to be known as the fund above named, the income to be applied toward the salary of the dean of the medical school.

**Surgeons' Tour.**—In connection with the fifth annual session of the Clinical Congress of Surgeons of North America to be held in London from July 27 to August 3, 1914, arrangements are being made for the American Surgeon's Clinical Tour. The first meeting place will be Baltimore, where a clinic will be given by Dr. H. A. Kelly; the next day will be spent in Philadelphia, and the next three in New York, the party sailing from this port on the Oceanic on June 13. In Europe the tour will include Paris, Bern, Zurich, Munich, Vienna, Berlin, Leipzig, Jena, Frankfort, Heidelberg, Brussels, and Amsterdam, in all of which places important clinics will be given. The party will reach London in time to attend the sessions of the Congress. The secretary of the American Surgeons' Clinical Tour is Dr. R. M. Harbin, Rome, Ga., from whom further particulars may be obtained.

**Measles in Orphanage.**—An epidemic of measles in the Brooklyn Orphan Asylum has been controlled by strict quarantine of the children affected. In

all forty-seven cases developed and were treated in the hospital ward of the asylum.

**Calcutta School of Tropical Medicine.**—The foundation stone of the new School of Tropical Medicine at Calcutta, India, was laid recently, the government having appropriated $195,000 for the site and the erection of laboratory buildings. The school will accept students from all over the world.

**Work for Convalescents.**—The Trade School for Cardiac Convalescents, which aims to provide work for patients recovering from heart disease and unable to resume their former occupations, reports great success during its first year of operation. Last July a home for such patients was opened at Sharon, Conn., and there they receive care and treatment while learning a trade. A workshop is also maintained in New York. The making of concrete flower pots has been found to be a suitable and profitable trade, and is now being pursued by a number of men who without it would be financially dependent.

**Aid for Defectives.**—The State Charities Aid Association and the Association for Improving the Condition of the Poor are making an attempt to induce the Legislature at its special session to appropriate $500,000 for additional beds at Letchworth Village, Craig Colony, and Rome. Each legislator has been sent a list of 1,000 feeble minded persons who experts believe should be cared for in an institution, and the Clearing House for Mental Defectives in New York has on file 3,000 additional names of persons who need institutional treatment. It is probable that if no appropriation is made a bond issue will be authorized.

**State Insane Hospitals.**—Startling conditions in the New York State Hospitals are said to have been uncovered by the investigators of the Commissioner of Efficiency and Economy during the last two months. It is charged that of the appropriation of $8,000,000 made by the Legislature for the maintenance of institutions with 30,000 inmates, one-half was spent on salaries of superintendents and employees, and that for the care of these 30,000 patients, 11,000 employees, including superintendents, doctors, stewards, and attendants, are engaged. A full report of various sorts of graft discovered during the investigation will soon be issued.

**Call for Hospital Corps Enlistments.**—The Surgeon-General of the United States Army has authorized the Department Surgeon at Governor's Island, New York, to enlist an unlimited number of men for the service in the hospital corps of the army.

**Changes at College of Physicians and Surgeons.**—At a meeting of the Board of Trustees of Columbia University on May 2, announcement was made of the acceptance of the resignations of Dr. Frederick Peterson, professor of psychiatry at the College of Physicians and Surgeons, and of Dr. J. Ramsay Hunt, associate professor of neurology, and of the appointment of Dr. Frederick Tilney to succeed the latter. The resignation of Dr. Theodore A. Janeway, Bard professor of medicine, was also accepted. As previously announced, Dr. Janeway has accepted the appointment as professor of medicine at Johns Hopkins University.

**American Gynecological Society.**—The thirty-ninth annual meeting will be held in Boston on Tuesday, Wednesday, and Thursday, May 19 to 21, 1914, under the presidency of Dr. J. Whitridge Williams. The scientific session on Wednesday will be held at the Country Club, Brookline; on the other days at the Boston Medical Library; and the headquarters of the society during the convention will be at the Harvard Club, 374 Commonwealth avenue. Dr. Leroy Broun of New York is the secretary of the society.

**Society for Sexual Research.**—Preparations are being made for the first congress of the International Society for Sexual Research, which will be held in Berlin on October 31 to November 2, 1914, under the presidency of Geh. Reg. Rat Prof. Dr. Julius Wolf. The congress will cover the entire field of scientific sexual research, and will probably be divided into a biological-medical, a sociological, a legal, and a philosophic-psychologic-pedagogical section. Proceedings will be conducted in German, English, and French. Participation in the congress is free to members of the society, and for non-members the registration fee is 10 marks. Further particulars may be obtained from the second-secretary, Dr. Max Marcuse, Berlin W. 35, Lützowstr. 85.

**Obituary Notes.**—Dr. Charles F. Wainwright, until recently of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1889, formerly professor of internal medicine and dean of the University Medical College, Kansas City, Mo., and later instructor in internal medicine at the New York Post-Graduate Medical School, died at his home in Englewood, N. J., on May 6, aged fifty-five years.

Dr. John William Dowling, Secretary of the Faculty of the New York Homeopathic Medical College and Flower Hospital, died in Middletown, N. Y., of apoplexy. He was born in 1869 and received his B.A. degree from Columbia University in 1883, and three years later was graduated from the New York Homeopathic Medical College. Soon after graduation he was appointed professor of physical diagnosis at the college and was also an attending physician at the Flower Hospital. He was a member of the American Institute of Homeopathy and the State Homeopathic Society.

Dr. Harry A. Smith, of Boston, a graduate of the Medical School of Maine, Portland, in 1890, and a member of the Massachusetts and Suffolk County Medical Societies, died at his home, after a short illness on April 27, aged 47 years.

Dr. John B. Lewis, of Hartford, Conn., a graduate of the New York University Medical College in 1853, a veteran of the Civil War, and a member of the Connecticut State and Hartford County Medical Societies, died at his home, after a long illness, on April 26, aged 82 years.

Dr. Oliver I. Halbert, of Waco, Tex., a graduate of the University of Louisville Medical Department in 1876, a member of the State Medical Association of Texas, and a member and for many years president of the McLennan County Medical Society, died at his home after a long illness, on April 22, aged 64 years.

## GENERAL MEMORIAL HOSPITAL FOR THE TREATMENT OF CANCER AND ALLIED DISEASES.

The recent gifts of Dr. James Douglas, aggregating nearly half a million dollars, to the General Memorial Hospital, places this institution in the front ranks of those devoted to the study and treatment of cancer. The conditions of the gifts are that the entire medical staff as well as the research staff shall be under the control of the Medical De-

partment of Cornell University in New York City, thus insuring the closest cooperation between the clinical and laboratory investigation of cancer problems. This recent gift has fulfilled to a striking degree the purposes and hopes of the founders of the Hospital. In this connection, a brief history regarding the foundation and evolution of the Hospital will be of interest:

The Institution was started largely through the influence and efforts of John E. Parsons, Esq., who was the first President and who still holds the office of President. The founders of the Hospital, Mr. and Mrs. J. J. Astor, and Gen. and Mrs. Cullum, held the first meeting for organization on February 7, 1884. The purpose of the Hospital is clearly shown in the following paragraph from the minutes of that meeting: "A hospital, with clinics for outdoor patients, for the treatment of cancer exclusively, in all its forms, is a much needed charity in this city. There is no such hospital in the United States. An institution of this kind would not only accomplish the cure or relief of many sufferers from cancer, but would afford invaluable opportunities for the study of disease and the advancement of medical science."

The corner stone was laid May 17, 1884, on which occasion Dr. William H. Draper, who took part in the ceremony, stated in his address: "I trust I shall not shock the prejudices of any of my hearers when I say that the highest object with which a Hospital can be founded is not simply to provide for those whose means are inadequate to command them the benefits of the best medical and surgical skill and the best nursing. * * * I believe I am stating truly the motive which led to the munificent endowments by which this Hospital is to be established, when I say that it was the intelligent conviction of this truth,—that while it was desired to confer the blessings of the best Hospital treatment upon the sufferers from the dread disease to which it is to be devoted, the higher purpose was to give the best possible opportunity for the scientific investigation of the causes and the treatment of a disease which has thus far baffled human insight and human skill."

These prophetic words of Dr. Draper have now been realized. In 1899, by an act of Legislature, the name of the Hospital was changed from the New York Cancer Hospital to the General Memorial Hospital for the Treatment of Cancer and Allied Diseases. The first research work in cancer in this country was done at the New York Cancer Hospital in 1892, in a systematic trial of the effects of the living cultures of the streptococcus of erysipelas upon inoperable malignant tumors. The building and funds for carrying on this work were provided by Archer M. Huntington now Vice-President of the Hospital.

Almost the first scientific laboratory research work in cancer in this country was done at the General Memorial Hospital under the auspices of the Collis P. Huntington Fund for Cancer Research. This Fund, which originated from the gift of $100,000 by Mrs. Huntington, in 1902, was turned over to the General Memorial Hospital under certain conditions, the principal ones being: (1) The $100,000 to constitute a special fund to be designated The Collis P. Huntington Fund, and to be invested and kept invested, the income only to be used. (2) The income to be applied to the study of cancer and malignant tumors generally, and to research in the direction of a remedy or remedies for the disease. (3) The use of the income shall be under the direction of a Committee of Five, of which, Mr. Archer M. Huntington and Dr. William B. Coley shall be permanent members.

The work was begun in 1903 at the Loomis Laboratory of Cornell University Medical College, under the direction of Dr. B. H. Buxton, who was later appointed Professor of Experimental Pathology at Cornell. In addition to the income of the Fund, considerably larger amounts have been given annually by Mrs. Huntington for carrying on the work. The resources of the Huntington Fund have been devoted practically entirely to laboratory investigations, lack of funds making it impossible to conduct side by side the clinical and laboratory studies, which is so essential in the study of the difficult problems in cancer.

The general plan adopted is similar to that of the Middlesex Hospital in London in which a pavilion of six wards has recently been devoted exclusively to cancer. In the new institution all modern methods of surgical and medical diagnosis and treatment of cancer will be developed to the highest degree possible. Owing to the growing importance of post-operative treatment by physical agents, which the hospital is fully prepared to supply, it is believed that the operative service should attract a large number of advanced cases in which operation alone is unsuccessful or uncertain. The physical agents of recognized value include fulguration, *x*-ray, and radium. The hospital has at present a moderate supply of high grade radium and a larger amount of low grade from which the emanation is used. The most approved apparatus for the collection of emanation has been installed and this work is in charge of a physicist. A further supply of radium up to 3 gm. is expected from the Colorado mines of Dr. Douglas. The *x*-ray department of the hospital is fully equipped with the latest apparatus for irradiation, diathermia, and desiccation. A chemical laboratory has also been installed and chemical studies have been in progress for a year past. The pathological service is in charge of the University staff. The affiliation with the University places at the disposal of the hospital the services of the laboratory staff of the Huntington Fund as well as those of the staffs of the various scientific departments of the University. The Huntington Fund for Cancer Research was one of the pioneer endowments for this purpose and it is to the existence of this Fund that the Hospital owes its present fortunate position. Through this Fund, administered by Cornell University, a staff of workers has long been maintained in the field of cancer research. This staff now finds an enlarged opportunity in the problems suggested by the cancer patient. The field of experimental laboratory studies remains intact and these will be pursued, with the support of the Huntington Fund, as before, and even with increased activity owing to the many new problems which the clinical material provides. The laboratory staff has long felt the need of association with a cancer hospital and Dr. Douglas' endowment is provided to supply this need and to bring about a combination of laboratory and clinical investigation.

The present plans therefore provide for a type of organization which has received world-wide approval. In it the Memorial Hospital enters its chosen field under University auspices, and the Huntington Fund reaps a just reward for consistent support of cancer research over many years.

## Correspondence.

### FAILURES IN TYPHOID VACCINATION

To the Editor of the Medical Record:

Sir:—Cases of typhoid fever occurring in patients vaccinated against the disease within a few months of its development are so rare that the following three cases which have come recently under my observation should be recorded.

Case I. was that of a woman 30 years of age who lived with a large family in a tenement house in New York. In August, 1913, her brother, mother, and sister all had typhoid fever. The patient was vaccinated at that time by agents of the Health Department and escaped the disease for the time being. Eight months later she entered Bellevue Hospital in the third week of typhoid fever, together with her four children, all of whom had the disease. She was very ill on admission with typical symptoms of typhoid fever, and a temperature which reached 105 F. daily for eight days, when she died with hyperpyrexia (106 F.), nephritis, and pulmonary edema. Four days prior to death she miscarried, the infant being six months old. Through the cooperation of Dr. Goldwater a Coroner's autopsy was secured which revealed typical swelling, induration, and ulceration of the Peyer's patches of the ileum. There was no hemorrhage or perforation.

Case II. was that of one of the above-mentioned four children. This child had been vaccinated at the same time with the mother in August, and was treated upon another division of the hospital, having definite symptoms of typhoid fever. This patient recovered. A blood culture gave a positive typhoid test.

Case III. was that of a young man seen in consultation, who was a student in Yale University, where he had received antityphoid vaccination last autumn. He presented in January of this year a mild case of typhoid fever from which he recovered.

W. Gilman Thompson, M.D.

61 West Forty-ninth Street, New York.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

PREVENTION OF SHOCK AFTER OPERATIONS—HOSPITAL SATURDAY—SCARCITY OF NURSES—FAMILY ENCYCLOPEDIA OF MEDICINE—BLUE BEAD NECKLACE CHARM—NATIONAL MEDICAL UNION—OBITUARY.

London, April 24, 1914.

Shockless surgery has become a rather more familiar term since last month William de Courcy Wheeler brought before the Dublin Academy of Medicine his experience of Crile's method of preventing shock, anoci-association, as it is called. He made no extravagant claim, but his own cases supported the view that a considerable advance has been made in the direction of rendering operations less formidable by making shock a less frequent sequel. Crile's experimental investigations are held to show that the essential lesion of shock is in the brain cells in which potential energy is changed into kinetic energy—probably at the expense of certain chemical compounds stored in the cells. This stored energy is discharged in response to a stimulus—say trauma or emotion—and that whether the person be conscious or unconscious. To prevent the effect of trauma on the brain cells local anesthesia is employed to intercept the stimuli. This is therefore combined with general anesthesia, and is the combination of the two which constitutes anoci-association. Mr. Wheeler, who illustrated his paper with lantern slides, has become convinced of the great value of Crile's work, and while admitting that there might be more to learn about anoci-association held it to mark a new era in surgery comparable with the antiseptic system in importance. He gave details as to the preparation of the patient for operation and his management after it, comprising the use of narcotics and other adjuvants. There was but slight discussion—certainly less than the paper deserved, considering the prior endorsement of Moynihan and other able observers of Crile's method.

Mr. Stoney, though he confessed he had no practical experience of the method, said many operations were not usually followed by a great deal of shock, some of them being among Mr. Wheeler's cases. Emergency and abdominal operations were of the most importance, but he suggested in some it would not be possible to avoid handling the intestines.

Mr. McConnell had seen Crile himself operate with his method. He objected to cases of ether anesthesia five or more years ago being used for comparison as Crile had used some. He was sorry Mr. Wheeler used etherization and thought nitrous oxide would be better. It was difficult to prove whether anoci-association prevented shock because many operations were done in the ordinary way without causing shock.

The annual meeting of the Hospital Saturday Fund was held at the Mansion House on the 18th inst. when a decrease of income had to be reported. This was attributed to the working of the Insurance Act. Some persons seem to have thought that act would render this fund unnecessary, but Sir T. V. Strong, who moved the adoption of the report, declared there was no room for doubt that there would always be need for generous voluntary assistance. Last year's receipts were £40,403 as against £45,118 the previous year. The benefits distributed included 8,200 surgical appliances supplied at half the cost, 33,543 dental wants, besides assistance toward cost of the treatment in convalescent homes and sanatoria. The distribution to hospitals and institutions amounted to £28,401.

A scarcity of nurses is being complained of. Sir V. Horsley, speaking at Leeds last week, said the country ought to have 50 per cent. more trained nurses than it had and they should be registered and made a profession. He was of the opinion that registration had conferred many benefits on the medical profession, but one meets with very few who agree with him. It is a common complaint with many that the nurses are apt to intrude in the sphere of the doctor instead of implicitly following his directions, and registration might increase their self esteem.

The "Family Encyclopedia of Medicine" continues to appear in instalments and the list of medical men who have assisted in its production is again issued with their qualifications and addresses, to the indignation of the man of the profession. One may say that everyone outside that list condemns the open breach of the long established ethical rule. The pretense that these socalled authorities are not responsible for this advertising is comparable to the various excuses and evasions of certain politicians. The only punishment the general practitioners can inflict is to refuse to call in or meet in consultation any one of the offenders.

On Wednesday Mr. E. Lovett gave a lantern lecture on the "Folk-lore of London," in which he said many children of the poorest people wore a necklace of common blue beads as a charm against colds and bronchitis. He had himself gathered sixty-seven independent records of this custom in all parts of London. The beads were worn under the clothing, put on in infancy and not taken off throughout life. He had seen several old women over 60 years of age who had worn the blue bead necklace from infancy. It must never be taken off on any account day or night. He suggested that this custom might account for the great number of beads often found in ancient tombs.

The National Medical Union was formed, according to *The Hospital*, which is its organ, at a conference of delegates of Non-Panel Societies last November. The title was taken over from one of these societies which had been formed the previous year at Manchester. The Edinburgh Guild and London Committee of Non-Panel Doctors also united. The union is absolutely hostile to the Insurance Acts and the first condition of membership is that the candidate be not on the panel directly or indirectly.

Dr. T. D. Griffiths of Swansea died on Friday last aged 77. He was M.D. Lond. with high honors, after a brilliant college career, taking amongst other distinctions the Atkinson Morley Scholarship and the Filliter Exhibition. He settled in South Wales and maintained a high position in public estimation throughout his life, as shown by his being made D.Sc. Oxford (honor's causa). He was president of the B.M.A. in 1903.

## Progress of Medical Science.

**Boston Medical and Surgical Journal.**

*April* 30, 1914.

1. The Art of Companionship in Mental Nursing H. R. Stedman.
2. Certain Aspects of the Medical History of Exophthalmic Goiter. R. Fitz.
3. The Demonstration of Gallstones by the Roentgen Ray. A. W. George and I. Gerber.
4. Intracranial Hemorrhage in the Newborn. R. M. Green.
5. Some Present Problems in Tuberculosis. P. C. Bartlett.
6. The Tuberculous Child. C. Floyd.
7. The Social Worker's Educational Influence in the Community. G. B. Underwood.
8. The Field of Work of the Antituberculosis Association. S. H. Stone.

**1. Companionship in Mental Nursing.**—H. R. Stedman enumerates a few of the daily duties involved in the private work of the expert mental nurse who is alive to her patient's needs. She reads to her charge systematically. She also sees that the patient reads, even training her to read aloud regularly for a definite time each day. Systematic occupation goes a great way toward distracting and engrossing a patient's thoughts. Almost all available kinds are helpful, according to the age, strength, and sex of the patients, from embroidery and arts and crafts work to wood cutting and chopping, provided it be free from drudgery and is varied and shared in by the nurse. The nurse will also often have to help in a patient's correspondence and to urge her to write to her relatives or friends. The accomplished companion-nurse will also have as a part of her armamentarium some proficiency at games of various kinds, indoor and outdoor. The mental nurse would suffer no loss of efficiency and have more time to get closer to her patient if such branches as bacteriology, uranalysis, gynecology and obstetrics, and much of the anatomy taught, were in some cases omitted altogether and in others materially curtailed. This done it might be possible to substitute with still a good margin of time, a "current events" class, for example, a lecture or two on the means for diverting the single patient, reports of personal interviews with patients and their domestic and other troubles, which might have a bearing on their condition and their future needs, etc.

**2. Medical History of Exophthalmic Goiter.**—R. Fitz states that the names of three men stand out above all others in connection with the medical history of exophthalmic goiter. These names are Caleb Hillier Parry, Robert James Graves and Carl Adolphus von Basedow. All three of these observers lived within fifty years of one another, all three recognized the symptom-complex which bears their names, all three described the disease from entirely different points of view and for entirely different reasons. Parry was born in 1755 and practised in Bath, the medical center of the most fashionable English society. His first case of exophthalmic goiter was described in his "Posthumous Papers" in 1825. Graves was born in Dublin in 1797. His original paper on exophthalmic goiter was published in 1835. Von Basedow was born in Dessau in 1799. His article on exophthalmic goiter appeared in 1840, and is the first complete monograph on this subject. Parry lived in the center of fashion, and his interests were associated with those of the people with whom he came in contact. Graves lived in a university town, where scholastic success represented the pinnacle of greatness. As a result the practice of medicine became to him of secondary importance. Von Basedow lived in a small German town. He was uninfluenced by the cares of a lucrative practice or the responsibility of a university professorship. Whether exophthalmic goiter be called Parry's disease, or Graves' disease, or Basedow's disease, all three of these physicians deserve places in the history of medicine. It is difficult to find more perfect models of the practitioner of medicine, the teacher of medicine, or the student of medicine.

**3. The Demonstration of Gallstones by the Roentgen Ray.**—A. W. George and I. Gerber point out that the demonstration of gallstones by the Rœntgen ray has already reached a position in this country that warrants its more general use as a dependable aid to diagnosis. It is advisable to examine the gall-bladder region for stones prior to every bismuth examination of the alimentary tract. The authors believe that gallstones can be demonstrated by the Rœntgen ray in nearly every case of gall-bladder disease of long standing where stones are really present. The chief sources of error are renal calculi, calcified mesenteric glands, and costochondral ossification. These can be differentiated by proper technique.

**4. Intracranial Hemorrhage in the Newborn.**—R. M. Green concludes that intracranial hemorrhage may occur in the newborn either from the trauma of operative or normal labor or in association with hemorrhagia neonatorum. It does not often present the typical clinical picture of increased intracranial pressure. Its presumptive diagnosis depends on the early recognition of refusal to nurse, pallor, and slight facial edema, which may be confirmed by the appearance of more classical signs. The diagnosis may be positively established and some therapeutic relief afforded by lumbar puncture (when the hemorrhage is infratentorial), or by cranial puncture (when the hemorrhage is over the cerebral convexity). If these measures give relief, operative decompression by craniotomy is indicated. The majority of intracranial hemorrhages in the newborn are subdural, but intraventricular hemorrhages may also occur. The source of bleeding may be from laceration of the tentorium, of the choroid plexus, of the longitudinal sinus, or of the pial vessels.

In cases associated with hemorrhagic disease preliminary transfusion may be indicated before craniotomy. The gravity of the prognosis demands an enlightened prophylaxis by avoiding all unnecessary occasion for fetal trauma.

5. **Present Problems in Tuberculosis.**—P. C. Bartlett points out that there are still altogether too many patients with active disease that are not recognized as tuberculous until their disease is moderately advanced or worse. Another problem is to find suitable employment for the arrested or partially arrested case of the disease. There is also a problem of duplication of effort. The local boards of health, the various tuberculosis societies and various other health agencies should realize that only through the most complete cooperation can the best results be obtained.

10. Variation in Drugs. W. M. Gregory.

1. **Theories of Aphasia.**—C. K. Mills states that the three theories regarding aphasia are: (1) The so-called classical view based on the discoveries of Broca, Wernicke, and others; (2) the mental deficit theory of Marie; and (3) Liepmann's doctrine of apraxia as applied to aphasia. The diaschisis of von Monakow must also receive consideration. The older or so-called view of aphasia is one that recognizes a subdivision of the cerebral zone of speech into at least two subareas, the one sensory and the other motor. According to some authorities, a third area, which might be called conceptual, although the term is open to objection, is intercalated between the sensory and motor speech regions. Accepting the subdivision into sensory and motor areas, the sensory region has generally been recognized as subdivided into at least two parts, one auditory and the other visual, these being respectively places of concentration or storage of auditory and visual images. The views of Marie are, in the first place, that auditory, visual and motor speech centers in the sense usually accepted do not exist, that aphasic phenomena are not due to interference with auditory, visual or other images, but to intellectual deficit, this deficit causing difficulty in the comprehension of speech and interfering with numerous didactic processes. Marie also holds that Broca's convolution takes no part in the function of speech, nor its lesions in the production of aphasia. The apraxia theory of Liepmann has lately come into much prominence. The movements concerned with phonation, enunciation, and articulation cannot be so made as to yield intelligible speech, although the patient may be able to use the musculature, out of tune as regards speech, for other purposes, like chewing, swallowing, or breathing. According to the diaschisis doctrine enunciated by von Monakow, circumscribed lesions give rise to symptoms-speech disturbance, paralytic phenomena, etc., much more marked than one would expect considering what is regarded as the special function of the part affected. Groups of associated neurons are injured and functionally affected because of the destruction of some important part of the system. The disturbance of function is widespread as the connections of the part affected are widely situated. Restoration in whole or part may take place as structures are released or new paths are formed. One important fact emphasized by von Monakow and others is that lesions of the brain are rarely purely cortical.

6. **Laryngeal Cancer.**—H. Smith observes that in a man past fifty years, with a history of hoarseness extending over a long period of time, with slight localized discomfort or pain, occasionally referred to the ear, with decreased movement of one side of the larynx, with a wartlike tumor, where the base is well supplied with bloodvessels which radiate from it toward the outer side, one may reasonably conclude that one has cancer to deal with. In the author's particular case the laryngoscopic image indicated syphilis, and a correct diagnosis was still further delayed by the microscopical findings in the first piece which indicated papilloma. If the patient had not had heart, kidney, and arterial complications and could have stood a general anesthesia, laryngectomy in the first instance would probably have proved successful. Under cocaine anesthesia it is difficult to remove the larynx, although there are a number of successful cases on record where local anesthesia alone has been employed. In subsequent cases the author has made deep injections into and around the laryngeal structures, of novocaine solution, before any cutaneous incision was made. In this way the deeper parts can be more successfully anesthetized than when the injections are made superficially and at varying times during the process of the operation. While radium has benefited many superficial epitheliomata, it has not been definitely determined that radium will materially affect deep-seated laryngeal cancer.

7. **Pituitrin.**—A. J. Rongy and S. S. Arluck conclude that pituitrin does not induce labor pains. It should not be used in the early part of the first stage of labor, for its action is too transient. It should not be used in complete inertia because of the danger of rupture of the uterus. It is contraindicated in cases of dystocia due to malposition or contracted pelves. It should never be used in cases in which a sudden rise of blood pressure may prove dangerous. A single dose of pituitrin may be used as an adjuvant in cases where pregnancy is interrupted, either by catheter or bag, and only when contractions of the uterus have already set in. It should be used only in cases in which the cervix is dilated or dilatable and the presenting part engaged in the pelvic outlet. It should be used cautiously in cases in which the fetal heart sounds are feeble or irregular. It should never be used unless a general anesthetic is within easy reach, for the contractions may become so violent that rupture of the uterus becomes imminent.

1. **Antityphoid Vaccination in the Army During 1913.**—F. F. Russell states that the best record obtained by sanitary measures alone is noticed in the year 1908; vaccination, beginning in 1909, has steadily diminished the number of cases, until in 1913 the rate was reduced to five cases per hundred thousand men. What this signifies may be appreciated when one realizes that the civil death-rate (not case-rate), in the registration area of the United States, was 16.5 per hundred thousand of population for the year 1912, the last for which the statistics have been published by the Census Bureau. As regards the death-rates for typhoid fever, one can see that the best record previous to the introduction of vaccination was 0.19 per thousand, made in 1907; this has now been far surpassed by the truly remarkable record of no deaths whatever from this disease in 1913. In the annals of preventive medicine there is only one other campaign with which to compare this, namely, the practical extermination of smallpox by vaccination.

2. **Drainage Versus Immediate Suture of the Common Duct.**—G. W. Crile states that drainage of the common duct presents three dangers: much bile is lost, cicatricial contraction occasionally occurs, and should the drain-tube be occluded, or even if it be not occluded, bile may escape into and infect the peritoneal cavity beyond the field of operation. Owing to an interesting physiological fact, the loss of bile may become a serious danger—a danger which is usually overlooked—as normally the bile passes through the intestinal tract, and the bile-salts are reabsorbed, return to the liver, again become a constituent of fluid bile, and thus continue their circuit. The continuous loss of bile by drainage in a good risk patient may cause no apparent damage, but in elderly subjects and in poor risks from any cause, the steady loss of bile-salts and of fluid may prove fatal. In gall-bladder drainage the bile can be collected and, as Yates has suggested, may be returned to the bowel; but in drainage of the common or hepatic duct much bile is sure to be lost beyond recovery. Occasionally also the bile may leak into and infect the abdominal cavity beyond the field of operation—a circumstance that may prove fatal despite the greatest experience and care. A third danger is also important: the presence of a drain-tube in a bile-duct may of itself cause a partial or a complete stricture of the duct. The author asserts that if a thousand normal common ducts were considerably traumatized and then drained by close-fitting drainage-tubes snugly sewed in and left for a considerable time, there would result a certain number of partial or complete strictures, just as strictures in the cystic duct are produced by the lodging of a stone and just as any other duct may be occluded by the effect of the presence of a foreign body. The common duct is drained as a matter of routine because the duct is handled in a needlessly rough manner when the stone is extracted. To overcome the needless local injury, and to reduce the necessity for drainage to a minimum, the author has evolved a sharp dissection technique. To accomplish the bloodless innocuous dissection which is the goal of the anoci technique, all adhesions are carefully divided with a sharp knife, the dissection being rigorously confined to the bloodless hair-line between the peritoneum and the adhesion. No bloodvessel ever crosses this white line. The whole line of dissection is therefore bloodless, no sponging is needed, and every tissue is accurately identified.

5. **Benzol in the Treatment of Polycythemia Rubra.**—J. S. McLester notes that the use of benzol as a medicinal agent was suggested by the observations of Selling, who studied its influence in the anemia of certain factory girls whose occupation led to the inhalation of benzol gas. His subsequent experimental work on animals showed that benzol caused, first, a marked reduction in the white blood-cells, and later a diminution in the red blood-cells. Examination of the tissues of animals thus poisoned indicated a selective action on the bone-marrow. Von Koranyi was the first to make practical use of these observations. Stimulated by Selling's work he administered benzol to a patient with splenomyelogenous leucemia and produced a remarkable fall in the leucocyte-count as well as reduction in the size of the spleen and improvement in the patient's general condition. He recommends its use in leucemia and also suggests that it might be of value in polycythemia. Numerous other observers have subsequently attested the value of this drug in leucemia. In the literature of polycythemia there are a number of instances of benzol administration. The author's case showed a slight fall in the number of red cells just before benzol was begun. It might be surmised that the subsequent fall to normal was due to natural causes rather than to the drug. On the other hand, such small fluctuations in the red cells are frequently seen in the polycythemias, while no case reported has without benzol shown the steady and complete decrease to normal which immediately accompanied the administration of this substance. The experimental and clinical experiences of various observers quoted, together with the improvement in the author's case, justifies the conclusion that benzol is a valuable therapeutic agent in polycythemia. At the same time in the author's case the ultimate result is as yet a matter of conjecture.

6. **Extraperitoneal Cesarean Section.**—S. J. Druskin discusses the advantages of the extraperitoneal section over the classical operation. In patients with contracted pelves with a conjugata vera measurement of 8¼ centimeters from 65 to 70 per cent. of cases of labor terminate spontaneously, and one cannot with tape and pelvimeter determine beforehand what the outcome of such cases will be. In primiparæ in particular the indication to operate must be exceptionally clear. Nothing but a fair trial for natural labor and careful observation on the part of the attendant during that time can determine whether labor will not terminate without operation. The advantages of the extraperitoneal cesarean section are : (1) Lessened bleeding; (2) non-exposure of peritoneum; (3) lessened danger of postoperative hernia, and (4), most important of all, the fact that the operation can be performed at a time when it would no longer be safe to do the classical operation. (1) Lessened bleeding: In cervical cesarean there is very little bleeding; first, because the lower uterine segment is distended and thinned out, the muscle often being of the thinness of paper; secondly, because no large sinuses are located there; thirdly, because the placenta is not encountered. (2) Non-exposure of peritoneum: The peritoneum remains sealed to infection. No blood or questionable liquor amnii can enter the peritoneal cavity. The intestines do not come into the field of operation. There is no cooling or lesion of the abdominal contents. The operative shock is reduced to a minimum. (3) Exclusion of postoperative hernia: In spite of the fact that the wound is drained, there is no tendency to postoperative hernia, first, because the abdominal wound can be sutured in layers except at the lower angle, and, second, the part drained is outside of the abdominal cavity in the space of Retzius. (4) Time of operation: The operation can be performed when it would no longer be safe to do the classical operation. In fact it is generally performed after the woman has

been in labor a considerable time, long after the membranes have ruptured and after repeated vaginal examinations by physicians and midwives.

**7. A Comparison of the Onset and Character of the Apoplexy Caused by Cerebral Hemorrhage and by Vascular Occlusion.**—W. B. Cadwalader concludes that spontaneous intracerebral hemorrhages are apt to be large; very small hemorrhages are rare. Of seventy-two specimens examined, only four measured less than 4 centimeters in their broadest diameter. It is certain that large hemorrhages are always fatal, and it is also certain that small hemorrhages may be fatal, and it even seems probable that hemorrhages are always fatal, no matter whether small or large. When repeated attacks of apoplexy with hemiplegia occur in the same patient at different times, the final or fatal attack may be due either to softening or to hemorrhage, but the former non-fatal attack is invariably caused by vascular obstruction and softening and not by hemorrhage. Repeated attacks of intracerebral hemorrhage are not compatible with life. Small and moderate sized lesions within the brain, generally described as cysts, are apt to be considered the result of vascular occlusion, but in some instances such lesions may be produced by hemorrhage which has become healed. Their true origin in some cases seems uncertain, but they have been classified here as softenings. The duration of life is generally longer with small hemorrhages than with large ones. Sudden death within a few minutes after the onset of apoplexy does not occur, even though the lesion is a large one. It is remarkable that fairly large hemorrhages may not in all instances cause rapid death. Spiller has recorded a case in which a clot was found partly encapsulated and measuring 7 by 2.5 centimeters, yet the patient lived almost two months. The type of apoplexy produced by hemorrhage and by vascular obstruction is not of a distinctive kind. The onset and character of the apoplexy may be exactly alike, though the lesion is entirely different. But a sudden onset with rapidly developing and persistent coma usually indicates hemorrhage. A slow onset with premonitory symptoms without profound coma may be due to hemorrhage or to softening, but the less severe the disturbance of consciousness the more likely that it is caused by softening and not by hemorrhage. Premonitory symptoms are not characteristic of the lesion; as a general rule they are recorded in the milder types of apoplexy in which the onset is not abrupt. Slowly increasing loss of consciousness ending in profound coma, known as ingravescent apoplexy, is generally due to hemorrhage. It is doubtful if hemorrhage ever occurs without causing very distinct disturbances of consciousness, but it is certain that many softenings do occur without producing distinct apoplectic attacks. Most non-fatal cases of hemiplegia are caused by vascular occlusion and subsequent softening. The mere fact that life is preserved is in itself indicative of the absence of hemorrhage. The type of apoplexy probably depends more on the size of the hemorrhage than on its situation, but with softening the rapidity with which the vessel is occluded may influence the rapidity of onset of the attack as well as the extent of the lesion.

**1. Modern Theories Concerning Hysteria.**—J. A. Ormerod states that there are two groups of very common nervous affections concerning the bodily nature of which one knows so little, that a tendency has now arisen to neglect this aspect of them and to study them chiefly from the side of psychology. These two groups are hysteria and neurasthenia: the first recognized from the early days of medicine and the second modern in name but as is supposed not in reality. These represent two distinct types of disease, though, of course, there may be cases in which they overlap. In hysteria one expects to find, at some time in the course of the disease, outward and visible symptoms, such as fits, paralysis, anesthesia, and the like, which are objective at least in this sense that they force themselves on the attention of the physician, whereas in neurasthenia the symptoms are subjective and cannot be verified by observation. The patients have a different mental outlook: to the neurasthenic his symptoms are always a source of distress and may be a burden to his whole life, whereas the disabilities of the hysterical patient (perhaps the author should say the confirmed hysterical patient) tell far less upon her, and she may even bear her cross with complacency, in short, the reality of the disease appears in the one case greater to the observer, and in the other to the patient. Many of the common and well-known symptoms of hysteria may reasonably be interpreted from the psychological point of view. This indeed is the kind of interpretation which most modern theories on hysteria employ. But there is another class of symptoms which are by no means easy to interpret in this way: the rarer class known as vasomotor and nutritional symptoms. Examples of this class are fever, muscular atrophy, certain skin affections, edema, congestions, not to mention obscure affections of secretion and excretion as of sweat, milk and urine. One can readily understand that hysterical convulsions may be produced by the overwhelming power of some terrible memory, that pain and loss of sensation (which after all are but modifications of consciousness) may be produced by affections of the mind, that paralysis or prolonged contractions of voluntary muscles might be due to some perversion of volition. Moreover, all these things may be artificially produced by skillful hypnotism. But it is difficult to see how such outward and visible signs as edema, congestion, or ecchymosis can be produced by purely mental agencies. One hardly knows as yet how much emotion may do towards modifying bodily states. And emotion is certainly an important factor in hysteria. Secondly, the same physical symptoms sometimes appear and disappear in a way that seems to suggest that they depend upon the patient's state of mind.

**3. The Drainage Tube in Abdominal Surgery.**—J. E. Adams notes that in recent years the value of drainage in the treatment of peritoneal infections has been very seriously called in question. There is much truth in the saying that it is better to drain than not to drain. The following conclusions appear to the author to be justified. (1) Owing to the adhesions which rapidly form around drainage-tubes their value is distinctly limited in the treatment of peritoneal infections. (2) Since the tissues of the abdominal wall possess a much lower degreee of resistance than the peritoneum, drainage of the former may frequently be called for where drainage of the peritoneum is not necessary. (3) The presence and pressure of the drainage tube in peritonitis may determine the transudation of organisms from the lumen of the gut to the peritoneal cavity. With regard to the last observation this secondary infection is of less

serious importance than might be supposed owing to the fact that the wound area has usually been cut off by surrounding adhesions before this occurs. To prevent adhesions between drainage-tubes and adjacent structures the tube should always be rotated whenever the dressing is done, and its gradual withdrawal from the wound should be begun from the third day after operation.

**5. Vaccination Against Hay Fever.**—J. Freeman concludes that hay fever treatment by active immunization with a pollen vaccine, whether judged by statistics or by the experimental method, has succeeded, and the immunity thus acquired seems to last for one year at least after treatment has been discontinued. Patients with marked constitutional disturbances, including asthma, do better than patients with slight and local symptoms. Patients with an inherited tendency do better than people without such tendency. Age makes no difference to the benefit derived from treatment.

**2. A Comparison of Inflammation and Tumor Formation.**—C. F. M. Saint states that inflammation may be either acute or chronic, though all gradations are met with. Both varieties may be produced by the non-infective or infective irritants. When due to the non-infective irritants, the type is determined by the severity of the irritation, whereas, when due to the infective irritants, it is generally determined by their nature—for example, acute inflammation is most commonly produced by the pyogenic bacteria, while chronic inflammation is usually dependent upon tuberculous or syphilitic infection. The degree of inflammation depends, in the non-infective variety, upon the quantity of the causative stimulus, whereas in the infective it depends mainly on its quality. In acute inflammation the blood changes are at a maximum, while the local cell proliferation is, speaking roughly, just sufficient for the repair of the tissues damaged in the process. In such a case the cell proliferation may lead to the regeneration of the tissues destroyed, or, as more usually occurs, the damage is repaired by the development of fibrous tissue—that is, a scar. In chronic inflammation the blood changes are less marked, while the cellular proliferation is increased and usually in excess of that required for repair. The result of this is the production of tumor-like formations, the granulomata, which are responsible for the frequent difficulty in distinguishing between tubercle, syphilis, and malignant disease. Inflammation, however, is not the only response to irritation which is met with. Some tumors are undoubtedly the direct outcome of irritation, others present indications of their dependence on such a cause, while in a large proportion of them no evidence is at present to hand as to their mode of origin.

**1. Therapeutic Value of Gases Introduced into the Pleural Cavity.**—H. M. Davies discusses the merits of nitrogen displacement (artificial pneumothorax) and oxygen replacement. As regards nitrogen displacement in the treatment of pulmonary tuberculosis the author states that many people are of the opinion that nitrogen displacement should be reserved as the last resort in the treatment of tuberculosis, an opinion formed probably from an erroneous impression that the collapse of the lung is permanent. This is a great misfortune, as it deprives the patients of the treatment while they are in a position to benefit by it, and tends also to bring discredit to the method. No case, so long as it is progressive, can be regarded as too early for treatment by nitrogen displacement. There are three types of cases, however, in which this form of treatment is particularly suitable: (1) In which there is a persistent rise of temperature. (2) In which there is profuse or repeated hemorrhage. (3) In which there is cavity formation in one lung. Acute miliary tuberculosis when confined to one lung is no contraindication.

**3. Pituitrin in Labor.**—P. A. Hendley notes that pituitrin is a very valuable aid towards shortening the long and often exhausting first stage of labor, especially in those cases in which the membranes rupture early and a "dry labor" results. It has proved in the author's hands to be a powerful remedy in cases in which shock and collapse have supervened on prolonged chloroform anesthesia, not infrequently inseparable from a difficult case of contracted pelvis. In patients of a nervous temperament pituitrin has also a great influence and the excitement is frequently calmed in an extraordinary manner. Recovery is almost invariably hastened and patients who have previously had pituitrin nearly always ask for its repetition. As a controller of hemorrhage pituitrin ranks very highly in the author's estimation. He worked out the following technique as the best routine method for the administration of pituitrin. When the os admits one or two fingers but not before, the author injects into the gluteal muscles from 0.75 to 1.0 c.c. of pituitrin; if the child is not born within fifty minutes he gives a second injection of from 0.5 to 0.75 c.c. and repeats this dose if necessary. If postpartum hemorrhage supervenes a further injection will almost always control it. Care should be taken, however, the author says, to make quite certain that the syringe and needle are entirely free from any trace of alcohol before filling with the pituitrin, as alcohol is said to interfere with its action.

**6. Erythema Nodosum and Tuberculosis.**—J. O. Symes believes that the association of erythema nodosum with tuberculosis is not merely accidental. This association is far more convincing than the evidence formerly adduced to prove that the disease is of rheumatic origin—a view that is now rapidly disappearing. The author is convinced that erythema nodosum is a distinct clinical entity, probably a specific infective fever, but it seems likely that there have been included under the same name other erythematous nodular rashes, some of which should be classed as rheumatic, some as erythema multiforme, and others again as a tuberculous manifestation, the last named being evidence of the presence of a widespread and not infrequently fatal septicemia.

*April* 6, 1914.

**Headache and the Eye.**—Jess enumerates many conditions of the eyes, mild and severe, which give rise to headache. Anatomically only about 25 per cent. of all eyes are normal, so that the neuro-muscular tissues may or may not be subjected to constant overwork. The results may be complex headache being one of a number of intracranial symptoms. The view that these disturbances tend to occur by preference in neuropathics is not completely borne out by facts. The disappearance of intracranial disturbances after wearing glasses is a very common phenomenon, but is by no means confined to connection of simple refractory errors. It is the use of prisms for muscular asthenopia, or of hyperopic glasses for accommodative asthenopia which relieves the average eye headache. Naturally astigmatism may be an additional factor. It is a peculiarity of hyperopia that it readily sets up blepharitis and conjunctivitis which aggravates the already present eye weakness and fatigue. Some bacterium is present if a true conjunctivitis develops, and special asepsis becomes a part of the treatment. While epileptics and other neuropathic degenerates do not suffer especially from eye headache the reverse is true in the case of simple neurasthenia, and these patients are subject to constant headache which cannot be traced to the eye. If a headache be unilateral it is especially prone to be associated with eyestrain, and it occurs as a rule in paroxysms. As a prodrome of both kinds of glaucoma we see headache and facial neuralgia of the severest types. A darkness before the eyes, followed by the appearance of colored rings about a light, after eye strain from near work suggests a fundal examination for glaucoma. Headache frequently acompanies choked disks, and of course any of the diseases which raise the intraocular tension. The author discusses headache and retinitis as they are associated in toxemia of pregnancy. The omission of migraine and its prominent eye symptoms is noteworthy.

**Rectal Feeding.**—D'Ayata discusses this subject thoroughly with especial reference to operations in the mouth and pharynx. The metabolism of these patients was carefully studied before the operations, and rectal feeding had already begun one day before operation. The bowels were rendered as empty as possible before the first enema was given. This consisted of 200 c.c. broth, two egg yolks, 25 c.c. Marsala wine, and a teaspoon of salt, and was given every six hours. The unabsorbed fluid was meanwhile withdrawn, when the bowel was being cleansed, and analyzed. During this period of feeding the entire ingesta and egesta were measured, the number of calories, the behavior of the N, the urinary and fecal discharges, etc. The logical conclusions are by no means final. There was naturally no nitrogen retention, but the loss was slight. Patients felt well throughout. It has been repeatedly shown that patients can be kept alive indefinitely by rectal feeding, and no further proof of this is necessary.

**Therapy of Syphilitic Nervous Diseases.**—Oppenheim has in the past two years treated from 130 to 135 cases, chiefly of metasyphilis, a minority representing cerebrospinal syphilis in the narrower and older significance. The latter comprise 20 cases of cerebral lues. But eight showed under salvarsan pronounced favorable results; nine showed no improvement; three became worse. There were four cases in which the disease followed upon the treatment, two of which improved under the continuation of treatment. There were 15 cases of lues spinalis (including a few of socalled cerebrospinalis). Six showed great improvement, seven no improvement, and two became worse. Fifty tabetics were treated with salvarsan, and 10 showed improvement in some respects. In 11 no amelioration of any sort was noted and some of the symptoms seemed greatly accelerated. In the remaining 29 there was no real improvement, nor was the rate of progression increased. Improvement in one quarter was offset by aggravation in another. In two special cases it was quite apparent that salvarsan properly used in early syphilis did not prevent an early development of tabes. In 24 cases of paresis there were but two of improvement. Fifteen were uninfluenced and six were rapidly made worse. The author also tested a number of miscellaneous cerebral and cerebrospinal diseases in syphilitics but without obtaining any positive results (save in one case which was shown later to be lues spinalis). The author warns against the unconditional adoption of his conclusions, because his control of the cases was incomplete—the drug having been administered by others, and many of the cases were seen first in consultation, after having been under treatment. Dreyfuss, Citron, and others, claim a greater degree of success from pushing salvarsan, *i. e.* increasing the dose at even intervals. The author, as one of the most experienced of neurologists, states that allowance must be made for the spontaneous improvement which occurs in tabes. Spontaneous arrest is by no means infrequent. In regard to untoward effects of the drug the author has fortunately seen no fatalities, but aside from the cases of acceleration of the disease process already mentioned he has seen two cases of encephalomyelitis gravis. One in a young, beautiful and accomplished actress was a tragedy. She had had intercourse with an infected man, and although there was no evidence that she had contracted the disease (Wa R doubtful) she was given salvarsan. She developed complete paraplegia, paresis of bladder and rectum, bed sores, affection of optic nerve, etc. For the past year, however, the author has not seen a single case of this character. In regard to the Wa R diagnosis (blood and cerebrospinal fluid) as advocated by numerous syphilographers, the author holds skeptical views. One count deals with the association of the latter fluid with the disease tabes. To be logical the investigators are pushing salvarsan until the cerebrospinal fluid in tabes shall give a negative Wa R. This suggests the cure of epilepsy by continuously giving bromides. The author feels scruples at opposing his clinical experience with the results of more rational methods. But when he recalls the number of ex-tabetics now useful members of society who once gave a positive Wa R yet received no salvarsan, he wishes to insist on this feature of the disease, without at all antagonizing the scientific work of Ehrlich.

*March* 31, 1914.

**Treatment of Delirium Tremens.**—Scharnke discusses this affection as one of relatively small mortality—in other words, a benign disease. Much confusion arises between this viewpoint and that which makes of it a deadly affection in which 50 per cent. die irrespective of treatment. The latter type was but recently discussed by two psychiatrists of Boston. The present author, a military surgeon, deals presumably with cases in troops, a class of subjects which by the very nature of things could bear little resemblance to old.

drunkards no longer able to "assimilate" spirits. Despite the great variation in material there is doubtless on the surface more or less resemblance between the two aspects of the disease. That is, the victim of a mere prolonged spree, himself sound at the outset, may develop the phenomena seen in the "terminal" delirium tremens of the chronic alcoholic. The author assumed charge of a psychopathic ward over a year ago. Many cases of delirium tremens were received here, and nearly all showed rapid pulse (up to 180), profuse sweating and marked weakness, coupled paradoxically with tireless activity. The chief treatment consisted of digitalis, with veronal as a sedative. Baths are absolutely contraindicated. Patients showed great aversion toward these remedies, and sherry or some other alcoholic was needed to disguise them. Milk is freely given, perhaps with a little brandy or sherry to give it zest. Rapid recovery is the rule. The Massachusetts men found it necessary to use opiates, bromides and chloral to control their cases, and even then half were lost—this mortality showing the great difference in delirium tremens material.

**Attempted Suicide from Digalen.**—Krönig believes that the following case deserves interest, because probably the first in which the above substance was used. The attempted suicide was a merchant of 33. While in the army he developed some cardiac lesion as a result of drilling, and was said to have an impure second sound. After his discharge and while engaged in business he developed an acute heart lesion with enlarged liver and edema. This attack yielded to digitalis and rest in bed. Later, after much physical exertion, he had what was doubtless cardiac dyspnea, for which he was given digalen. The patient then consulted the author, who found evidence of early intercurrent syphilis. All the organs seemed negative, save the heart, which was the seat of mitral stenosis of a serious type. On account of the recent lues salvarsan was considered, but rejected by reason of the cardiac lesion. Mercury was given in inunction and intramuscular injection. The patient gave the disease to his wife, who was treated both with salvarsan and mercury. The accident of a venous thrombosis in connection with the use of salvarsan led to a quarrel, as a result of which the husband drank 15 c.c. digalen. He was found in an agitated state, but with good pulse and heart action. He was induced to drink cognac and coffee. Aside from a drop in the pulse rate to 52 and profuse diuresis there was nothing further to record. In a few days patient resumed his occupation.

*April* 2, 1914.

**Studies of the Spirochete in the Paralytic Brain.**—Forster and Tomasczewski give an excellent summary of our knowledge on the subject including their own contribution. About one year ago Noguchi first made the discovery of the spirochete in the cerebral cortex of a paralytic. Their number was found to be considerable, while the type was that which occurs in ordinary syphilis. Anatomically the case was one of typical paresis. The first obstacle was the inconstancy of the finding, for only in a minority of cases was the germ discoverable (Noguchi, 24 per cent. in 200 cases, while in the material of others this percentage was much lower). As the great preponderance of negative finds should have been due to defects of technique the authors in a material of sixty-one cases sought to improve the latter and succeeded to such a degree that 44 per cent. positive finds were obtained. The authors, unlike their predecessors, worked with small bits of tissue. It was apparent, however, that the absence of the spirochete was often genuine and not due to careless technique. There is a certain ill-defined relationship between the clinical type or stage of disease and the frequency of spirochete finds. Thus in juvenile and pure dementia forms they seem to be numerous. Aside from certain tinctorial peculiarities these spirochetes cannot be shown to differ from the ordinary type. Noguchi first succeeded in inoculating matter containing spirochetes into rabbits, with transmission of the parasite. Others also succeeded in inoculating puncture material into rabbits and apes. There was nothing learned here, however. Successful inoculations were infrequent, the lesions were insignificant; in fact it appeared that the spirochetes' sojourn in the cortex had brought about a biologic alteration.

**Twilight State with Successive Amnesia after Slight Commotio Cerebri.**—Kirschgässer refers back to a case which was not long ago reported to the *Wochenschrift*. The original reporter, Dr. Meyer, believed the case to be one of epilepsy. The woman committed a crime during this supposedly irresponsible state and was placed under the observation of Dr. Kirschgässer. The latter regarded the woman's case as primarily one of hysteria aggravated by her husband's neurasthenia. There was general disharmony between the couple. On a Sunday morning the wife lay abed because of an ulcus cruris. The stepdaughter then had to prepare a breakfast before churchgoing. The fact that she cooked bacon infuriated the husband, who was vegetarian. He and his wife began to quarrel and at last he beat her badly. The quarrel was renewed off and on during the day, the wife submitting to physical abuse, but continuing to preside over the household. During the entire day the husband ordered her to leave the house and threatened divorce proceedings. Fearing for her own children she drowned them, an act which she seemingly failed to remember. Kirchgässer repudiated the idea that the beatings given the woman contributed in any direct way to her lack of responsibility; that is, there was no material lesion present like commotio cerebri. The entire process was psychic, a mental trauma produced upon a hysterical subject possessed of intense egotism. The beatings, threats of divorce, commands to leave the house, etc., caused a state of mind which led to infanticide.

---

**Lichen Planus Hypertrophicus.**—D. Corbett reports the case of a girl aged fifteen years who came under observation a fortnight ago with this condition which had started six weeks previously. The patches had a linear distribution on the anterior aspect of the right arm, extending to and involving part of the thenar eminence. The lower patches were raised above the level of the surrounding skin and were covered with a dense layer of horny epithelium. The patch of the upper arm was of more recent origin and it could be seen that the process had started in the hair follicles. Pigmentation was evident in the older lesions, being of a bluish red color. There were no other lesions on the body. The patient had had two one-third pastille doses of *x*-rays at an interval of a fortnight, which had altered the appearance of the lesions considerably, all the hyperkeratosis had disappeared, and the patches were now level with the surrounding skin. No other treatment had been used and no arsenic had been given. The condition at first sight resembled a unilateral nævus, but closer inspection, and the fact that improvement under *x*-rays had been so rapid, showed that it was a hypertrophic lichen planus with a linear arrangement. The age of the patient and the unilateral distribution marked this as an unusual case.—*Proceedings of the Royal Society of Medicine.*

## Insurance Medicine.

**Mortality of War.**—Florschütz's paper on this subject is naturally very largely statistical, and he brings the disease mortality as far as the War of Insurrection in Austria, in 1882, going back as far as the Crimean war, 1854. The gross mortality includes the consequences of fighting and disease combined, and this is brought down much later. The net mortality does not include remote deaths from injuries. The table of mortality from disease shows plainly the great part played by the folk plagues. In the Franco-Italian war of 1859 "typhus" and dysentery prevailed alike in the French army, and the same disease caused much of the mortality among the German troops in the Franco-Prussian war, 1870-1, dysentery being a minority factor. Also in the Russo-Turkish war (1877-8) the Bosnian occupation (1878) and the Austrian war of insurrection (1882), the same affections were chiefly in evidence in such bodies of troops as furnished statistics. The mortality from dysentery as contrasted with that of typhus appears to have fallen off considerably as a whole. Cholera was the chief cause of mortality in the Crimean war (1854-6) and in the conflict between Bohemia and Prussia in 1866. In regard to "typhus" the author makes no distinction between the exanthematic and abdominal forms, but he clearly refers to the latter (typhoid fever) as the army plague.

A study of the infectious diseases from the Crimean war to date shows that, in the order named, five of them are to be reckoned with as causing mortality; these are typhoid, dysentery, and cholera, with a much smaller contingent of smallpox and malaria. These would be scourges to-day had not the recent marvelous advances in prophylaxis come into practical usage. In the most recent wars, notably the Russo-Japanese, the author gives only the relative mortality from warfare and disease, the latter not being analyzed. While in the Spanish-American war the loss from disease was far greater than that from warfare, the later conflict shows a marked reversion of percentages; the Russians lost about 34 men in battle to 9 killed by diseases, and the Japanese about 60 men from wounds to 37 from diseases. In the Turko-Bulgarian war cholera was fairly jugulated after it gained some foothold. The authors only conclusion is that in future wars the mortality from pestilence is bound to decrease progressively.—*Blätter für Vertrauensärzte der Lebenszersicherung*, Vol. V, No. 1, January and February, 1914.

**Effect of Alcohol on Longevity.**—In an address given by Arthur Hunter, actuary New York Life Insurance Company, at the Conference on Race Betterment, a synopsis of which is published in *American Medicine*, February, 1914, the effect of alcohol on longevity is considered. It is pointed out that the results of various tests made by Kraepelin and others into the effects of small doses of alcohol on muscular power, indicate that it has a detrimental effect. Opinions from famous soldiers like Kitchener and Roberts show that in warfare abstainers stand more hard work than those who drink in moderation. The popular opinion that more work can be done with alcohol than without it is not supported by the facts, and is doubtless due to the pleasant feeling of buoyancy which alcohol produces. As for mental efficiency, tests of translating from one language to another, of adding, of writing, of memory, etc., show a marked loss of efficiency through small doses of alcohol. The Rosanoffs contend that "alcohol impairs every human faculty that has been tested; the higher and more complex the faculty, the more pronounced is the effect." The opinions of the medical profession are in the main in the same direction, although attention is drawn to Col. C. E. Woodruff's paper on the beneficial effect of alcohol in the tropics. In order to demonstrate the effect of alcohol on mankind statistics are given of the mortality of men engaged in the manufacture and sale of alcohol. These men were insured by forty-three of the leading life insurance companies, and their habits at the time of application were considered satisfactory. The mortality shown in the following tables represents the extra mortality over the normal experience of these companies:

Liquor and Beer Saloons—Proprietors and managers not attending bar, extra mortality, 82 per cent. Proprietors and managers attending bar, extra mortality, 73 per cent. Hotels with bar—Proprietors, superintendents, and managers attending bar, extra mortality, 78 per cent. The following deals with men who do not attend bar, although liquor is served on the premises: Hotels with bar—Proprietors, superintendents, and managers not attending bar, extra mortality, 35 per cent. Restaurants with bar—Proprietors, superintendents, and managers not attending bar, extra mortality, 52 per cent. Statistics were also supplied of persons in two other branches of the liquor business as follows: Breweries—Proprietors, managers, and superintendents, extra mortality, 35 per cent. Wholesale liquor houses—Proprietors and managers, extra mortality, 22 per cent. With regard to the formerly intemperate it was shown that the life insurance companies had experienced about 50 per cent. extra mortality among men who occasionally drank to excess more than five years prior to date of application, and had been temperate up to that time. The steady so-called moderate drinkers, men who were considered average lives by the insurance companies, were found to have a very considerably higher mortality rate than among the more abstemious class.

A prominent life insurance company divided its policy holders into four classes, depending on the extent to which they used alcohol. The following table gives the percentage of the mortality on the basis of the American table: Total abstainers, relative mortality, 59 per cent.; rarely use, relative mortality, 71 per cent.; temperate, relative mortality, 84 per cent.; moderate, relative mortality, 125 per cent.

In a table is given the extra mortality in the non-abstainers over the abstainers' section. United Kingdom—Temperance and General Provident Institution, extra mortality of non-abstainers over abstainers, 35 per cent. Scottish Temperance Life Assurance Company, extra mortality of non-abstainers over abstainers, 40 per cent. Sceptre Life Assurance Company, England, extra mortality of non-abstainers over abstainers, 50 per cent. Australia Temperance and General Life Assurance Society, extra mortality of non-abstainers over abstainers, 60 per cent. Manufacturers' Life Insurance Company, Canada, extra mortality of non-abstainers over abstainers, 75 per cent. The author is satisfied from a study of the foregoing statistics that total abstainers live much longer than non-abstainers.

# Book Reviews.

DENTAL ELECTROTHERAPEUTICS. By ERNEST STURRIDGE, L.D.S. (England), D.D.S., Fellow of the Royal Society of Medicine, Member of the British Dental Association, Member of the British Society for the Study of Orthodontics, Associate Member of the American Dental Society of Europe, Member of the American Dental Society of London, Contributor on Dental Electrotherapeutics in "The Science and Practice of Dental Surgery," etc. Illustrated with 154 engravings. Price $2.75 net. Philadelphia and New York: Lea & Febiger, 1914.

THE scope of this volume as outlined by the author includes a concise exposition of the fundamental principles of dental electrotherapeutics. Particular emphasis is placed upon the value of ionic medication in the treatment of periodontal diseases, which form of treatment is within the reach of every dentist. Part I deals with electrophysics, including chapters on frictional or static electricity, galvanic electricity, cells, magnetic field, dynamo currents, batteries, battery accessories, dental electrical apparatuses and appliances, and the Roentgen rays. Part II takes up the subject of electrotherapeutics and includes chapters on electrophysiological effects, physiological effects of current, electrotherapeutic effects, technique of ionic medication in dental operations, high frequency and static currents, electrotherapeutics in dentistry, treatment of pyorrhea alveolaris, and anesthesia, bleaching, and neuralgia. The book is well written, contains a large number of excellent illustrations, and should prove of eminent practical value to the dental student and dental practitioner.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. Embracing the entire range of scientific and practical medicine and allied science. By various writers. Third edition, completely revised and rewritten. Edited by THOMAS LATHROP STEDMAN, A.M., M.D. Complete in eight volumes. Volume three. Illustrated by numerous chromolithographs and six hundred and sixty-five half-tones and wood engravings. Price $7.00 net, cloth. New York: William Wood & Company, 1914.

IN these days of pet theories and fluctuating standards, with the vast accretions of knowledge from the outlying domains of research, the need of an authoritative work of reference such as this, that mirrors the essential facts of medical progress, is more urgent than it has ever been. In previous reviews it has been pointed out that the student and practitioner may use this work in the systematic study of certain topics, or they may use it solely for reference. The present volume admirably illustrates this dual character. Some of the articles of unusual interest are the following: Congenital family cholemia is described with full reference to the most recent knowledge of this subject. In the article on Huntington's chorea the eugenic studies of Davenport, Muncie, and Jelliffe are alluded to and the fact is pointed out that the study of one thousand cases of this disease shows that the condition appears at earlier years in succeeding generations. The question of heredity is again discussed in the article on the chromosomes, in which it is shown that there is a remarkable parallel between the behavior of the latter and the distribution of the unit characters. A series of articles on the physiology and pathology of the thoracic duct and of its tributaries throw considerable light upon this very much neglected subject of medical study. In the article on chylangioma it is noted that this condition is not synonymous with chylous cyst. There is a special article on chylous accumulations, including mesenteric cysts, chylous ascites, chylocystocele, chylothorax, chylopericardium, and chyluria. The last is also discussed in a separate article. Fourteen pages are devoted to the subject of climate. Climatotherapy is also discussed in its general aspects, in addition to the separate articles on the various health resorts. Color perception is treated in full detail, nineteen pages being given to this subject. There is an interesting historical review of the various international congresses of medicine, from the first congress held in Paris in 1876 to the seventeenth congress held in London in 1913. The various other national and international congresses are also described.

The article on diseases of the conjunctiva is illustrated by an excellent colored plate showing the different types of this disease. The biological and legal aspects of consanguinity provide an interesting topic. It is pointed out that consanguineous marriages if properly safeguarded are capable of insuring an unusual degree of mental and physical excellence in the resulting progeny. In the article on disorders of consciousness there are discussed such subjects as somnambulism, nightmare, catalepsy, compulsion neuroses, etc. A very useful article of six pages on cosmetics contains a large number of prescriptions. The subject of cough is discussed in its general aspects and the principles that govern its treatment are presented in detail. The article on coxa vara contains a number of excellent illustrations. A section of eighteen pages is devoted to the cranial nerves and one of five pages to cranioencephalic topography. A timely article is that which deals with the asexualization of criminals and defectives. Criminology is also dealt with in its modern aspects. The care of cripples is discussed from the viewpoints of history, statistics, systems of care, principles of care, primary education, industrial education, and American and foreign institutions. This article is an eminently practical one, as is also that which is devoted to the subject of deaf-mutes. Death is dealt with from the viewpoints of certification, modes, physiological theories, and signs. There is an excellent and timely article on demography.

The subject of diabetes mellitus is discussed with reference to the latest methods of treatment. Of special interest is the fact that there are given definite directions as to where the various forms of diabetic bread and biscuits may be obtained. Physical diagnosis is discussed in satisfying detail with the aid of two excellent colored plates. The diseases and injuries of the diaphragm are dealt with in an interesting manner. Diathermy is one of the recent therapeutic methods that comes in for its proper attention. There is an article of twenty-one pages on the digestive tract. The article on diphtheria presents all the latest facts in connection with this disease, particularly with reference to the use of massive doses of antitoxin and the question of anaphylaxis. There is a table showing the comparative germicidal powers of various disinfectants. Thus, bichloride of mercury has a germicidal power of four hundred while that of carbolic acid is represented by the figure 1 and formaldehyde by the figure 0.70. Disinfection is discussed in its most practical phases. There is an elaborate and well illustrated article of thirty-four pages on dislocations. The article on dreams contains an exposition of Freud's theory of their interpretation. The subject of the ear, including its anatomy, the diagnosis, and the general therapeutics of its diseases, the intracranial complications of otitis media, syphilis of the ear, and tuberculosis of the ear, comprises a section of nearly one hundred pages. There is a rather extensive article of twenty pages on eczema. Among the concluding articles of this volume may be mentioned those on electricity, including discussions of the destructive effects of high-pressure currents, electrocoagulation, electrodiagnosis, electrolysis, and electrotherapeutics. Among the large number of illustrated biographical articles in this volume may be mentioned those on Sir Andrew Clark, Credé, Jean Cruveilhier, Charles Robert Darwin, Nathan Smith Davis, and Wilhelm Ebstein. The descriptions of health resorts are particularly complete, that on the city of Denver being a good example.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE, Herausgegeben von Dr. L. KATZ. Spezialarzt für Ohren, Nasen- und Halskrankheiten in Ludwigshafen A. Rh.; Dr. H. PREYSING und Dr. F. BLUMENFELD, Prof. der ohren, Nasen, Kehlkopfheilkunde; ord, Mitglied der Akad. für Prakt. Medizinzu Cöln A. Rh.; Spezialarzt für Nasen, Hals- und Lungenkrankheiten in Weisbaden. Price 3 marks. Würzburg: Curt Kabitzsch, Kgl. Univ. Verlagsbuchhandler, 1914.

THE subject of the present installment of this comprehensive work on the special surgery of the ear and of the upper air passages is the functional testing of the organ of hearing. The article is written by Gustave Bruhl of Berlin. All of the modern developments in this important field are represented in fullest detail. The various appliances employed in this rather difficult field of diagnosis are illustrated with the aid of many drawings. There are illustrations of the different tuning forks, of Pulitzer's akumeter, of Struyken's monochord, of Buys' nystagmograph, etc. The subject of otocalorimetric investigation is presented in minute detail. The modern otologist cannot dispense with a volume of this kind.

## MEDICAL SOCIETY OF THE STATE OF NEW YORK.

*One Hundred and Eighth Annual Meeting, Held in New York City, April 27, 28 and 29, 1914.*

(Special Report to the MEDICAL RECORD.)

(*Continued from page 867.*)

### SECTION ON SURGERY.

DR. LUCIUS W. HOTCHKISS OF NEW YORK, CHAIRMAN.

*Tuesday, April 28—First Day.*

**Exophthalmic Goiter; Its Treatment.**—Dr. JOHN ROGERS of New York presented this subject. He said that there were three stages of thyroid disease; the first simple hypertrophy; second, following or alternating with this, hypothyroidism; third, exophthalmic goiter. The first stages might persist indefinitely; the disease might retrogress and the symptoms disappear. If hyperthyroidism persisted a gradual rise of arterial tension occurred. Only a small proportion, 25 per cent., became exophthalmic. This might develop slowly or suddenly. High pressure accompanied this symptom. In the chronic condition disturbance of the heart, lungs, kidney, digestive tract, etc., followed. The disease terminated with toxic symptoms and the patient died of myxedema. In some cases there was no thyroid enlargement, but the nervous symptoms were very marked. In these the prognosis was bad. Others showed considerable exophthalmos but little tachycardia. In these cases radical operation was uncertain. Deaths were more frequent in the exophthalmic stage. Grouping was important on account of the treatment. In young, undeveloped girls operation was contraindicated as the disease might recur. In older women hemithyroidectomy gave good results. In small, symmetrical enlargements ligation was the safer course. The history of cases showed characteristic symptoms of fatigue; sleep was disturbed; in the hypothyroid cases sleep came early in the night and the patient woke early, in the hyperthyroid, sleep came late and lasted late. The pathology of the disease showed proliferation of the alveoli; in toxemic cases changes in the colloid; in chronic cases there were sclerotic lesions in the heart. The physiological importance of the gland was in its production of secretion. It aided in oxygenization, and its content of nucleoprotein and of iodine was large. This was decreased in the more serious disease. The cause of hyperthyroidism was fatigue of the gland. The demand of the system was greater than it could supply.

Dr. M. B. TINKER of Ithaca said that if the disease were recognized early enough many patients might be saved, and some cases of insanity prevented. Physicians failed to give proper treatment simply because exophthalmos was absent. It was a mistake to suppose that patients suffering from goiter had too much thyroid secretion. They had not enough, because the normal substance of the gland was crowded out.

Dr. EMILY BARRINGER of New York said that in girls and young women suffering from thyroid disease there was a very frequent history of overwork. This was a more frequent cause than fright. There was often a history of infectious disease, causing lowered resistance; various disorders of menstruation played a part—this was delayed rather than profuse; or anemia (with low hemoglobin and a lymphocytosis) was found. Many cases which she classed as incipient exophthalmic goiter cases were in school girls, college girls, or shop girls. These cases responded to rest, iron, and general tonic treatment. Fatigue seemed to be the chief causative factor and early treatment was of the highest importance.

**The Present Status of the Surgery of Spastic Contractures.**—Dr. A. S. TAYLOR of New York read this paper, in which he considered only those procedures which depended upon the central nervous system rather than upon orthopedic measures. There were three methods of attack: upon the peripheral nerves, upon the posterior spinal roots, and upon the cranium. In the former the nerve trunks running to the spastic groups of muscles had been isolated and dissected out and injected with 50 to 80 per cent. alcohol, causing complete paralysis of the muscles. During the period of flaccid paralysis the antagonists were exercised in order to balance up the function. Satisfactory results had been reported from this method. It had also been demonstrated that the spastic condition depended on exaggerated condition of the spinal reflexes and damage to some part of the tract removed inhibitory control and caused excessive reaction of the muscles. The activity could be diminished by breaking the reflex arc, and the balance could be restored. This was shown in spastic paraplegiacs who had developed locomotor ataxia. Development of the ataxia, which was a disease of the posterior spinal roots, caused disappearance of the spasticity. In Dr. Taylor's experience cases of spastic paralysis of the upper extremity could be relieved by this operation but the functional results were not good. The results were far better in the lower extremity. The after treatment in these cases was as important as the operation. It required intelligent co-operation on the part of the patient. These cases were often mentally defective, but the patient must have the mental capacity of four years, to grasp the necessary muscular movements. Education in these, and massage and passive exercises constituted the correct after-treatment. Often a child who would otherwise have been a hopeless cripple, could get about fairly well. In cases with marked intercranial pressure the pressure must be determined by the eye grounds and a subtemporal decompression made. The treatment was recent, but the operation was simple and free from danger and the results so far had been good.

Dr. E. BEER of New York said that in 1904-5 he was doing some work with Dr. J. Fraenkel of this city. He thought that by cutting the posterior nerve roots flaccidity might be produced, basing his conclusions upon cases where the lateral tract was involved and locomotor ataxia developed. A series of injections were done by them at the Montefiore Home, using eucain or tropocain; one worthy of comment was a child with bilateral spasticity of all extremities. He developed hemianesthesia with relaxation on one side, on the other (non-anesthetic side) spasticity continued. In Dr. Beer's experience the cases were not so satisfactory as at first reported. It might be that the Stoffel operation would replace the cutting of nerve roots. One important point was that only cases should be tried in which the spinal lesion was not progressive; if progressive spasticity would recur.

Dr. TAYLOR, in reply to Dr. Beer, said that as regarded results one did not hope to get a perfect child, but if anything could save the child from being a hopeless cripple it was worth while, even if the results were not brilliant. In the class of people from which most of these children came it was hard to get the mothers to give them the necessary after treatment.

**The Value of the Various Tests for Determining the Functional Activity of the Kidney before Operation.**—Dr. JAMES N. VANDER VEER of Albany said that he considered it would be valuable to present the section with the relative value of various reactions of the kidney. He had written 150 letters to various genitourinary surgeons as to the importance of tests. The genitourinary men were more in touch with these tests of kidney function. We could not compel the general surgeons to use laboratory evidence. They preferred to take the case as a clinical entity. In a large number of cases the patient was hurried to the operating table without complete examination. This added to the death ratio, but it half an hour were given to examination, death might be averted. A case which recently came to his attention was one in which the patient was told she had carcinoma of the breast and that there was no time to be lost. Although the urine contained large quantities of albumin she was hurried to operation, put under ether anesthesia and 36 hours later she died. In another case the surgeon took the precaution to make a preliminary examination, and, finding the kidney condition bad, kept the patient in hospital till it cleared up. Ether was not used, but some other anesthetic, and the patient came through well. No doubt death might have occurred in the first case in any circumstances, but the second case also would have died, if examination had not been made. Objection had been made to the various tests—study of sodium chloride excretion, the phloridzin test, the methylene blue stain test, the phthalein test, etc., that they were too long and too difficult. The phenolsulphonephthalein was the simplest and was of great value. The diastase test was complicated and required technical work. Each test, however, had its importance, and his plea was that some test or tests be used before

operation to reduce the ratio of deaths that occurred from too hurried examination.

Dr. E. WARE of New York said that his criticism was destructive rather than constructive. Now and then a doctor would say he wished he had done tests but the statistics showed that those who did got no better results than those who did not. No man living knew what the function of the kidney was. The latest definition of the function of the kidney was the excretion of solids in solution, and no one knew more than that. More evidence could be obtained clinically than functionally. A surgeon who had a case of anuria with two stones could not stop to take a phthalein test. Many men were opposed to them.

Dr. GIBBONS of New York said he had 40 years' practice of general surgery. He had never lost a patient on the table or from operation. It was a matter of common sense not to operate when a person was dying. He called it "surgical cunning." There was a saying that if the pathologist said "cancer" the patient was safe; if he said "non-malignant" the patient was doomed. There were as many new-fangled tests 40 years ago as there were today.

Dr. PILCHER of Brooklyn said that urologists were earnest men and trying to accomplish something. We did not know what the function of the kidney was, but if it failed the patient must die. In some cases it was necessary to know which kidney was functionating the best. It was worth while to work on the tests and save the life of the patient.

Dr. E. BEER of New York said he was absolutely of the opinion of Dr. Vander Veer and Dr. Pilcher. Much loose thinking went on in this field. It was not logical to conclude that because a patient excreted much phthalein that the kidney was good. He might excrete a quantity and yet have uremia. Each test had its own indication. Tests required interpretation and a minimal "combined excretion" of these various test substances in symmetrical supravesical disease spelt disaster. In asymmetrical supravesical disease it might be ignored as due to inhibition.

Dr. VANDER VEER agreed with Dr. Beer as to the loose thinking that prevailed. He did not agree with Dr. Gibbons that "surgical cunning" was sufficient. A man with "surgical cunning" might operate on the wrong kidney.

**Transfusion of Blood, Direct and Indirect; A Consideration of the Technique and Relative Value of Different Methods.**—Dr. JOHN A. HARTWELL of New York gave this paper. He said that his viewpoint of the subject might possibly be considered a destructive one. A broader aspect of the subject of blood transfusion was essential to advance. The methods of transplant and the avoidance of coagulation had been chiefly considered. The blood had not been considered in the light of homologous transplant of tissue but simply as the infusion of chemical substance. Important points to be studied were: Was the tissue transplanted so that it could live; was the pathological condition of the host favorable to the life of the tissue; did any condition exist in the new tissue that was deleterious to the host? The recent literature showed the trial of this remedy to be based largely upon speculation. Only in the condition of loss of blood by hemorrhage was there direct evidence of service to the patient. Provided no hemolysis occurred the new blood met the requirements. Anemia without hemorrhage was a symptom, not a disease, and nothing could be gained by adding new blood unless the disease were controlled. In the case of hemophilia and hemorrhage the indications were not only to infuse blood but to alter the disease as well. Blood serum might do as well. In infectious diseases we might expect some help from transfusion, from the bactericidal activities of the serum, but experience had not realized this hope. The chief methods were the direct transfusion, advocated by Crile and Carrel, and the indirect, or syringe-cannula method of Lindeman and others. By the latter 1000 c c. of blood might be passed from donor to recipient in 15 minutes. The cannula did not pass through any traumatized tissue. Simplified technique in these two methods would afford opportunity for further study.

Dr. G. CRILE of Cleveland said that there was no question that in surgical shock transfusion was of the greatest benefit. Anastomosis could be made before operation and as much blood given as was necessary to keep up normal pressure. Direct transfusion became easier with practice and with a well-trained staff. To measure the blood was unnecessary. Enough should be given to make the patient safe. In pernicious anemia, where chemical change had taken place in the recipient's blood, transfusion could do no good.

Dr. D. KALISKI of New York said it was important to do preliminary tests to ward off accidents due to hemolysis and agglutination; also a Wassermann test was important.

Dr. E. LINDEMAN said the advantage of the indirect method was that it was done without skin incision. The length of time the blod was outside the body was 6 seconds. Hirudin was not necessary. In less than 15 minutes 1000 c.c. of blood had been transfused.

Dr. R. DAWBARN of New York said one could get the same results by infusing hot saline, on the operating table. Intravenous or hypodermic doses of ergot, .5 to 200 of saline, gave excellent results.

Dr. HARTWELL said Dr. Crile had been very fortunate in his staff. In New York one could not get donors to take to the direct method. They did not like the incision and they would not come back. Dr. Crile could make them do as he wished in Cleveland, apparently.

*Wednesday, April 29—Second Day.*

**The Surgery of Cranial Fractures, with a Brief Consideration of the Results, Immediate and Remote, of Fractures of the Vault and Base of the Skull.**—Dr. CHARLES A. ELSBERG of New York read this paper. He stated that fractures of the skull formed 5 per cent. of all fractures treated. Their essential difference from other fractures was that the injury to the bone was unimportant. The importance lay in the injury to the brain and nerves and vessels surrounding it. There were two types of cranial fractures, and treatment depended upon the type. First were those caused by direct impact in which the injury occurred at point of impact; second, those where the injury occurred at a distance from the blow. The direct fractures called for operation, but in the indirect the indications for operation were much less. Conservatism in treatment of fractures was important. The patient should be watched and diagnosis should decide whether the lesion was stationary or advancing; if stationary, operation was not indicated. With increasing signs of cranial pressure in fractures of the base, careful examination of the eye grounds by an ophthalmologist should be made; temperature, pulse, and respiration should be taken every ten minutes. If signs of paralysis or convulsions occurred an exploratory puncture under local anesthesia should be made into the subdural space. If no blood was found the patient should be still further watched before attempting decompression. In fractures of the vertex, with partial loss of consciousness and exaggerated reflexes, there was often marked depression of bone with collection of blood in the subdural space. The bone frgaments should be removed and reimplanted. In hemorrhage of the brain the vessel must be found and tied. In cases with marked cranial pressure a neurologist should be consulted. A subtemporal decompression was required. The clots must be washed out with saline. Dr. Elsberg showed a number of lantern slides, illustrating different types of fractures, and showing where operation was indicated.

Dr. L. W. HOTCHKISS of New York said that this was an admirable presentation of a subject which concerned every hospital surgeon. Very careful examination of the fundus of the eye was necessary to determine whether operation was indicated or not.

Dr. W. H. STEWART of New York said that the location of the fracture in relation to the injury was most important. He asked what was the proportion of cases with traumatic epilepsy and what proportion recovered. Dr. Stewart showed a number of lantern slides illustrating fractures of the skull.

Dr. C. A. ELSBERG said as many cases developed epilepsy among the operated as among the non-operated patients. It was due to injury to the brain substance. It could not be prevented by fresh operation. Epilepsy might stop for a while and then redevolp. Extreme conservatism was necessary in operating for traumatic epilepsy.

**The Surgery of Compound Fractures of the Extremities.**—Dr. WILLIAM L. ESTES of South Bethlehem, Pa., read this paper. He said that he presented the general management of fractures rather than any particular kind. With compound fractures there was always great traumatism, with dislocation of bone and wound of soft tissue and skin. The treatment was for an infected wound. Important considerations were the general condition of the patient; his habits and general health; whether or no he had to pursue an active call-

ing; whether amputation of limb would be quicker and better in the end; whether the limb should be saved, and, if saved, whether it would be of use to the patient. His surroundings were important, as it was better to risk a few hours' travel and treat the patient in a first-class hospital than to have him treated uncomfortably at home. The first question was to relieve suffering and control hemorrhage. Next a thorough physical examination should be made to ascertain amount of injury, blood pressure, degree of shock, etc. If great exhaustion was present operation should be delayed. A general anesthetic was often necessary to avoid pain, and thorough cleansing and disinfection of the wound was imperative. For the latter tincture of iodine was most valuable. Amputation was indicated where severe annular crushing of tissue had occurred. In fixation of fragments instruments should be used and the fingers kept as much as possible out of the wound. Plates were better than wiring, and silver and copper plates had been found to be actual inhibitors of bacterial growth. After fixation, ends of soft tissue should be joined by vascular anastomosis. Arteries should be ligated and divided nerve trunks, fascia, muscles and tendons should be sutured. Drainage should be thorough and, where much blood supply had been cut off, multiple incisions should be made. A dry sterile dressing should be applied and should be left for three weeks. The plate could be removed at first dressing.

Dr. William Darrach of New York said the life of the patient was the first consideration. It was better to wait 24 to 48 hours before fixation, to give the body time to recover from injury and to get ready to stand additional trauma. Bone might be attacked through a clean incision apart from the original wound, leaving the first wound open for drainage. When internal fixation apparatus was used it was wiser to remove it when the purpose had been served. Three weeks was rather early. Open repairs were slower than closed ones.

Dr. J. M. Hitzrot of New York said that the worst thing that could be done was to immediately reduce a fracture. The end of the bone was infected and carried infection inward. Iodine was valuable in increasing serum reaction which tended to wash out the wound.

Dr. Tinker of Ithaca said that iodine would not kill spore-forming bacteria. Pure carbolic acid or formaldehyde was preferable. Dead tissue could be cut out and the wound closed without drainage. If the wound was clean any method would give good results.

Dr. R. H. M. Dawbarn of New York said that if the treatment of fractures was delayed to the second week the leucocytes would give help. He had recently tried aluminum plates and screws as the alkalinity of the blood destroyed the plates in time.

Dr. Hotchkiss of New York said that one had to depend upon phagocytosis in complicated, infected wounds. Treatment should be given at a time most convenient to the patient.

**Conservatism in the Operative Treatment of Simple Fractures.**—Dr. G. Woolsey of New York said that for generations fractures had been treated in the same way. Surgeons were slow to use innovations. The *x*-ray showed that methods were responsible for poor results. With new methods the pendulum swung to the opposite extreme and many cases were uselessly operated upon. The proper course was to judge each case by itself. Open operations were too frequent. The *x*-ray led to closer study and good function was more important than position of fragments. A careful diagnosis was necessary, as the public and employer were more alert in regard to treatment. Reduction should be attempted early; it should be made under anesthesia, and if not successful a traction apparatus, such as the Steinman nail, should be used. Traction should be tried before the use of the Lane plate was resorted to. Fractures of the shaft required special treatment. Metal plates should be avoided on bone covered only by skin. Fragments should be held with bone splints which would not act as a foreign body. Important points were perfect asepsis and the avoidance of foreign bodies.

Dr. Darrach of New York said that now more reasons were given for not operating than for operating. The pendulum had swung too far. We had learned, however, that operation on fractures needed special technic and special instruments. Without this infection was a real danger. As regards screws, they would withstand a severe strain, but not a long-continued, slight strain. Machine screws were better than wood, and steel plates better than Lane plates. In the last seven years at Roosevelt there were 4,000 cases of fractures, of which 200 had been operated upon, a proportion of 5 per cent. Operation should be decided upon early, if at all. The less foreign material left in the wound the better.

Dr. J. M. Hitzrot of New York said that if transverse fractures were reduced within 48 hours under anesthesia the results were excellent in both children and adults.

Dr. William L. Estes said that employers had made the results of fractures a bugbear to the surgeon and that some definite standard of results should be established, so that requirements might be met.

Dr. R. H. M. Dawbarn of New York advocated his method of "osteophonic percussion" to determine whether it was necessary to operate or not. By comparing the percussion sound of whole bone with the injured portion of bone a note could be obtained which would be a definite guide.

**Nonoperative Treatment of Fractures of the Neck and Upper End of the Femur in Adults.**—Dr. John B. Walker of New York read this paper. He said that while brilliant advances had been made in surgery of the gastrointestinal tract, the treatment of fractures, unfortunately, remained where it was generations ago. In no fractures was the disability so great or of so long duration as in those of the neck of the femur. Scudder reported from the Massachusetts General Hospital that in 12 per cent. only of cases treated did patients regain functional use of the leg. Of 112 cases at Bellevue, from 1906-10, 15 per cent. made full recovery. British statistics showed 19 out of 91 cases, or 20 per cent. of cures. Two important observations should be made on these results: first, the inefficient reduction of the deformity; second, too early attempts at walking. The aim in treatment should be the normal restoration of function of the leg to secure which a normal anatomical function must be restored. Methods which were necessary to secure good results in other fractures must also be employed here. Longitudinal and lateral traction—methods used by Maxwell and Whitman—were both necessary to overcome displacement of the fragments. Treatment should begin immediately after the injury before the muscles had had time to contract and displace the fragments. The method was to carefully examine the patient to determine the wisdom of giving an anesthetic for 20 minutes, for the application of a plaster bandage. Under anesthesia the patient was lifted to a pelvic support, with a perineal bar for counter pressure, the extended limbs being supported by assistants. The extended limb was flexed to disengage soft parts between the fragments; it was then completely extended and the assistant overcome the shortening by direct manual traction. The limb was then abducted, the pelvis being level, the extended limbs in exact correspondence; a plaster spica was then applied, being carefully adjusted over the pelvis and trochanter. This maintained complete immobilization during period of repair. Abduction for 4-6 weeks was important in aiding patient and sparing unnecessary pain. In treatment of late fractures, those cases which were not brought at once to the surgeon, deformity had been reduced, but shortening persisted. Even under anesthesia a great deal of force was necessary to overcome shortening. A traction apparatus was here necessary. Dr. Lemon's extension apparatus had been found of the greatest possible help in these late cases and relieved anxiety as to displacement of fragments when lifting patients from the table. In many of these late cases the joint was affected by traumatic arthritis. There was unusual strain upon the slender femoral neck. In such cases a Taylor splint was of great service to relieve the neck of the femur from the strain of the weight of the whole body.

**Diagnosis by the X-Rays in Case of Fracture, Based on the Records of 10,000 Fractures in Bellevue Hospital.**—Dr. Isaac S. Hipsch of New York in this paper said that statistics of hospital records were not always correct because patients with fractures did not always seek hospital care. Combined hospital and dispensary records were also erroneous because of the differences of occupation and mode of life of patients. He had thought, therefore, that records of an *x*-ray laboratory would contribute data as to the frequency of fractures of the various bones. The results which they had gotten from this, however, were at variance with those of other writers, the percentage of 19 per cent. was obtained, instead of 6 per cent. elsewhere. This was per-

haps because Bellevue received many fracture cases from other hospitals. The fracture service at Bellevue was constantly on the increase, so it was hard to tell in which month fractures were most prevalent. The data from several *x*-ray laboratories would have to be compared to get accurate results. Some surgeons placed too much reliance on the *x*-ray while others relied entirely on clinical diagnosis. The proper course was between the two, using the *x*-ray to check off and correct clinical results. The *x*-ray, it had been said, was impartial, it could not lie; but the results were often entirely misinterpreted. Correct interpretation was essential. The *x*-ray had modified our ideas of frequency of various fractures and had given accurate determination of trauma to various parts of the body. It had shown that absolutely accurate restitution of the parts was desirable, but not essential for function. The *x*-ray distinguished between fractures and dislocations as in epiphyseal separation. Criticism had been made that the *x*-ray method was inaccessible and unreliable and that the clinical method was always handy; but the advantage of the former lay in the fact that it prevented unnecessary meddling with the injured part. Some fractures, of course, were more easily diagnosed clinically, such as fractures of the skull and of the ribs. Sometimes even with the *x*-ray the diagnosis had to be delayed; there was no indication in the plates until callous formation denoted the site of the injury. In some compound fractures the *x*-ray showed comminution of the fragments which might otherwise be overlooked. The plates should be as carefully studied as the patient was by the surgeon. Dr. Hirsch showed a large number of plates illustrating fractures in various parts of the body, lower end of fibula, lumbar spine, skull, pelvis, clavicle, scapula, etc.

(*To be continued.*)

## NEW YORK ACADEMY OF MEDICINE

*Special Meeting, Held April 6, 1914.*

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

**A Study of the Movements of the Intestines Under Artificial Circulation; Demonstration by Motion Pictures.**—Dr. GUSTAVE T. MONOD of Vichy, France, said that he was sent by the French government to report on the organization of graduate study in the United States and to see by what means the American and French profession could be brought into closer contact. In fact, it was under the guidance of Sir William Osler that he had been working to determine how to bring the medical profession of various countries into closer relation. For three years he had been working in England and, at the end of that period, through the influence of Sir William, he had been made a member of the College of Physicians, the first time an honor of this kind had ever been conferred upon a French confrère. Why were there fewer and fewer visitors to medical colleges in Paris? That was a question the dean had asked him. He believed that the reason was that the science of medicine had developed in America to such an extent, and in such a marvelous way during the last few years, with its college equipment, organization, etc., that nothing new could be shown the students, especially as regards teaching. So soon as he landed in this country he said that he had found this out. In Paris they really had nothing new to offer the student but the French point of view—l'ésprit français. He said that the question of to-day was how to send their best young men to America. What held the French students back was that they were called to military duty at the age of twenty; he worked hard till that age, became enthusiastic in his work, and then had to give up to assume military duty, and go to the barracks. It was so different in America, where no such calls were made upon the student. France had three things to offer its visitors—university organization, specialized schools in Paris, and its friendship. He emphasized the importance of doing postgraduate work in foreign countries. Some said they would not go abroad because they could not speak the language, but that he believed was the reason why they should go; the study of a foreign language was important. The dean thought that he should offer prospective students lectures; but he thought that if they came to Paris they should come to work with their fingers and with the eye at the microscope, and not to listen to lectures. The actual organization in Paris was such that visitors might just drop in and follow the work. They did not believe in giving special courses as they did in Germany and Vienna. They had organized a little society to make things easy for their visitors and he asked them to inquire for Dr. Monod, Vichy, Hon. Sec. As soon as the visitor landed they wished to make him feel at home and establish a friendship. He wished the visitor to get in touch with men privately, and advised him to go to see the head man of any department; decide upon the work to be done, and the wards wanted for the pursuance of the work. He said they were thinking of sending French medical men to America. The French Government extended a friendly invitation to Americans to visit France. Every country had had its turn as regards medicine and now the American era had begun.

The first film showed the work of Carnot and Glénard in transfusing the intestine of a cat. It demonstrated the following: (1) Normal peristalsis. (2) Peristalsis increased by heat. (3) Peristalsis increased by warmth. (4) The action of hormones, *i.e.* the serum of a cat purged with senna had acquired the power of starting in another organism, marked peristalsis. (5) Intestine of a rabbit. (6) Action of serum (ring contraction). (7) Study of the movements of the cecum and especially the rhythmic movement of every "pouch." Not only did the pouches bulge, but there was also a decided movement of the appendix. The cecum of the rabbit was immensely developed.

Dr. Monod took up the subject of enteroptosis as seen by a Vichy doctor. It seemed probable that incompetence of the intestinal wall led to a lowering of the intraintestinal tension, and to the visceral prolapse. The prolapse began with the intestines; then followed in the order of their descent the right kidney, stomach, liver, and spleen; for these organs were interdependent both as regards their suspension in the abdomen and as regards their functions, circulation, and innervation. Intestinal prolapse, which was pathogenic, was rarely primary, but was secondary to causes which were either infective or toxic; and the malady of which movable kidney was nothing more than a frequent symptom was enteroptosis. He wished to point out that British treatises labelled as enteroptosis (or as Glénard's disease) only cases of dislocation of all the abdominal organs; this was, according to Glénard's teaching, the last and most severe phase of the disease, and was a very rare occurrence. The common form was marked by one or two symptoms only, *e.g.* coloptosis and nephroptosis. Exactly in the same way "floating kidney" had for long been the only recognized form of movable kidney. Glénard classed this malady in the large family of "Hepatism." The Galenic teaching was thereby modernized. This view was supported by the fact that the etiology, symptomatology, and treatment of enteroptosis, on the one hand, and the inadequacy of the bile function on the other, authorized by their similarity this doctrinal theory. Enteroptosis was a malady of nutrition. The subjective symptoms of enteroptosis were general weakness, intestinal troubles, and disturbances of sleep, all of which were periodic in appearance, closely following the periodicity of meals; these symptoms were aggravated by the ingestion of acids, of fats, and more particularly of milk. The most conspicuous objective symptoms were a delimitable and palpable cecum (an early sign of enteroptosis), the great relief that occurred when the abdomen was mechanically supported (*épreuve de la sangle*), and perhaps, and very often, a movable kidney. But the movable kidney was nothing more than an epiphenomenon. They were still waiting for a single case in which the movable kidney syndrome could be demonstrated to be due to movable kidney alone. On the other hand, they were prepared to show scores of cases in which they could demonstrate that movable kidney was not the cause of the symptoms observed; and these were the cases in which all troubles disappeared, and the kidney remained unfixed. In the latter cases, careful investigation would always find some other cause which accounted for the troubles; most often gastrointestinal atony, frequently more or less visceroptosis, sometimes unsuspected lithiasis. Dr. Monod called attention to a new syndrome which he had discovered clinically while Crile found it out by experimental work, namely, insufficiency of liver, suprarenal gland, and brain together. This was a question to be studied.

Dr. JACOB KAUFMANN said that since Glénard first published his paper on enteroptosis there had ap-

peared an enormous amount of literature upon the subject and yet they must confess that in spite of this there was a great deal of confusion as to the meaning of enteroptosis. In France they explained it as caused by "hepatism," a term with which they were not familiar in America. The prevalent idea in America was that there was more of a mechanical derangement which was paramount in the production of enteroptosis. Dr. Kaufmann said he did not believe that any abdominal displacement constituted disease; abdominal displacements did not necessarily produce symptoms. The stomach and colon might be deeply situated and yet perform their functions in a perfectly normal manner. Enteroptosis in the majority of cases was found in people who showed other traits as well; they were subject to certain functional disturbances. He believed that the best definition of this condition was "a general congenital asthenia." These patients developed neurasthenia as well. There was a marked tendency to an atonic condition of the gastrointestinal canal associated with secretory disorders, but also some functional derangement of the liver caused by some disturbance of the internal secretions. The blood pressure was usually low in the development of this atonic condition. This tendency to develop asthenia of various organs, especially of the digestive apparatus, was the paramount factor of the condition, not the displacement of the abdominal viscera. In speaking of the treatment he thought that the application of the belt was helpful, but these patients should be treated as general neurasthenics not only by dietetic means but medically, too.

Dr. Max Einhorn said that as early as 1889 or 1890 he demonstrated this condition by gastrodiaphany, a method now used less since the advent of the *x*-ray. As to the conception of enteroptosis Stiller considered it a congenital disease and Dr. Einhorn believed that while this might be true it might be an acquired disease as well. It was interesting to note that the causes which produced gastroptosis might be removed by the application of methods which were apt to produce reversed conditions. A man weighing 150 or 160 pounds might have typhoid fever, pass through his illness, and then not pick up. In such a condition he was apt to develop enteroptosis. Any thing that caused a loss of fat or other tissue, with the usual change in configuration, was apt to be followed by enteroptosis. Again, after childbirth, when the woman got up to early and not bandaged properly, after four or five months enteroptosis would develop as a rule. This proved that enteroptosis was not always congenital, but could be acquired. By building up the body and putting on flesh one could cure the condition. He had demonstrated that many times and described it years ago. When enteroptosis was associated with cardioptosis, if one built up the body, the heart would return to its normal position quicker than any other organ. In four or five weeks after the patient had gained from ten to twelve pounds one would find a change in the position of the heart as demonstrated by means of percussion and the *x*-ray. If this was purely a congenital affair it would be impossible to so alter the position of the heart. Was enteroptosis a disease or not? In his paper, written in either 1889 or 1890, he stated that he found prolapsed kidneys, liver, stomach, and other organs at times without any symptoms whatever. That was not saying that it was a normal condition; it was not; it was an abnormal condition giving rise to the development of abnormal changes and functional disorders. With regard to the treatment Dr. Einhorn said he was in accord with the teachings of Glénard, who laid stress upon certain points which he, Dr. Einhorn, considered important. A sufficient diet, ample amount of food, and building up was what these patients needed. One should try to increase their size by building them up, not alone increasing the amount of fat, but the muscles as well. He considered the use of the bandage as of secondary importance. The bowels should be regulated. The aperient and alkaline waters at the spas did not play a great part. He had had success without giving these waters at all. Dr. Einhorn then requested Dr. Monod to demonstrate an *x*-ray photograph, which showed the course of that small intestine for about two meters beyond the papilla of Vator. The picture had been taken by Dr. Stewart, radiologist of the German Hospital, on one of Dr. Einhorn's patients with the intestinal delineator inserted.

Dr. George R. Lockwood said that the condition of enteroptosis was interesting from a geographical standpoint and appeared to differ when considered in various countries as, for instance, in Budapest, France, or England. It seemed to him that the whole proposition of enteroptosis might be simplified by simple rules. Mankind could be divided into two classes: (1) those with broad costal angles and with transverse stomach, robust individuals; (2) those with narrow costal angles and vertical stomach, the thin nervous individuals. Such a condition of ptosis suggested a reversion to the embryonic type. Gastroptosis produced no local gastric symptoms until the stomach became atonic, to which condition it was predisposed by reason of the nervous instability of that type of case, and when atony advanced symptoms of alimentary toxemia usually intervened.

Dr. J. W. Draper said that from the standpoint of surgical therapeutics the alimentary canal was divisible into three regions: (1) The duodenum and oral portion of the jejunum, bacterially dead, biochemically alive. (2) The aboral and terminal ileum. (3) The cecum and colon, biochemically dead, bacterially alive. The duodenum, preeminently the vital part of the gut, the seat of unknown biochemical reactions, was first demonstrated by Roger, the gifted and far-seeing countryman of the essayist, and was destined to yield to future research students knowledge which would profoundly alter our present conceptions and improve our therapy. This organ concerned them for two reasons: First, because of its ulcers, the prevalence and importance of which had been surgically known for several years, but the etiology of which was still unknown. Second, because of its enzymes, hormones, and other biochemical bodies which bore so striking a relation to the cause of death in intestinal obstruction, and which stood, furthermore, in significant relation to the etiology of duodenal ulcer. Undoubtedly Patterson of England, Kanavel of Chicago, and others were right in teaching that in their dealing with the oral part of the gut, as, for instance, in the creation of a gastroenterostomy for the relief of duodenal ulcer, they were altering the subtlest biochemical relations and this alteration effected the cure rather than the much overrated gastric drainage, thought by some to result from the operation. Again the aboral ileum was of great physiological surgical interest because of the new knowledge which scientific surgery had added to the physiological knowledge of the region and because of the relation of the terminal ileum to the fecal storehouse, the colon. Likening the small gut, according to the familiar simile, to a test tube, the fiery biochemical reactions of the duodenum might be said to cool in the jejunum and to chill in the ileum. Terminally, they were *nil*, and the chief, if not only gut function, was conduction. Jerome Lynch, working in Lusk's laboratory at Cornell, had shown in human beings that the stream of chyme passing to the cecum was not continuous, but intermittent, strongly suggesting the rhythmical squirting of stomach contents into the duodenum; that the ileal contents were solid or fluid, depending wholly upon the diet. On a nitrogenous diet the ileal contents were always fluid. On a mixed diet, with carbohydrates in excess, the ileal contents were well formed, often solid. Lynch further showed that the reaction of the ileal contents was always acid, that of the mucous membrane always alkaline or neutral. Significant corroboration of these nutritional studies was found in the field of applied surgery. Ileostomy was always followed by a gain in weight. The cecum and colon being biochemically dead and bacterially alive held an interest equal to and in inverse proportion with that of the duodenum. Where one might be looked upon as dead the other was very much alive and *vice versa*. The therapy of this part was concerned with its evacuation. Walter Cannon had well said that surgeons operated upon the human alimentary canal as though it were a simple system of rubber tubes in which holes could be bored at will, rather than an indescribably complex physiological mechanism. In no part of the canal was the truth of this saying better shown than at its termination. In their extreme ignorance of its functions, the colon had been excised, it had been twisted and contorted into bizarre shapes, in well-intentioned but ill-directed efforts to hasten or complete its emptying. The whole question of the surgical therapy of the colon hinged on the little understood problem of anastalsis. George D. Stewart had recorded what was probably the most direct and amazingly interesting proof of human colonic anastalsis. The patient, a constipated carpenter, while engaged in removing, as was his custom, impacted feces from his rectum with his pencil, suddenly

felt it gripped by the bowel and the next instant it was lost in the rectum. Three days later Dr. Stewart was unable to find the pencil by the proctoscope and opened the abdomen. It lay not in the sigmoid or colon, but in the cecum. This was to be explained only by anastalsis. LeWald, Cannon, Case, Lyman, and others agreed that anastalsis was normal to the human colon. It was no exaggeration to say that in excess it might be a predominant factor in certain types of constipation.

Dr. Lewis Gregory Cole said that a stomach, although greatly prolapsed, might continue to functionate well. What he wished to especially emphasize, however, was the relation between the level of the chyme in the stomach and the position of the cap (first portion of the duodenum). This he considered a very important factor, because if the pylorus as well as the stomach were prolapsed gastric evacuation would take place on scheduled time. If, on the other hand, the pylorus were high and the stomach prolapsed, gastric retention might result.

Dr. Monod closed the discussion. He said that the methods in the diagnosis of Glénard's disease, as well as in the treatment, were based on the physical signs and these signs were brought forth through Glénard's technique and no other. He agreed with Dr. Einhorn that the waters played but a secondary part. They had the waters at hand and they used them. In making a diagnosis of these cases one should forcibly lift with both hands and then suddenly let the parts drop; if the pupils dilated the patient should be treated. This phenomenon was due to the influence on the nervous system. The pulse went up as well. Dr. Monod threw upon the screen a slide loaned him by Dr. Einhorn showing distinctly a thread which had passed through the whole intestine. He said that he had never seen anything so good in *x*-ray work. The radiograph was taken by Dr. W. H. Stewart of the German Hospital.

# State Medical Licensing Boards.

## STATE BOARD EXAMINATION QUESTIONS.

### New Hampshire State Board of Medical Examiners.

*January* 6 and 7, 1914.

#### ANATOMY.

1. Classify joints and give illustration of each.
2. Give origin and complete course of the nerve that has most to do with respiration.
3. How is the heart itself nourished?
4. Give the anatomical relation of the small intestine to the other abdominal viscera.
5. Describe the perineum.
6. Place and describe the nasal bones.
7. Describe the internal jugular vein.
8. What do you understand by the mesentery?
9. Place and describe the thyroid gland.
10. Describe the axillary space and give its contents.

#### PHYSIOLOGY AND HYGIENE.

1. What is the difference between lymph and serum?
2. What causes an extremity to go to sleep?
3. What is the result of injury to or removal of the semicircular canals?
4. What different vascular conditions may lead to a paling of the face?
5. What changes are produced in milk by boiling?
6. What is the function of the pancreas?
7. Describe locomotor ataxia.
8. (*a*) Upon what does the clotting of blood depend? (*b*) What is the cause of this conversion?
9. (*a*) What do you consider the best method of heating a dwelling, and (*b*) give the reasons for your answer?
10. What is the best method of ventilating the plumbing system?

#### MATERIA MEDICA, THERAPEUTICS, AND THE PRACTICE OF MEDICINE.

1. Describe angioneurotic edema.
2. Name the principal causes of pleuritis.
3. Outline the treatment of pneumonia.
4. Define bronchopneumonia and give its etiology.
5. Give a clinical description of pericarditis with effusion and name some of the diseases with which it is associated.
6. Give the physical signs of exophthalmic goiter and discuss its treatment.
7. Name the principal causes of chronic nephritis.
8. Describe diabetes mellitus, name its complications and discuss its treatment.
9. Describe tetany and give its etiology.
10. Name the exanthematous diseases and give the period of incubation of each.

#### CHEMISTRY.

1. What is a chemical salt?
2. How is nitroglycerin prepared?
3. From what is phenacetine derived?
4. What are the chemical properties of radium?
5. In what is phosphorus the most readily soluble?
6. Urine sediments are how classified? Give example.
7. What are enzymes? Give some of their chemical characteristics.
8. Name an efflorescent salt, a deliquescent salt, a hydroscopic liquid.
9. Where is sulphur found in the body, and under what form? What is its function?
10. In a systematic examination of stomach contents, what are the physical properties and normal constituents?

## ANSWERS.

#### ANATOMY.

1. Varieties of Articulation. 1. *Diarthrodial*, or freely movable; as hip and knee. 2. *Amphiarthrodial*, or slightly movable; as symphysis pubis and joints between bodies of vertebræ. 3. *Synarthrodial*, or immovable; as ethmoid with vomer and parietal with frontal.

2. *Pneumogastric nerve. Superficial origin:* Groove between restiform and olivary bodies. *Deep origin:* Nuclei in floor of fourth ventricle. *Course:* Outward across the flocculus, to jugular foramen through which it passes, where it is joined by the accessory portion of the spinal accessory nerve. As it goes down the neck, it lies in front of the rectus capitus anticus major and longus colli muscles. It passes in the carotid sheath behind and between the artery and vein. In the thorax the nerve on each side runs a different course. The *right* passes between the subclavian artery and vein, by side of trachea to root of lung, behind esophagus, through esophageal opening in diaphragm to posterior surface of stomach. The *left* passes between the subclavian and carotid arteries, in front of arch of aorta to root of lung, along anterior surface of esophagus, through diaphragm, to anterior surface of stomach. *Distribution* is shown by the names of the branches: Meningeal, auricular, pharyngeal, superior and inferior laryngeal, cardiac, pulmonary esophageal, and gastric.

3. The heart is nourished by the right and left coronary arteries.

4. Relations of duodenum. *First part: In front*—Liver, gall-bladder. *Behind*—Bile-duct, vena portæ, hepatic artery, gastroduodenal artery. *Below*—Head of pancreas.

*Second part: In front*—Hepatic flexure of colon. *Behind*—Right kidney, suprarenal capsule, renal vessels, and inferior vena cava. *Left side*—Head of pancreas, common bile-duct, and pancreatic duct. *Right side*—Hepatic flexure of colon.

*Third part: In front*—Superior mesenteric vessels and plexus of nerves. *Behind*—Aorta, vena cava, crura of diaphragm, and left psoas. *Above*—Pancreas.

The *jejunum* is in relation with the under surface of the pancreas and the transverse mesocolon.

5. *The perineum* is a diamond-shaped space corresponding to the inferior aperture of the pelvis. It is bounded in front by the symphysis pubis and the subpubic ligament; behind, by the coccyx; and on each side by the rami of the pubis and ischium, the tuberosity of the ischium, and the great sacrosciatic ligament. It is generally divided into two parts by an arbitrary line drawn between the ischial tuberosities, just in front of the anus; the anterior triangle is called the urogenital triangle, and the posterior the rectal triangle. The floor of the perineum consists of: Skin, fascia, triangular ligament, superficial perineal vessels and nerves, accelerator urinæ, transversus perinei, sphincter ani, erector penis, compressor urethræ.

6. The *nasal bones* are situated about the middle and upper part of the face, the two together forming the bridge of the nose. They are small oblong bones and articulate with the frontal, ethmoid, superior maxillary, and with each other. They are generally described as having two surfaces (an outer and an inner), and four

borders (superior, inferior, external and internal).

7. The *internal jugular vein* commences at the jugular foramen, and is formed by the junction of the lateral and inferior petrosal sinuses; it passes vertically down the side of the neck on the outer side of the carotid artery, and at the root of the neck it unites with the subclavian vein to form the innominate vein. It collects the blood from the interior of the cranium and from the superficial parts of the face and from the neck. Its tributaries are the facial, lingual, pharyngeal, and superior and middle thyroid veins.

8. The *mesentery* is a broad fold of peritoneum which connects the jejunum and ileum to the posterior abdominal wall.

9. The *thyroid gland* is situated on the sides and in front of the upper part of the trachea, and extends upward on each side of the larynx. The *thyroid gland* consists of two lateral lobes and an isthmus: it is situated at the front and sides of the neck. The lobes extend from about the middle of the thyroid cartilage to the fifth or sixth tracheal ring; the isthmus generally covers the second and third tracheal rings. The lobes measure about 2x1¼x¾ inches; the gland usually weighs about one ounce. *Blood supply:* Superior and inferior thyroid arteries, with thyreoidea ima; and superior middle, and inferior thyroid veins. *Nerve supply:* Branches from the inferior laryngeal nerve, and from the middle and inferior cervical ganglia of the sympathetic.

10. The axillary space is *bounded: Anteriorly,* by the clavicle, subclavius, pectoralis major, costocoracoid membrane, pectoralis minor; *posteriorly,* by the subscapularis, teres major, and latissimus dorsi; *internally,* by the first four ribs, first three intercostal muscles, serratus magnus; *externally,* by the humerus, coracobrachialis, and biceps.

*Contents:* The axillary vessels and brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymphatic glands, all connected together by a quantity of fat and loose areolar tissue.

PHYSIOLOGY AND HYGIENE.

1. Blood serum is practically the same as blood plasma, except that serum contains no fibrinogen, but more fibrin ferment. The following figures (from Hammarsten) show the differences between lymph and plasma:

| | | |
|---|---|---|
| Lymph contains: | Water | 939.9 |
| | Solids | 60.1 |
| | Fibrin | 0.5 |
| | Albumin | 42.7 |
| | Fat, cholesterin, lecithin | 3.8 |
| | Extractive bodies | 5.7 |
| | Salts | 7.3 |
| Plasma contains: | Water | 908.4 |
| | Solids | 91.6 |
| | Total proteids | 77.6 |
| | Fibrin | 10.1 |
| | Fat | 1.2 |
| | Extractive substances | 4.0 |
| | Soluble salts | 6.4 |
| | Insoluble salts | 1.7 |

2. An extremity may go to sleep from pressure on a nerve; as when the hand goes to sleep after pressure on the ulnar nerve at the elbow, or the foot goes to sleep from pressure on the sciatic nerve when the legs are crossed. A poison circulating in the blood may also irritate the peripheral nerves and cause a similar sensation.

3. "The *semicircular canals* are, through the vestibular nerve and the cerebellum, the most important agents in the preservation of equilibrium. When in a pigeon the horizontal canals are divided, the head moves from left to right and from right to left, with nystagmus and a tendency to revolve on its vertical axis. When the inferior vertical or posterior canals are divided, the head oscillates from front to rear; the animal has a tendency to fall backward. A section of the superior vertical canal causes the head to oscillate from front to rear, with a tendency to fall forward. A section of all the canals is followed by contortions of the most bizarre nature. After a destruction of all the canals the animal cannot maintain his equilibrium. Similar phenomena have been observed in man in disease of the semicircular canals, known as Menière's vertigo. In the fixed position of the head there is equilibrium, but with each movement the varying tension of the liquid in the ampulla changes and irritates the hair-cells."—(Ott's *Physiology.*)

4. Paling of the face may be caused by spasm of the arterioles, increased vasoconstriction, or defective action of the heart.

5. When milk is boiled, a thin scum of albumin appears on the surface, it takes longer to coagulate, and also longer to sour; the taste is changed; the color is also changed, and various bacteria and fungi are destroyed. The digestibility and rate of absorption of boiled milk and raw milk do not differ materially.

6. The *function of the pancreas* is to provide the pancreatic juice, which changes proteids into proteoses and peptones, and afterward decomposes them into leucin and tyrosin; converts starches into maltose; emulsifies and saponifies fats; causes milk to curdle. It also supplies an internal secretion.

7. *Locomotor ataxia* is a disease of the spinal cord, characterized by loss of coordination, characteristic and unsteady gait, a tendency to stagger when standing up with the feet together and the eyes closed, sharp and paroxysmal pains called *erises,* girdle sensation, Argyll-Robertson pupils, and loss of knee-jerk and other reflexes. In locomotor ataxia the posterior columns of the spinal cord and the posterior nerve roots are involved. The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion. The spinal ganglia may also be affected, and the membranes over the affected parts are adherent and opaque.

8. In the plasma a proteid substance exists, called fibrinogen. From the colorless corpuscles a nucleoproteid is shed out, called prothrombin. By the action of calcium salts prothrombin is converted into fibrin ferment, or thrombin. Thrombin acts on fibrinogen in such a way that two new substances are formed: one of these is unimportant and remains in solution; the other is important, viz., fibrin, which entangles the corpuscles and so forms the clot.

9. "*Hot-water heating.*—This is regarded as the best form of central heating for small dwellings. Instead of an air jacket over the combustion chamber, there is provided a water receptacle, from which a continuous pipe ascends through the house to its uppermost part, whence it returns by a continuous descending pipe and connects with same water receptacle. The water being heated, circulates freely throughout the system of pipes and the radiators attached thereto, and by heating of pipes and radiators warms the air of the rooms. Between the ascending and descending pipes there is usually placed an expansion tank to allow for the expansion of the water by heat. This system of heating is simple, needs little attention, produces a pleasant and not too high temperature, is not subject to sudden variations, and consumes a relatively small amount of coal.

"*Steam Heating.*—In this system the pipes are filled with steam instead of with hot water, and the water in the boiler is converted into steam. The temperature of the pipes and radiators is higher, their size correspondingly smaller, more fuel is needed to convert the water into steam, a higher pressure gained, more expert attention necessary, a greater degree as well as variation of heat reached. This system is especially suitable to large houses. Steam-heating plants may be located outside of the house and convey the heat by means of underground steam pipes."—(Price's *Essentials of Hygiene*).

10. "The whole plumbing system is ventilated by vertical pipes led through the roof and left open to the outside air, while air from the outside is provided by means of the 'fresh-air inlet,' which, beginning with an air box in the sidewalk, runs into the house drain, inside of the main trap, and by a 4-inch iron pipe. The vent pipes also aid the ventilation within the pipes."—(Price's *Essentials of Hygiene.*)

MATERIA MEDICA, THERAPEUTICS, AND THE PRACTICE OF MEDICINE.

1. "*Angioneurotic edema* is a neurotic condition in which transient circumscribed, edematous swellings appear on the skin, and sometimes on the mucous membranes, and disappear after a variable period without leaving behind any structural alterations. It arises usually without obvious cause and is in all probability a vasomotor neurosis. Certain drugs in susceptible individuals may induce it. Recurrences are frequent, and when the larynx is involved the affection assumes a grave aspect."—(Hughes' *Practice of Medicine*).

2. The *Principal Causes of Pleuritis* are: Exposure

to cold or damp, tuberculosis, pneumonia, pulmonary abscess, bronchitis, nephritis, cancer, various specific fevers, traumatism of the chest; the microorganisms usually found are the pneumococcus, tubercle bacillus, and streptococcus.

3. The *treatment of pneumonia* "consists in fresh air, good nursing, rest in bed, milk diet, and the administration of fractional doses of calomel followed by a saline in the early stage. The nervous symptoms and temperature may be controlled by applying ice-bags or compresses wrung out of cold water (60°-70° F.) to the chest or by the use of the warm or cold wet-pack. The heart and pulse should be sustained by the administration of alcohol, strychnine (gr. 1/60-1/20), atropine, caffeine, strophanthus, and nitroglycerin. Digitalis may also be employed. Inhalations of oxygen afford temporary relief when the dyspnea and cyanosis are extreme. In young, vigorous, and plethoric adults, with hyperpyrexia and a high-tension pulse, bleeding may be beneficial in the first 48 hours. Convalescence should be guarded, and tonics, stimulants, etc., will be found very useful in this period of the disease."—(*Pocket Cyclopedia.*)

4. *Bronchopneumonia* is an acute inflammation of the bronchioles and the alveoli of the lungs. It may be due to a bronchial catarrh, one of the infectious fevers, influenza, heart disease, uremia, nephritis, diabetes; the microorganisms generally present are the *Micrococcus lanceolatus, Streptococcus pyogenes, Staphylococcus aureus* and *albus*, Friedländer's bacillus, and occasionally the colon bacillus, typhoid bacillus, Klebs-Loeffler bacillus, or bacillus of pneumonia.

5. *Pericarditis with effusion.*—"The symptoms are somewhat obscure and may be masked by previously existing disease. Taking a typical case as it occurs in the course of rheumatic fever, we usually find precordial distress; sharp pain is rare, but when present it is most marked at the lower end of the sternum. Moderate fever, or exacerbation of already existing fever, at the onset; dyspnea, and dusky appearance of the face; rapid action of the heart, sometimes with feeble pulse; symptoms due to pressure by the fluid on the neighboring organs (trachea and esophagus, etc.); great restlessness. The physical signs are: Marked increase of the cardiac dulness; displacement of the apex beat; muffling of the heart sounds; displacement of other organs (if effusion is great). The shape of the dulness is characteristic. It is conical, the apex of the cone being truncated, and situated at the level of the second rib, owing to the close attachment of the pericardium to the great vessels at this point. The apex beat is generally pushed upwards and to the left. It lies, when it is palpable at all, distinctly within the left border of cardiac dulness, not, as in enlargement due to valvular disease, in close relationship to it. The marked distention of the pericardial sac surrounds the heart limits of the organ itself. The amount of bulging and displacement of organs will, of course, vary with the amount of fluid present. As resolution takes place the friction returns, and may be very coarse in character. Muffling of the heart sounds is not always present, and is not entirely due to the presence of fluid. The muffling is therefore due mainly to weakness of the cardiac muscle from accompanying myocarditis, although where the quantity of fluid is very great, in serous and chronic pericarditis, this may in part account for it."—(Wheeler and Jack's *Handbook of Medicine*).

6. The *physical signs of exophthalmic goiter* are: Exophthalmos, goiter, tachycardia, and muscular tremor; anemia, hemic murmurs, cardiac hypertrophy or dilatation, palpitation of the heart; there may be a systolic thrill over the goiter. The *treatment* demands rest, fresh air, and light but nutritious diet; digitalis, bromides, iodides, arsenic, and electricity have all been recommended; partial thyroidectomy, section of the cervical sympathetic, and ligature of the thyroid arteries have been advocated; the newest remedy is probably antithyroidin.

7. The *principal causes of chronic nephritis* are: Arteriosclerosis, alcoholism, gout, lead poisoning, syphilis, acute nephritis, malaria, excess of nitrogeneous diet.

8. *Diabetes mellitus* is a constitutional disease, characterized by polyuria, excess of sugar in the blood and excretion of the same in the urine, and accompanied by severe emaciation. It generally occurs after the fortieth year, but may come on at any age; it is more common in males, among Hebrews, and in the well-to-do classes. The direct cause is not known. *Complications* are: Pruritus, eczema, boils, cataract, retinitis, neuritis, albuminuria, cirrhosis of kidney, acidosis, and tabes. *Treatment* consists in a quiet, regular mode of living, without worry; gentle exercise; daily bathing in lukewarm water; flannel underwear; the carbohydrates in the food should be cut down until there is no sugar in the urine or a non-carbohydrate diet is reached. Codeine, morphine, antipyrin, arsenic, and strychnine have been recommended.

9. *Tetany* is a condition characterized by tonic muscular spasms of the extremities, which occur at intervals, are painful, and usually bilateral. The *cause* is unknown; toxins acting on the peripheral motor neurons, removal of the thyroid gland, rickets and hysteria are said to be etiological factors.

10. *Exanthematous diseases.*—Cerebrospinal meningitis, incubation period is unknown; erysipelas, a few hours to 3 or 4 days; measles, 10 to 12 days; rotheln, 8 to 16 days; scarlatina, 1 to 21 days; typhoid, 5 to 30 days; typhus, 4 to 12 days; varicella, 4 to 14 days; variola, 7 to 14 days. The figures are approximate.

CHEMISTRY.

1. A *Salt* is a substance derived from an acid by substituting a metal (or its equivalent) for part or all of the replaceable hydrogen of the acid.

2. *Nitroglycerin* is prepared by the action of a mixture of sulphuric and nitric acids upon glycerin.

3. *Phenacetine* is derived from para-phenetidin, which is derived from phenol.

4. *Chemical properties of radium.*—"The emitted rays convert oxygen into ozone and change yellow phosphorus to red. The alpha rays immediately coagulate a sensitive solution of globulin. The beta and gamma rays liberate iodine from iodoform in the presence of oxygen."—(Holland's *Chemistry.*)

5. Phosphorus is soluble in carbon disulphide, and in the fixed and volatile oils.

6. *Sediments in the urine* may be classified according to their presence in *acid* urine, and in *alkaline* urine. In *acid* urine, are found: Uric acid, urates, calcium oxalate, cystin, and calcium phosphate. In *alkaline* urine are found: Phosphates, calcium carbonate, and ammonium urates.

7. *Enzymes* are organized ferments produced by living cells; they cause definite chemical changes in certain substances. They are capable of causing change in a large amount of material, and they themselves remain unaltered; they only act in a medium of certain reaction, some in an acid medium, some in an alkaline; for each enzyme there is a certain temperature at which its action is the most energetic; the products of their activity must be removed, or the accumulation of these products will hinder further activity.

8. An *efflorescent salt*, sodium carbonate; a *deliquescent salt*, calcium chloride; a *hygroscopic liquid*, alcohol.

9. Sulphur occurs in the body chiefly in the hair, nails and epithelium, but it is a constituent of most proteids. It is found as hydrogen sulphide and as sulphates.

10. *Gastric juice* is a liquid, slightly cloudy, almost colorless, acid, with specific gravity of 1001 to 1010; it deposits a sediment which may contain food particles, gland cells, nuclei, epithelium, and mucus. It consists of water and solids, and free hydrochloric acid; pepsin, chlorides of sodium, potassium, and calcium; phosphates of calcium, magnesium, and iron; mucin, a thiocyanate, and nucleo-proteid.

(*To be concluded.*)

---

**Deformity of the Spine Possibly of Congenital Origin.**—L. E. C. Norbury reports the case of a girl aged five and a half who was brought to the Belgrave Hospital with history of pain beneath the left costal margin of some two or three weeks' duration. On examination: Healthy-looking child. Prominence of lower dorsal and first lumbar spinous processes. Slight mid-dorsal lateral curvature with convexity to the left. Movement of spine good. No pain elicited on "jarring" spine. No alteration in length of limbs. No abnormal physical signs in chest. Von Pirquet's reaction slightly positive. *X*-ray examination revealed wedge-shaped condition of first and second lumbar vertebræ, and the interval between these was less than between the bodies of adjacent vertebræ. The skiagram suggested the presence of an extra lumbar vertebra.—*Proceedings of the Royal Society of Medicine.*

## Books Received.

*The* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

IMMUNITY METHODS OF DIAGNOSIS AND THERAPY, AND THEIR PRACTICAL APPLICATION. By Dr. JULIUS CITRON. Second Edition, Revised and Enlarged. Illustrated; cloth; 267 pages; price $3.50 net. P. Blakiston's Son & Company, Philadelphia.

PATHFINDERS OF PHYSIOLOGY. By J. H. DEMPSTER, A.B., M.D. Cloth; 66 pages; illustrated; price $1.00. The Detroit Medical Journal Company, Detroit.

KRIEGSERINNERUNGEN. By Dr. M. PELTZER. Paper; 41 pages; price 1.00 M. August Hirschwald, Berlin.

MAN'S REDEMPTION OF MAN. By WILLIAM OSLER. Cloth; price 50c. net; 63 pages. Paul B. Hoeber, New York.

A WAY OF LIFE. By WILLIAM OSLER. Cloth; price 50c. net; 62 pages. Paul B. Hoeber, New York.

LECTURES ON DIETETICS. By MAX EINHORN. Cloth; price $1.00 net; 156 pages; illustrated. Paul B. Hoeber, New York.

MODERN SURGERY, GENERAL AND OPERATIVE. By JOHN CHALMERS DACOSTA, M.D., LL.D. Seventh edition; revised, enlarged, and reset. Illustrated; cloth; price $6.00 net. W. B. Saunders Company, Philadelphia and London.

A HANDBOOK FOR THE POST-MORTEM ROOM. By ALEXANDER G. GIBSON, D.M., F.R.C.P. Cloth; price $1.50; 140 pages; illustrated. Oxford University Press, New York.

TREATMENT OF NEURASTHENIA. By DR. PAUL HARTENBERG. Cloth; price $2.50; 283 pages. Oxford University Press, New York.

BEHANDLUNG KOSMETISCHER HAUTLEIDEN. By DR. S. JESSNER. Paper; price 2.50 mks.; 529 pages. Curt Kabitzsch, Wurzburg.

OPHTHALMIC SURGERY. By CHARLES H. BEARD, M.D., Second Edition, revised and enlarged. Illustrated; cloth; 745 pages; price $5.00 net. P. Blakiston's Son & Company, Philadelphia.

TREATMENT OF CHRONIC LEG ULCERS. By EDWARD ADAMS, M.D. Cloth; 122 pages; price $1.00. The International Journal of Surgery Company, New York.

A SHORT PRACTICE OF MIDWIFERY FOR NURSES. By HENRY JELLETT, B.A., M.D., F.R.C.P.I. Cloth; price $2.50 net; illustrated; 508 pages. Paul B. Hoeber, New York.

THE JUNIOR NURSE. By CHARLOTTE A. BROWN, R. N. Illustrated; cloth; 208 pages. Lea & Febiger, Philadelphia and New York.

A MANUAL OF INFANTILE PARALYSIS. By HENRY W. FRAUENTHAL, A.C., M.D., and JACOLYN VAN VLIET MANNING, M.D. Illustrated; cloth; 374 pages; price $3.00 net. F. A. Davis Company, Philadelphia.

STUDIES FROM THE ROCKEFELLER INSTITUTE For Medical Research Reprints Volume XVIII. Paper; illustrated; 596 pages. The Rockefeller Institute For Medical Research, New York. 1914.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. First and Second Editions Edited by ALBERT H. BUCK, M.D. Third Edition completely revised and rewritten. Edited by THOMAS LATHROP STEDMAN, A.M., M.D. Volume Three. Illustrated; cloth; price $7.00 net; 930 pages. William Wood and Company, New York.

TEN SEX TALKS TO GIRLS. By IRVING DAVID STEINHARDT, M.D. Illustrated; cloth; price $1.00 net; 193 pages. J. B. Lippincott Company, Philadelphia and London.

THE INTERNATIONAL MEDICAL ANNUAL. A Year Book of Treatment and Practitioners' Index. By Various Contributors. Cloth; illustrated; price $3.50; 716 pages. E. B. Treat & Company, New York.

LA STASE INTESTINALE CHRONIQUE. Par le Docteur E. SORREL. Paper; illustrated; 254 pages. G. Steinheil, Paris, 1914.

ÉTUDES SUR LES RÉSISTANCES GLOBULAIRES. Par le Dr. ETIENNE MAY. Paper; price 5 fr.; 164 pages; illustrated. Librairie Felix Alcan, Paris.

ACHONDROPLASIA. Its Nature and Its Cause. By Dr. MURK JANSEN. Paper; price 6/- net; 98 pages; illustrated. Balliere, Tindall and Cox, London.

## Therapeutic Hints.

**The Treatment of Chilblains.**—Every evening before retiring the patient should lightly rub the affected part with a piece of gauze soaked in glycerin, and then after having wiped off the latter, he should apply the following ointment:

℞ Balsam of Peru, 10 grams.
Tannin, 2 grams.
Spirit of turpentine, 3 grams.
White vaseline, 20 grams.
—*Bulletin Général de Thérapeutique.*

**The Treatment of Migraine.**—M. Allen Starr has recommended the administration of the following pill in cases of migraine associated with intestinal fermentation:

℞ Sodium phenolsulphonate, 5 grains.
Potassium permanganate, 1 grain.
Beta-naphthol, 1 grain.

This pill should be coated with salol to insure its entrance into the bowel before it is dissolved. The dose is one pill after meals and at night.

**The Subcutaneous Injection of Quinine.**—The following solutions are adapted for the subcutaneous injection of quinine:

℞ Quinine hydrochloride, 1 gram.
Urethane, 0.5 gram.
Distilled water, ad 10 c.c.

One c.c. of this solution contains 0.1 gram of quinine.

℞ Quinine hydrochloride, 2 grams.
Antipyrine, 2 grams.
Distilled water, ad 10 grams.

One c.c. of this solution contains 0.2 gram of quinine.

**The Treatment of Irritable Cough.**—A. P. Luff has found the following a very useful mixture for the relief of irritable cough, and especially of post-influenzal cough:

℞ Morphine hydrochloride, 1/24 grain.
Heroine hydrochloride, 1/24 grain.
Apomorphine hydrochloride, 1/48 grain.
Dilute hydrochloric acid, 5 minims.
Syrup of wild cherry, ½ dram.
Chloroform water, ad ½ ounce.

This dose should be taken every four hours. The medicine is very palatable and the presence of the hydrochloric acid effectually prevents the precipitation of any of the alkaloids.—*Lancet.*

**Treatment of Depilating Folliculitis.**—G. T. Jackson and C. W. McMurtry state that Brocq advises epilation of all loose hair and the application of either mercury or sulphur, the latter usually being the more useful. The scalp is to be washed with soap and water in the evening and when dried the following solution should be applied:

℞ Acetic acid crystals, 75 grains.
Corrosive sublimate, 7½ grains.
Glycerin, 6 drams.
Alcohol (85 per cent.), 2½ ounces.
Distilled water, 5 ounces.

**The Management of Mucous Colic.**—W. A. Edwards notes that Mummery uses belladonna to prevent spasm of the colon, in the following:

℞ Tincture of hyoscyamus, ½ dram.
Tincture of belladonna, 6 minims.
Sodium bicarbonate, 20 grains.
Tincture of ginger, 15 minims.
Spirit of chloroform, 20 minims.
Peppermint water, ad 1 ounce.

This dose should be given three times daily. A laxative should be administered at the same time.

### THE PROGRESS OF EDUCATION OF THE DEAF AND DUMB, AND SOME OF THE DIFFICULTIES OF AURAL INSTRUCTION.

By N. J. POOCK VAN BAGGEN,

THE HAGUE, HOLLAND.

THE principal intention of the instruction of the deaf and dumb child has always been to withdraw it from its spiritual isolation and to facilitate intercourse with its fellow-creatures. Many are the attempts made and various the methods applied to attain a more or less satisfactory result. However, when we retrace the historic of those various attempts and methods in its great lines, we can state that in the course of time there is a constant progress in the results of the instruction of the deaf mute.

One of the first efforts we read of to teach the deaf and dumb was that of the physician and philosopher, Jerome Cardan (born at Pavia in 1501), who demonstrated that "connected thought and reasoning is possible without the intervention of the spoken word," hence the deaf mute can be taught to read and write. This statement formed the fundamental principle of the so-called "Silent System." In the same century but later appear three Spaniards, Ramirez de Carrion, Juan Pablo Bonet and Pedro Ponce de Leon, who consecreated their lives to the education of the deaf and dumb, and had a great influence on their instruction. From Bonet and Ponce de Leon we read that they taught their pupils to speak, read, and write, and thus Bonet and Ponce de Leon must be considered as the originators of the aural system.

However in those early times we can not trace a regular course in the various methods used. The reports tell us the names of several men (Ramirez de Carrion, Arnoldi, Lasius, Van Helmont, Amman, Pereira), who instructed the deaf mute with considerable and remarkable results, but their efforts remain isolated attempts and do not form a complete system. Some of them have described their method, for instance Bonet, who wrote: "Reduccion de las Letras" (1620) and Amman who published a book: "Surdus Loquens." Others concealed their method as much as possible with the intention of making as much money as they could out of their business. It was only in the eighteenth century that the French Abbot de l'Epée created a regular and complete system for the instruction of the deaf mute, which has since been adopted by many institutions and which has gained a world-wide reputation. Not satisfied with the results of his teaching the deaf mute articulate speech, the Abbot de l'Epée worked out a systematic language of signs, which to the deaf mute should take the place of articulate speech. He perfected his system in such a degree that his pupils were not only able to indicate concrete objects but even to express abstract notions.

They could hold a conversation with each other and write down a dictation on different subjects. This system of de l'Epée called the "sign system" gained a great popularity, partly because of the great ease with which the deaf and dumb learned and still learn by this system to hold intercourse with each other; partly because of the open-mindedness of its author, which he showed in giving his system away to everybody, who wanted it, and of his never-relaxing efforts to raise his unfortunate fellow-creatures out of their spiritual isolation. About the same time that de l'Epée founded his institution in France, Samuel Heinicke founded a school (1777) for the deaf and dumb in Leipsic under the patronage of the Elector Frederik Augustus of Saxony.

Heinicke adopted the same principle as Bonet, Amman, Wallis and Van Helmont, to wit, that in the education of the deaf mute the artificial restoration of the voice and the use of oral speech must hold the first place. To Heinicke belongs the credit of first founding the German or oral system on a solid basis. When we follow the historical course of both the Oral and Sign Systems, until the present time we find the former supplanting more and more the latter in such a manner that actually there is hardly an institute where the sign and manual language is not brushed aside by the oral system. There are different reasons for this prevalence of the oral system. In the first place the oral system allows its disciples to hold intercourse with everybody and consequently to take a position in the community which, although not on a par with that of hearing and speaking people, nevertheless allows him to be his own independent advocate in society. The deaf and dumb who converse in the sign and manual language can only speak with each other and with the few that are initiated in this mode of exchanging thoughts.

Besides this first great advantage of the oral system there is another of far deeper meaning still. The sign and manual system is a purely artificial language, which avoids the difficulty that exists for the deaf mute in using articulate speech. The oral system, on the contrary, combats that difficulty; it contains an attempt at the restoration of normal speech and therefore must be considered as the healing or hygienic system, with which the hope of improvement is not excluded. Also continuing our investigations as to the progress in the instruction of the deaf and dumb we see how the oral system, by and by going further in its efforts to restore speech to the deaf mute, begins to try to take advantage of the remnant of hearing which a large percentage of the deaf and dum possess.

Already in the first half of the nineteenth century serious efforts to awaken and develop the hearing of the deaf mute had been made by Itard, Beck, Wolf, Toynbee and several others. These efforts, however, did not lead to the formation of a regular system and the interest in the aural exercises slackened again until the end of the nineteenth century when one perceives in the United States as well as in Europe a growing attention given to the important question of the development of the hearing of the deaf mute. At about the same time that the reports of the remarkable results in improving the hearing, attained by Gallaudet, Currier and Gillespie, were published in America, Javal begins his experience and investigations in France, Urbantschitsch in Austria, and Bezold in Germany. To the latter two famous aural surgeons Professors Urbantschitsch and particularly to Professor Bezold belongs the credit of having opened new possibilities for the instruction of the deaf and dumb and of having given to their education a course with deeper perspective than it ever possessed before. Professor Victor Urbantschitsch published the results of his achievements in his highly interesting book: "Ueber Hörübungen bei Taubstummen," to which I refer.

One of the principal and direct results of Professor Bezold's investigations is the classification of the deaf and dumb in different groups. In the schools where Bezold's method is adopted, the totally deaf and the partially deaf remain together only during the first year; after which time they are divided into two classes. In the first are placed the totally deaf and in the second the congenital deaf with a remnant of hearing and those with acquired deafness. This latter class is instructed after the "mirror method," whereby the words are directly spoken in the ear of the child while it has a mirror in the hand wherein it can follow the movement of the lips of the teacher. The children learn in this manner to hear and read from the lips at the same time and this method is thus a combined form of the oral and the aural system.

As the advantages of the method of Bezold we noticed a quicker perception and a better understanding of the language, a more intelligible and smoother pronunciation, and, last but not least, a greater progress and a higher degree of intellectual development.

Another advantage, not less important, of the investigations of Bezold and Urbanschitsch is that the hearing power of each deaf and dumb person is henceforward the subject of a careful examination. The hearing for sounds, for vowels, for words and for sentences is calculated as carefully and as exactly as possible. And as a consequence of these examinations appropriate exercises come forth to improve the remnants of hearing and to develop a hearing for sounds in a hearing for vowels, for words, and for sentences, if possible. The results attained in this respect by Urbantschitsch and his helpers are so satisfying that they induce him to go further still and to try to awaken the hearing of the totally deaf in which he is, as the reports tell us, in many cases successful.

New questions arose with this new course in the treatment of the deaf and dumb: (1) Which is the best method by means of which to calculate the hearing of deaf and dumb pupils? (2) How can we best awaken and improve their hearing power? (3) What are the obstacles we meet during the process of exercising the hearing?

As to the testing of the hearing I presume that the different systems are sufficiently known, so that I need not insist on this question.

With the object of awakening and improving the hearing Urbanschitsch used in the beginning only the human voice, as being of course the best medium for the understanding of speech. But as this method proved to be very fatiguing for the instructors, he tried to employ instruments of which the vibrating tones acted as a stimulant to the hearing. He constructed therefore a kind of harmonica or tonometer with which he could produce tones of all pitches which the human ear can perceive. He made the pupil hear especially those tones of the scale which correspond with the tones contained in human speech, thus from $b^1$ to $g^2$. This harmonica of rather primitive construction proved, however, to be a good help. Since then ever so many instruments have been applied with more or less success with the intention of raising and stimulating the slumbering and reluctant hearing by the vibration of sounds, until some twelve years ago when Professor Marage of Paris succeeded in constructing a kind of siren, which indeed proves to be of great merit if it is not indispensable for the instruction of the deaf and dumb on a modern basis. The instruments hitherto used produced non-periodic irregular vibrations, or continuous periodic regular vibrations (simple or complex). Now the fundamental vibrations of human speech are discontinuous, periodic, regular, vibrations, and thus when we want an instrument to revive and improve the hearing for speech this instrument must reproduce those characteristic vibrations of speech. This was the principle on which Marage constructed his apparatus. (For an ample description of the siren I refer to "Les Travaux Scientifiques de René Marage," Masson et Cie., Paris). The siren (sirène à voyelles) reproduces the fundamental vibrations of the vowels aa, a, ee, o, oo. The success obtained by the treatment with this siren in different kinds of deafness induced Marage to apply the treatment to the deaf and dumb. Experiments were made with 23 deaf mutes of which 19 were reputed totally deaf. We find the results of those experiments in: "Mesure et Développement de l'Audition chez les Sourds Muets." Masson et Cie., Paris.

From those results we can deduce the following conclusions: The siren renders a great service in enabling one to test the ear of the deaf mute. It proves to be of excellent use for the development of the hearing of the deaf and dumb, also for the awakening of the hearing of the totally deaf. With the siren we attain in six weeks results which we can hardly attain in a year or more by exercising with the voice only. After the results of a daily treatment of five minutes during six weeks we can state if the progress of the hearing has reached such a degree that we may expect any success in exercising with the human voice.

We need not insist on the importance of the apparatus and the classification of the pupils ought not to be made until after the treatment with the siren. By the results obtained we can immediately decide which system must be applied: Whether the combined form of the oral and the aural system should be used or whether the pupil would be best instructed by the pure oral system, or whether the sign and manual system should be used, which would be the case in a few instances.

Besides the treatment with the siren of Marage I apply the exercises with a tonometer composed of

tuning forks of heavy caliber and the sound increasing resonator of Montalbetti. Those exercises are to be recommended in those cases in which some series of tones of the scale are not heard or are heard only insufficiently. Special attention must thereby be given to that region of the scale which lies between $b^1$ and $g^2$, as between these intervals lie the tones which are absolutely necessary for the perception of speech.

For the exercises to sharpen acoustic attentiveness I use by preference a large cithern. It is also highly desirable that the aural pupils should attend concerts, specially those of the full orchestra or of a big organ. When there is any possibility of making a pupil himself play an instrument, we immediately take profit of this disposition, for not only will the vibrations of the instrument strengthen the hearing but also at the same time the playing of an instrument forces the pupil to listen and to appreciate all the differences of pitch and the intervals.

Of course the treatment with the siren of Marage and exercising with all the instruments are intended in the first place to support and to facilitate the exercises with the human voice. To make speech perceptible to the ear there is no medium except the human voice. Also when by the treatment with the siren of Marage the hearing power is awakened and sufficiently developed to render aural instruction possible, the most important part of the aural instruction begins, namely, to make the deaf and dumb understand by the ear the spoken word, and to make him speak the word he perceives. This difficult part of the instruction demands all our patience and an utter consecration to the task. This is not the place to mention the exercises and I pass on to the obstacles we meet during the course of instruction.

During the exercising we soon perceive the difference between the power of perception and that of association and the action of the motor nerves of speech of the deaf and dumb with acquired deafness and of those who suffer from congenital deafness. And again we will notice a difference between those children with acquired deafness who became deaf in early infancy, before they had ever spoken, and the children who lost their hearing after the formation of the power of speech. We will observe that the children of this latter group, when once they have heard the vowel, word, or sentence and are invited to speak it, reproduce immediately without any hesitation and with full understanding what they heard, with the same accent with which it is pronounced.

In the second group, in the children who have acquired deafness in early infancy, we notice that the understanding of what is heard is very slow and reluctant, but when once the vowel, word, or sentence is understood, it is pronounced, somewhat weakly, but without much difficulty. Often also they utter fluently what is heard, but without understanding the meaning of the word they pronounce. In that case the understanding of what is spoken comes only after the action of the motor nerves of speech. The children of these two groups are dumb while they are deaf. The first group, including children who acquired deafness after the formation of speech, are dumb because of the fact that their speech was not specially attended to after they became deaf; they have forgotten their language because they were not able to entertain it by their hearing. The pupils of this group are distinguished by the possession of a more melodious voice.

In the children who acquired deafness in early infancy the understanding of what is heard is slow and reluctant while they do not know the sounds of the language. They do not recognize the sound they hear; their treasury-room of memory is still empty of words and syntax. In those pupils we must resort to the oral system in order to help the aural instruction. The recognition of the word by the eye must lead to the understanding of the sound of the word. Generally the pronunciation and articulation of these pupils is weak and the voice is monotonous, but the instructors will notice that the exercising of the voice and the speech muscles is far more easy than is the case in the congenital deaf.

In the pupils who suffer from congenital deafness and dumbness the power of perception and of association and the action of the motor nerves of speech are generally all equally slow, hesitating and weak. These pupils are the real deaf and dumb. When we succeed in developing their hearing power even to a high, almost normal degree, the instruction has to seek with the greatest difficulty to combat their dumbness or, what is the same, to develop the inner cerebral mechanism that governs speech. To reach a correct understanding of the cause of the difficulties mentioned we must remember the formation of speech by the normal infant. We distinguish different periods in the development of the infant's speech. In the first period, during the first year, the infant utters involuntary sounds, which must be considered as a simple muscular action of the apparatus of speech produced by an unconscious reaction of the numerous stimuli which the child receives from without. Later on the stimuli becoming more intense reach, through the spinal marrow, the centers of the cortex, and the child begins to feel the muscular movements and to be conscious of them. About the same time, however, the child begins to hear the sounds it produces. Henceforward it feels those sounds as well as it hears them. Both sensations now leave their traces on the cortex of the brain in those parts which are destined for the motor center of the muscles of articulation and for the center of hearing. The sensations of feeling and of hearing the word occur simultaneously and therefore they become united by simultaneous association. The child now begins to imitate the sounds it produces itself and soon thereafter it notices the sounds produced by others and it tries to imitate them.

The child now commences to appreciate the conformity between the sounds it hears and the sounds it utters, the imitation becomes more and more complete, and finally syllables and simple words are pronounced. However, this pronouncing of words is simply mimicking what the child hears: the words have not yet any meaning for him. It is only gradually that the association between the heard and pronounced word and the realization of its significance takes place. This association is brought about by the simultaneous hearing of the word and the seeing of the object which the word indicates. Whenever the child sees its doll the word doll is repeated till at last the child unites the word doll inseparably with the object itself and henceforward the heard word and its characteristic meaning are fixed in the child's memory. The child enters the third period when it begins to use the words which it knows by memory. When it wants its doll it will

pronounce the word doll even without seeing the object or hearing the word pronounced by standers by.

Through what has been explained above, it is obvious that the hearing plays a predominant rôle in the learning of speech. Comparing now the normal case with the case which has acquired deafness in early childhood (which case is found suitable for aural instruction, where there is no serious organic defect either of the ear or of its nerves) it is clearly perceived to what extent the deafness causes a backward development of the centers of perception and of speech and of their association. These retardations in development and non-development take the form of a sensory and motor aphasia, which is more or less serious according to the period in which the child became deaf. Here the deafness is primary and the aphasia secondary: the child is dumb because it is deaf.

In the congenitally deaf and dumb (who, of course, are also found suitable for aural instruction provided there is no serious organic defect either of the ear or of its nerves) we cannot draw conclusions with the same assurance as in the preceding instance, for in the congenitally deaf and dumb the deviations in the development have already taken place before birth and consequently it is still more difficult, if not impossible, to determine the nature of the disease. However, while the preliminary treatment has awakened and later on has produced an appreciable amelioration of the hearing, we believe that we are justified in speaking here also of an arrest in development. It is only during the course of the instruction that we can determine whether this method of instruction is justifiable. It is evident, however, that the non-development of the parts has a greater extension and goes deeper in the congenitally deaf mute than in the deaf and dumb with acquired deafness. Also during the course of the instruction we will meet with greater difficulties in combating the sensory and motor aphasia. But we cannot say if the results will be less satisfactory, as the intelligence and the general disposition and the character of the child have a great influence on the instruction. A pupil with a favorable disposition and a good character but with serious retardation in the cerebral mechanism for hearing and speech will sometimes give more satisfactory results than the unintelligent and lazy child who has only a slight arrest in development.

A statement that we can make with all assurance and which we cannot repeat with too much emphasis is that the instruction cannot begin too early. This teaching of the very young child is essentially a woman's task. It is infinitely delicate and is the subject of the greatest efforts of patience on the part of the instructors, but the results will largely pay for all the exertion, labor, love, and attention lavished on the unfortunate child.

Plaats, 10.

## CALCIUM THERAPY OF TUBERCULOSIS.

By MAX KAHN, M.D., M.A., Ph.D.,

NEW YORK.

DIRECTOR BETH ISRAEL HOSPITAL CHEMICAL LABORATORY; ASSOCIATE IN BIOLOGICAL CHEMISTRY, COLUMBIA UNIVERSITY

Practitioners of medicine have used the lime salts in the treatment of tuberculosis for several centuries. It was prescribed empirically at first, and later on physicians based their therapy of phthisis with this element on the ground that the disease was due to a demineralization of the organism of its lime salts. Others have recommended the use of the calcium salts, not as a curative agent of the disease proper, but as a means of preventing the hemorrhages to which the tuberculous are so prone. But not all physicians are enthusiastic regarding the use of this remedy, in spite of the fact that very good results are reported in the literature. There are several proprietary medicines on the market purporting to cure tuberculosis, which contain as their main ingredient 4 per cent. of the chloride of calcium. It was thought proper to summarize our knowledge of this matter so as to be in a position to draw some conclusion regarding this subject.

In 1783 Fourcroy suggested the use of lime in the treatment of tuberculosis, and, though his results were inconclusive, he urged a general tryout of his plan. It was his custom to administer one gram calcium chloride internally, and to apply externally compresses soaked in a solution of this salt. Fourcroy's recommendation was but an empirical one, for he had no scientific data upon which to rest his claims. Since his time rather little work has been done on calcium metabolism in general, and very desultory have been the researches on the metabolism of lime in the tuberculous. Our knowledge of this subject is, therefore, very meager, but certain important facts and principles have been established.

A portion of the calcium present both in animal and vegetable food exists in loose combination with certain albumens of acid character, but by far the greater part occurs in the inorganic state as salts of phosporic and carbonic acids. Vegetable foods are generally richer in calcium than are flesh foods. Eggs and milk are particularly rich in lime because the embryo and infant need much calcium in their period of growth. The greater part of the calcium which enters the body passes into the feces, although in varying proportions, according to the nature of the food supplied. According to Bertram[1] there is present in the urine of man 18 to 43 per cent., and in the feces 60 to 80 per cent. of the calcium consumed. The fate of calcium in the body is very closely connected with that of phosphoric acid. The quantity of calcium excreted in the urine increases when calcium phosphate or carbonate is administered in the diet; thus Soborow[2] found that in two cases so fed the amount of lime excreted daily in the urine rose from 0.28 to 0.87 gm.

The insoluble inorganic calcium salts are dissolved in the stomach depending on the amount of hydrochloric acid present. The greatest absorption, however, is not in the stomach but in the upper part of the small intestine.[3] There the dissolved calcium salts are transformed again into neutral or acid calcium carbonate or phosphate, and into the salts of fatty acids, the amount taken up by the body depending on the reaction of the intestine, on the quantity of carbonic and phosphoric acids present, and upon the various fermentation acids present. During starvation a part of the calcium set free through the breaking down of the cell tissues appears in the feces. Müller and Munk found in two such cases 69 and 32 mg., respectively, in the feces, and 377 and 446 mg., respectively, in the urine.[4]

In adult dogs the calcium requirement is entirely dependent on the diet; the more protein, fat, and probably even carbohydrate in the diet, the greater

the amount of calcium required to keep an animal in calcium equilibrium. The explanation of this is that calcium combines with injurious or useless metabolic products in order to assist in their elimination.

For adult rabbits 0.006 gm. of CaO in vegetable form per day per kilogram of body weight was sufficient to maintain calcium equilibrium during five months. The CaO content of the bones was 300 times greater than the combined CaO content in the albuminoid material.[6] Calcium salts, when injected subcutaneously or intravenously, pass out quickly and almost entirely through the intestine, the large intestine being chiefly selected, although minute quantities are excreted by the small intestine. Voit[7] concluded that calcium was excreted by the intestinal wall, and Rey[8] showed that the amount thus put out may reach 50 per cent. of the intake. The addition of sodium chloride appears to increase the output of lime. In diabetes, these authors found, there was generally a calcium salt loss. From these experiments we may conclude, therefore, that the primary organ for the excretion of calcium is the intestinal tract, and the organ of next importance is the kidneys.

On these grounds, hence, it is futile to attempt to determine the amount of calcium absorption in the body, or the condition of the normal body upon which this absorption depends. For the same reason the attempts to refer those diseases which depend on an imperfect deposition of lime in the bone (rachitis) to an imperfect absorption of calcium salts have failed completely.[9] The general statement may, however, be made that the greater the amount of acid constituents present in food or produced in the body (for example, from the sulphur of protein) the greater is the amount of lime appearing in the urine. With an increased acidity of the urine its power to dissolve calcium is also increased. This explains why so little calcium is found in the alkaline urine of the herbivora, and so much more comparatively in the urine of carnivora.[10] On the same grounds Bunge explains[11] the greater percentage of calcium in the urine from meat diet compared with that from vegetable diet. More calcium appears in the urine after administration of acid calcium phosphate than after the corresponding basic salt. Hydrochloric and sulphuric acids increase the calcium output by the kidneys. Administration of alkalies somewhat diminishes it.[12] In diabetic acidosis, and in other conditions in which greater quantities of organic acids are present in the tissues, the urinary calcium is considerably raised, but falls when such cases are treated with sodium bicarbonate.[13]

A few years after the aforementioned Fourcroy, Quarin also recommended the use of chloride of lime in the treatment of tuberculosis, and he reported good results. In 1832 Cohen,[14] after a lapse of almost forty years, gave a new impetus to the use of calcium for the phthisical. Despinay,[15] in 1860, recommended calcium carbonate for tuberculous patients, and Hahnemann, ten years later, attested to the efficacy of Despinay's method by recommending the use of "calcaria carbonica" in phthisical individuals.

Senator,[16] the great authority on physiological chemistry, asserted that in pulmonary phthisis an abnormal quantity of calcium is excreted in the urine, even if little food is administered, and the patients suffer from diarrhea. This results in a poverty of calcium in the organism.

Crighton[17] obtained very excellent results in the treatment of tubercular adenitis by administering internally a solution of calcium chloride for a period of two or three years.

Before administering the lime salts to patients it is important to be cognizant of the general pharmacology of this remedy. Velden[18] administered to patients 4 to 6 gm. of calcium lactate daily per os; to others he only gave 0.5 gm. of the lactate per diem; while to a third group of patients he injected intravenously a few cubic centimeters of a 5 per cent. solution of calcium chloride. He found that calcium enhances the coagulating power of the blood, and renders the morbidly permeable vessel walls less permeable. The latter effect is strikingly evident in hemorrhagic affections, such as scurvy. The hemostatic effect, therefore, can be anticipated only in cases of bleeding by diapedesis. This fact should be remembered when treating cases of pleural effusions, where the use of calcium will render the vessel walls less pervious, and will thus check absorption of the fluid. The absorption of calcium depends on a variety of factors, especially on good gastric secretion and on the absence of fermentation acids in the intestine. However, it must not be forgotten that animals develop cachexia when given lime salts over long periods.

Our knowledge of the salts excreted through the urine in phthisis is not settled. In phthisis the balance sheets show, according to certain authors, that there is a demineralization in the tuberculous, but according to others, it can not be regarded either as a constant or as an early sign of phthisis.

From a study of the metabolism of six cases, Vanini[19] found that while the tuberculous organism generally lost salt this loss was not a regular phenomenon, periods of salt retention even being noted. The general salt loss is regarded by Vanini as a result of the general disturbances of the nourishment of the body, and hence, not a primary symptom.

The results of Vanini were not corroborated by the researches of Sarvonat and Rebattu.[20] They found that the tuberculous suffer with marked absorption disturbances and especially with high mineral secretion. Lung tuberculosis patients show high calcium content of the feces. Perhaps this is a method of getting rid of excess of calcium from the body, but the urine does not take part in this decalcification.

Halpern[21] also found that in cases of tuberculosis there is a marked demineralization of the organism, which results in an increase in the neutral sulphur of the urine when the patients are on a diet rich in inorganic sulphur. In a paper on the influence of tuberculosis on the mineralization in guinea pigs Sarvonat and Rebattu[22] gave analyses to prove that in the ash of the skeleton and soft tissues the content of phosphorus varied irregularly, tending to be high in the soft tissues. The relative content of calcium of healthy and tuberculous tissue (guinea pig) is shown in the following table:

| | Normal pigs, grams | Tubercular pigs, grams |
|---|---|---|
| Calcium of bone | 6.342 | 4.6 |
| Calcium of soft parts | 1.253 | 0.774 |
| Relation of calcium to total (bone) | 0.496 | 0.357 |
| Relation of calcium to total (soft parts) | 0.179 | 0.162 |

It is a fact, that according to the extensive metabolic experiments carried out by Ott,[23] that there is a demineralization in tuberculosis. But it is wrong

to assume that it is an inevitable symptom, or that it is a symptom that occurs in the early course of that disease. This contradicts the findings of the French observers.

The author[24] found that tuberculous lung areas are twice or thrice as rich in calcium salts as normal lung areas. He also found that guinea pigs inoculated with tubercle bacilli cause a deposition of lime salts in the tuberculous areas. But this is not to be taken as an argument for the treatment of tuberculosis by calcium salts, according to Peittre.[25] He found that a large number of the calcified tuberculous foci (which were examined during a sanitary inspection of beef) showed that a large proportion of such lesions contained virulent tubercle bacilli. From this he concludes that calcification of the lesion is not a sign of their healing, and therapeutic methods based on the introduction of calcium salts into the body are illusory and perhaps dangerous. He also states that the age of a lesion can not even be approximately estimated by the presence or absence of calcium carbonate deposits.

In 1905 Ferrier[26] recommended the use of lime salts for the treatment of tuberculosis. His therapy is based on the theory that tuberculosis induces a decalcification of the organism. His method of treatment has won many admirers, especially among the French and Italian physicians, and lately the British and American medical journals have published articles lauding this procedure. This so-called calcium therapy of tuberculosis is as follows:

The patient is placed in the best hygienic surroundings. Strict attention is paid to the diet. He is forbidden to use wines, beers, ales, etc. All acid fruits like lemons are interdicted. The patient is fed on potatoes, carrots, eggs, meats, fish, etc. As much rest as possible is urged. In addition to this the patient receives several times a day calcium carbonate, 0.5 gm.; tricalcic phosphate, 0.2 gm.; calcium and magnesia, 0.15 gm., and sodium chloride, 0.15 gm. Although Ferrier claims very good results for his method, still he emphasizes the fact that it is not *per se* a complete therapeutic method, and must not be looked upon as a specific. He states that the method of "recalcification constitutes the best means at our disposal for resisting tuberculosis. It has for its object to combat the humoral conditions which prepare the soil for the germination of the tubercle bacillus, and which facilitate its dissemination throughout the organism."

Letulle,[27] working in collaboration with Ferrier, obtained very good results with this method. They treated tuberculosis in all its stages, and they found that the condition became much ameliorated. The respiration became regular and dyspnea was diminished. The expectoration disappeared in many cases or else became less. Night sweats ceased from within one week to one month. The appetite was very much improved.

Even before Ferrier, Michelazzi[28] suggested the general use of lime in the treatment of tuberculosis. He personally obtained very good results, and he based his opinion on clinical and experimental observations. A little before the work of this author appeared in press Rudolph[29] reported very happy results from administration to five phthisical patients, tuberculin, together with 120 to 250 gm. of lime water per os daily. Defotenay[30] recommended that a drink containing a salt of calcium and syrup of tolu be given to patients suffering from tuberculosis. He obtained good results.

In his dissertation Colin[31] reported that the method of Ferrier is very commendable. He found that the procedure regulates the digestion, induces calcification in the lungs, and stops hemoptysis. The lime administration is of value, also, in tubercular peritonitis, laryngitis, epididymitis, etc. The good results are due to the calcification of the tuberculous areas.

Courtellement[32] found the method of Ferrier very efficient. He used it in the treatment of a whole sanitarium of patients with very good results. Likewise, Rostaine[33] obtained good results with the Ferrier treatment. He claimed that this is the only logical treatment, and he recommended it highly.

Several authors, however, have expressed themselves as opposed to the Ferrier school. Cosimo[34] found that saturation of the body with lime salts does not increase the calcium content of the lungs, owing to the presence of a substance in the lungs which "repels" the deposition of the lime. This finding is a corroboration of the report of Bracci. From these experiments which he performed on rabbits Cosimo concluded that calcium is not a remedy for lung tuberculosis.

Another criticism of Ferrier was made by Robin.[35] He stated that the treatment urged by Ferrier is based upon the fact that in the tuberculous there is an increased phosphaturia. But Robin did not believe that this symptom required treatment. Even if demineralization does occur in phthisis Robin did not believe that this demineralization can be cured by the administration per os of small quantities of calcium. He disagreed with Ferrier that there is present in the tuberculous a gastroenteric disorder which aids lime excretion, thus inducing the decalcification of the organism.

But seven years before Robin reported his results Angiulli[36] found an increased phosphaturia in the pretuberculous and the tuberculous, which, he considered, induced a breaking down of the natural protective forces due to the accompanying increase in lime excretion. He, therefore, injected into his patients monocalcium phosphate in increasing doses. Of course, this treatment took a long time, but he reported several cures.

Ferrier had said that in the tubercular there is a gastrointestinal derangement which causes an increased calcium excretion. This observation could not be confirmed by Robin. Loeper and Bechamp,[37] however, indirectly corroborated Ferrier's observation. They found that certain chronic intestinal diseases cause a loss of calcium, and from this arise symptoms such as asthenia, loss of weight, decrease of coagulation, hemorrhages, and nervous disturbances. In a later communication they reported[38] that in gastrointestinal lesions the calcium content of the blood is decreased.

Another author also reported lack of success with the Ferrier treatment. Lewisohn[39] administered per os calcium salts to thirty febrile tuberculous individuals for a period of four weeks. He found that this treatment did not in the least affect the temperature or the general condition of the patients. It was his custom to prescribe 0.5 gm. calcium lactate every four hours.

Crofton[40] indorsed the calcium treatment of tuberculosis. He explained the increased lime excretion in the tuberculous by the fact that "there is a selective affinity recognized to exist between calcium and an albumose (deutero albumose) known to be universally present in tuberculous foci, culture media, in the bacillus and in the excreta of

tuberculous subjects." Crofton brought evidence to show that this albumose produces fever in tuberculous subjects, and this pyretogenic power is lost by combination with calcium. He recommended the use of calcium in phthisis.

Sergent[44] used the Ferrier treatment for six years in his practice, and he obtained very favorable results. Four years ago Russel[42] declared that the treatment of tuberculosis should be based on the consideration that it is a disease due to a lime starvation of the body, which can be remedied only by furnishing the body with enough calcium to overcome this deficiency.

Lately Bruhl and Buc[43] reported the results of injection of 30 per cent. solution of calcium chloride crystals in twelve tuberculous patients with advanced lesions. In all cases the condition was very grave, with high fever, and tubercle bacilli in the sputum. In the majority of the patients treated the local signs improved rapidly; the expectoration became less profuse, and the cough less harassing after the third injection. There was marked increase in body weight, but the reduction in temperature was comparatively slight.

In 1905 Hacker[44] expressed the opinion that the inhalation of fine particles of gypsum dust is very beneficial in tuberculosis of the lungs. The effect is due to calcification of the diseased areas in the lungs, which is induced by the fine particles of calcium sulphate. This has been corroborated by Boston,[45] who reported the case of a man who was suffering from pulmonary tuberculosis, and who accidentally inhaled lime dust, and was completely cured.

Another American physician, Wells,[46] had used calcium in the treatment of tuberculosis for several years before Ferrier wrote his first report on this subject. Wells prescribed calcium suiphide. 15 grains three times daily. It is to be understood that he attended to the diet and general hygienic surroundings of the patients as well.

In looking over the mass of literature on this subject one is left in doubt whether the use of lime in the treatment of tuberculosis is to be recommended. There is, however, no danger in its use, and according to the observations of a number of physicians, it is of marked benefit.

# PULSE PRESSURE IN DIAGNOSIS AND PROGNOSIS.*

BY J. S. LANKFORD, M.D.,

SAN ANTONIO, TEXAS.

MEDICAL DIRECTOR, SAN ANTONIO LIFE INSURANCE COMPANY

THE range between the diastolic and the systolic is the pulse pressure. A blood pressure reading is not complete, and may be very deceiving, if the pulse pressure is not ascertained. Further experience is daily proving the truth of this statement.

Some abbreviated case reports showing the importance of the pulse pressure may be of interest:

CASE I.—W., aged 47, insurance agent, sought advice for embarrassed breathing. Upper chest slightly heaving with each heart beat, anxious expression, marked pallor. Systolic pressure 230, diastolic 90, pulse pressure 140 mm. Diagnosis, aortic regurgitation. This diagnosis was made on the blood pressure reading, as no other condition produces this extensive pulse pressure. Of course, the diagnosis was confirmed by other methods.

CASE II.—G., aged 27, farmer, applicant for life insurance, reported by competent examiner with diastolic 55, systolic 120, pulse pressure 65 mm., otherwise a first-class risk. Aortic trouble was suspected and the examiner requested to re-examine after vigorous exercise. Rapid pulse, great irregularity, air hunger, and an aortic murmur were reported and the applicant was declined. Later reports indicate serious disease. It will be noticed in this case that the systolic pressure was normal, and the applicant would have been accepted but for the pulse pressure revealed by the diastolic reading.

CASE III.—K., aged 58, construction contractor. Gallbladder drained one year ago. At that time was in

*Read before the Sixth District Medical Society, Corpus Christi, Texas, April 8, 1914.

serious ill-health, with systolic pressure 210, and a trace of albumin. Diastolic pressure not taken. Now in the terminal stage of nephritis; myocarditis marked, mitral stenosis and insufficiency; labored respiration, general anasarca; systolic pressure 120, diastolic 105, pulse pressure 15 mm. This is a case where the myocarditis and insufficiency make it impossible for the heart to respond to the stimulus of the accumulated poisons in the blood. (This patient died a week after this report was written with the remarkable pulse pressure of 10 millimeters.)

Case IV.—S., aged 55, railroad builder. Hypertrophy with arteriosclerosis, myocarditis, auricular fibrillation; Cheyne-Stokes respiration, great restlessness, "traveling delirium," with occasional violence; kidneys fairly good; systolic pressure 137, diastolic 120, pulse pressure 17 mm. Patient died suddenly in the ninth week. In this case it would seem that the peripheral resistance caused by the toxic blood and the rigid blood-vessels maintained a high diastolic pressure while the heart had not the strength to keep the systolic high. With 25 millimeters additional systolic pressure he might have lived longer.

Case V.—M., aged 40, government inspector, Cardiovascular renal disease, far advanced with great hypertrophy but without leaking; urine rich in albumin and casts, systolic pressure 210, diastolic 165; usual attending symptoms, dizziness, headache, wakefulness, disturbed digestion, irritable. Patient developed rather suddenly air hunger, which was continuous and very distressing. As the heart was compensating and the pulse pressure was compensatory, it was suspected that acidosis was affecting the breathing center and liberal use of alkalies soon afforded relief.

Case VI.—P., aged 38, paving contractor; living under very heavy nerve strain; restless, wakeful, weak; intestinal digestion impaired, autointoxication pronounced; a trace of albumin, several hyaline casts, indican excessive; systolic pressure 118, diastolic 100, pulse pressure 18 mm. There was no indication of organic disease of the heart to account for the rather low systolic pressure and the abnormal pulse pressure, and it was believed that the toxemia was spending its force on the heart muscle, limiting its power. When the poison had been swept from the intestinal tract and eliminated from the blood the systolic pressure promptly rose to 135, striking the proper balance. That organic disease would soon develop in such a case is more than probable.

All these cases were examined repeatedly and the pressures were fairly stable, as reported.

These condensed reports of a few cases selected from a great many similar ones in practice and in life insurance work show that we may be greatly deceived if we depend on systolic pressure alone. Examination of 1000 men and women in average health showed a pulse pressure of 20 to 50 mm. A safe range is 25 to 45 mm. Experience has proven that less than 20 or over 50 mm. is pathological.

The best way to obtain the pulse pressure is by the method of auscultation. The sleeve is rolled well up, but constriction avoided; the cuff is adjusted, the arm laid at rest with the palm of the hand nearly upward; the stethoscope is applied over the artery near the condyle and compression is made till a sound is heard, and is increased till it disappears. Then the pressure is released slowly, and when the collapsed artery fills with blood there is a thumping or snapping sound with each pulse beat. This will continue while the indicator or mercury column traverses about five millimeters, and for the next five or ten millimeters, in many cases, there will be a murmur not unlike a moderate mitral murmur; then follows the sound, increasing in intensity to a high point, then rapidly disappearing. The first return appearance of the sound is the systolic and the high point before disappearance the diastolic.

These illustrative cases show the valuable aid of pulse pressure reading in diagnosis and prognosis in several different conditions, but there are other cases where it will be found useful and by the method of auscultation it is simple and easy to obtain.

It is quite possible to learn the extent of disease of the myocardium by means of the blood pressure. If a patient is exercised vigorously the systolic and diastolic pressure will usually rise. Testing the pressure every three minutes will show a prompt return to the normal in a sound heart, but very slow return in disease of importance. If there is serious myocarditis the systolic pressure may fall and diastolic remain stationary, thus developing small pulse pressure.

A study of the sound in average normal hearts is very interesting, especially in life insurance, and will readily reveal weakness, or lack of size, or, on the other hand, the strength and the power to fight disease successfully.

We have much to learn about blood pressure, but three things have been clearly demonstrated:

1. The sphygmomanometer is so valuable in the diagnosis and prognosis and in the treatment of disease that it is indispensable to the progressive physician, the successful surgeon, the competent medical examiner.

2. The pulse pressure is absolutely essential and therefore the diastolic pressure must be taken.

3. The method of auscultation is the best.

## THE FRENCH ASPECT OF FUNCTIONAL LIVER TESTING.

By MARTIN E. REHFUSS, M.D.,

PHILADELPHIA, PA.

Standard methods belong to no one country. The rapid diffusion of scientific knowledge at the present day makes a method which claimed the attention of a little group of workers on one day the property of the world on the next. To label a method French or German is to deny that it has earned that dissemination which attends any worthy effort. But to say that the aspect or general method of approaching a problem is somewhat different in the various centers is to voice a truth which must be apparent to anyone who has had an opportunity of seeing different schools at work. In France, for example, the teaching of the Widal school is the dominant thing in the study of renal lesions and examinations of the blood sera are the order of the day. In Germany these methods give way to the cryoscopic index and functional color tests. If the French have devoted more time to cholesterinemia, azotemia, oxalemia, hemolysins, and sensitized vaccines, the Germans have erected their framework on an elaborate system of physiochemical and metabolic studies. It is therefore of interest to simply discuss the aspect of functional liver testing in France, together with a short description of the classical syndromes attending liver disturbances.

Diseases of the liver have remained in our textbooks on a more or less well-defined pathological basis, with a tendency through the recent application of functional tests towards the recognition of certain faulty functional conditions. The greatest interest attaches to the various methods which have been advocated recently toward the elucidation of hepatic function, namely the phenoltetrachlorpthalein test (Rowntree, Hurwitz, Bloomfield, Whipple) and the estimation of blood lipase and fibrinogen (Whipple, Mason, Peightal). These methods seem to be clinically applicable, and it is hoped that extensive data will soon be forthcoming. In the meantime it seems to me that clinical appreciation of

these syndrones dependent on functional disturbances does not seem to have crystallized to the same degree as the French clinicians have attempted the problem.

Bearing in mind the topography, anatomy, and contiguous relations of the liver as an explanation of the pathological processes in that region, we are requested to pay careful attention to its physiology. The functions of the liver as they are recognized are tabulated below in the first column, and the functional tests which have been based on a disturbance of each function are to be found in the second column.

| INTERNAL SECRETIONS | FUNCTIONAL TESTS |
|---|---|
| 1. On carbohydrates: glygenic function. | Alimentary glycosuria. |
| 2. On fats: adipopexic = arrest of fat in the Kupfer cells; adipoetic = formation of fat from carbohydrate; adipolytic. | Lipuria. Lipemia. Ultramicroscopic test. |
| 3. On albumins; ureopoetic formation of urea. urea nitrogen ÷ total nitrogen = nitrogen coefficient; normal = 0.85—0.95. | Reduction of nitrogen coefficient, increase of amino acid polypeptid, and ammonia nitrogen at the expense of urea. |
| 4. Thermal function. | Hypothermal condition. |
| 5. Antitoxic: alkaloids, bacteriopexic, metal salts. | Hypertoxicity of the urine. Intermittent elimination methylene blue (Chauffard), basis methylene blue test of Roch, |
| 6. Blood: hemolytic. | due to (a) disease of the liver cell, (b) excessive fragility of the red cells. |
| 7. Coagulation of the blood:—formation of thrombin; formation of fibrinogen. | Lessened coagulability. Hemorrhage. |
| 8. Conversion of urobilinogen into bilirubin. | Urobilinogen in the urine. |
| EXTERNAL SECRETION | |
| 9. Bile. | Giving rise to the general urinary, fecal, and serum changes. |

Therefore it is evident that if there is a disturbance of the liver cells, a corresponding disturbance in function will result. Whether there are isolated disturbances in function due to focal lesions as those determined experimentally remains to be demonstrated.

The urine is examined for bile pigments, bile acids, the elimination of urea, which decreases in insufficiency, to rise in certain cases of exalted function. Ammonia which normally oscillates around 0.70 grams per liter can be doubled or tripled, while the elimination of the sulphur (Robin), namely the relation of completely oxidized to total sulphur which is normally 80-90 per cent. is reduced in certain cases of retention icterus and hepatic insufficiency. Indican for certain observers like Gilbert and Weil is a sign of hepatic insufficiency, but its presence in so many varied conditions and its obvious dependence on intestinal function makes it of little value as an hepatic test. Urobilin is considered the product of the diseased liver cell, the product of the "hematolyse hepatique" as Robin styles it. Since the researches of Hayem, urobilin was considered to be the result of the imperfect elaboration of hemoglobin liberated by the destruction of the red cells which the hepatic cells were incapable of transforming into normal bile pigment. Gilbert and Herscher, on the contrary, consider it to be renal in origin, formed on the level of the renal tubules from the bilirubin of the blood serum. Chauffard in admitting the possibility of its renal origin says that the small amount of the bilirubin in the blood serum is not without significance. This is different from the view commonly accepted, which is expressed in Ewald's recent work on "Leberkrankheiten," namely, that the urobilinogen is due to the transformation of the bilirubin in the intestines which is absorbed and taken back to the liver. The hepatic cells being diseased are unable to produce the transformation back into bilirubin, with the consequence that it reaches the general circulation and is eliminated by the kidneys. This would seem to indicate that the property of converting urobilinogen into bilirubin was a specific one of the hepatic cell.

While the feces are examined for the presence of bile pigment, stercobilin, and for fat determinations, the examination of the blood seems to be, if anything, more important. Here it is possible to demonstrate the bile pigment and measure it according to the method of Gilbert, Herscher and Posternak, which is based on the fact that beyond a dilution of 1:40,000 a reaction (Gmelin's) is not obtained. While normal individuals show a bilirubin to the extent of 1:36,000, the so-called "cholémiephysiologique," individuals afflicted with the so-called familial jaundice show a bilirubin which oscillates between 1:10,000 and 1:25,000, on an average 1:18,000; those with biliary cirrhosis 1:3,000, and those with the so-called simple chronic jaundice (Castaigne) 1:3,500 to 1:9,000. Urobilinemia (Troissier) cholesterinemia (Chauffard) determination of the refractivity of the red cells to graded solutions of NaCl have also been suggested. Here the red cells seem to have a normal or diminished resistance, and instead of there being hemolysis at 4.6:1,000, this takes place, for example, at 6:1,000. The demonstration of toxic and hemolytic substances in the sera, the presence of the so-called granular red cells (Chauffard and Fiessinger), and the demonstration of autoagglutinins of the red cells (Widal), and finally the dosage of the serum for urea (Widal), are all of great importance in reaching a solution of hepatic disturbances. Finally the method of Lemierre and Brule of testing for alimentary lipemia is deserving of mention, even though its application is too recent to enable us to determine its value. It consists in giving the individual 30 grams of butter and bread and testing the serum with the ultramicroscope for the presence of little brilliant fatty granulations, the so-called hemoconies. In icterus with obliteration of the bile passages they are not to be found owing to the fact that the bile no longer penetrates the intestines, and absorption is prevented.

Various experimental methods have been used, among which are the following:

1. Alimentary glycosuria: This question is still an unsettled one. The old school, Rodger, Achard, and Castaigne, and Fiessinger, in their recent handbook on "Maladies du Foie et des Voies Biliares" still recommend the use of pure glucose. But Strauss long since demonstrated and advocated the use of levulose, claiming that 78.3 per cent. of liver cases gave the levulosuria, while only 6.3 per cent. gave dextrosuria. This was more or less gen-

erally confirmed and the general feeling was that this test is but a link in the chain of evidence and is by no means to be used alone. Strauss used 100 grams of dextrose in 500 c.c. of water while Castaigne recommends 150 grams in 300 c.c. to be taken over a period of one quarter of an hour, and the urine collected for the next ten hours and examined with Fehling's Solution. Lactose and Saccharose have the objection of first being converted into glucose before objection. Castaigne says that we are by no means to depend on this reaction alone—it is a "complimentary test," but the difficulty in establishing normal tolerance and the fact that there are so many outside factors make it by no means conclusive.

2. The elimination of methylene blue (Chauffard), 1 c.c. of a 5 per cent. sterile solution of chemically pure methylene blue is injected into the buttock or subcutaneously and its elimination studied in fractional specimens. Normally it commences in one-half hour, to attain its maximum in 3-4 hours, and gradually disappears in 50 hours. If on the other hand the elimination of the pigment is made in periods or cycles where there is a diminution and then an increase in output of pigment, in other words where the output is intermittent, there is present most often hepatic insufficiency. I have been able to perform this test on a number of renal cases and have observed this phenomenon on several occasions. The explanation seems difficult, and is best set forth in the statement of Chauffard, "Le bleu ne sert du reste qu'a mettre en evidence le phénomène plus general du rythme intermittent des eliminations urinaires chez les hepatiques."

3. Roch of Geneva has proposed a test which has found some application, but which lacks sufficient clinical confirmation. The patient is given a pill of 0.002 milligrams of methylene blue and the next twelve hours the urine is collected in three samples of four hours each. If the liver is not able to fix this amount which it normally should, the second sample should be green. I have used this on repeated occasions and in slight undoubted functional disturbances of the liver, the second sample was green. Only a few days before writing this communication I gave it to an individual who had a liver distinctly reduced in volume and definite symptoms of hepatic insufficiency and the urine over the entire three samples was green in color!

4. Experimental indicanuria: Gilbert, Weil and Delon claim that a normal individual on a milk diet after ingestion of 1 mmg. of indol does not exhibit indicanuria, while cne afflicted with hepatic insufficiency does. We see therefore, as Florand states, there is no pathognomonic sign for insufficiency or superactivity of the liver, nevertheless we have at our disposition a whole series of tests which taken collectively are extremely suggestive. Therefore, says Florand, when we are in the presence of a patient with persistent urobilinuria, diminution of urea and hypertoxicity of the urine, and when we can provoke alimentary glysosuria and an intermittent or cyclic elimination of methylene blue, we have the right to assume the hepatic activity is diminished. When, however, the urobilin is absent or only slight and passing, the urea is augmented and the urine is hypotoxic, and if all the glucose ingested is fixed in the liver we can believe that hepatic function is increased. Hepatic hyper- and hypo-states are therefore clinically appreciable and the information which these various methods give us form the basis of the study of that organ in France today.

If anyone will pick up the "Elements d'Anatomie et de Physiologie Médicales" by Landouzy and Léon Bernard, he will find after the description of the anatomo-physiology an account of the four great syndromes around which most of the clinical aspects of the diseases of the liver center. Castaigne in his little book "Les Maladies du Foie et des Voies Biliaries" gives five. The whole tendency is to group the symptomology of liver conditions in these four syndromes. Bearing in mind these states, especially the first two syndromes, many of the minor hepatic troubles will be explained.

1. Syndrome of hepatic insufficiency: This syndrome is present all the way from the slight insufficiencies which may characterize the infectious fevers to the severe cases with massive degeneration of the organ. In this syndrome there is an alteration of the hepatic cell and a corresponding alteration in function. From the reduction in bile formation, the stools are soft, fetid, greasy and pale; owing to a lessening in urea formation, there is a diminution of the output of this substance in the urine and an increase in toxic substances producing the hypertoxicity of that excretion. The liver is no longer able to fix urobilinogen and it appears in the urine. Owing to the fact that the liver is the great center for the neutralization of various toxins, these are not removed or neutralized and there results the general symptoms of intoxication, in this case characterized by an earthy tinge of the skin which is pale and dry, dry lips and emaciation from disturbances in nutrition, the fibrinogen and thrombin functions are impaired, resulting in an increased tendency toward hemorrhage, mucous, cutaneous and gastrointestinal; there is a subicteric tint to the conjunctiva; while the nervous system is the seat of more or less marked toxic symptoms resulting in cerebral torpor, somnolence, and even coma. In profound processes there is an alteration of the heat mechanism so that hypothermal state may result. Depending on the extent of the change, the alimentary levulosuria becomes positive, the elimination of methylene blue cyclic or intermittent, and there may even be a complete cessation in the elaboration of bile pigment. It must be remembered that this syndrome may be present in every degree from slight disturbances to those of intense type resulting in an almost complete cessation of function. This type is obviously improved by hepatic opotherapy.

2. Syndrome of hyper function: In certain cases, as in biliary hypertrophic cirrhoses, pigmentary cirrhoses, and in certain cases of diabetes, this syndrome is encountered. It is far less frequent than the former, but it seems that under certain conditions, especially those mentioned above, the liver function is capable of being exalted. There is an augmentation in the quantity of bile formed, resulting in the deep greenish brown coloration of the feces, and at the same time an icterus from the bile resorbed in excess, while the urine shows an inncrease in urea up to 50 grams in 24 hours. The alimentary glycosuria test is never positive, but on the contrary these individuals will often have a sugar tolerance above normal. Nevertheless the liver will in certain cases transform more of the glycogen into sugar than under normal circumstances resulting in a diabetes by hyperactivity of the liver. With this glycosuria, and hyper-urea

formation there are polyphagia and polydipsia and the glycosuria which is moderate after eating increases some five or six hours later. This type is aggravated by the administration of hepatic opotherapy in contradistinction to the former which is improved. In this syndrome pancreatic opotherapy finds its application.

3. Syndrome of portal hypertension: This we all know as the typical syndrome attending Laennec's cirrhosis. This corresponds to the stasis of the portal area and the congestion and alteration of all the organs drained by it. The gastrointestinal catarrh, and hemorrhages, hemorrhoids, splenomegaly, collateral circulation, arterial hypotension, irregular and lessened excretion of urine, and ascites are too well known to merit description. Suffice it to state that joined to this syndrome is usually the syndrome of hepatic insufficiency owing to sclerosis of the liver lobules.

4. Biliary syndrome: While icterus is but a symptom and symptoms which it produces are too well known to merit discussion, it has received a great deal of attention from many French observers, principally Gilbert, Chauffard, Widal, Lereboullet and many others. To discuss the aspect of this phase would require an amount of space entirely incommensurate with the limits of this article. Suffice it to say that while cases are extremely numerous, for simplicity's sake they can be divided into two great groups: (a) Those due to the obstruction of bile, namely icterus by retention whether it be extrinsic, outside of the ducts such as new formations, glands, adhesions, etc., intramural or some change in the ducts themselves such as inflammation or stenosis, or intrinsic due to the blocking of the duct with a calculus or inflammatory material. In all cases there is a partial or total obstruction resulting in the systematic absorption of the material and a more or less complete obstruction to the flow of bile into the intestine. (b) In certain cases there is an excessive formation of bile resulting in the systematic absorption and the so-called pleochromatic icterus in others there is an hemolytic process at the seat of the trouble due either to congenital or acquired weakness of the red cells or to the introduction or formation within the organism of hemolytic substances which are capable of destroying the red cells. The important thing is to study such a case from every aspect; that is, to search the history carefully for antecedents: colic, hematemesis, and the congenital element from the so-called familial jaundice; to make a careful examination of the blood, urine, and feces which by comparison will enable us to determine its probable nature. In suspicious cases the blood is examined for auto agglutination, granular reds, lessened refractivity, and hemolysis. If to this we join a functional examination of the liver, we have sufficient information to enable us to determine the type and probably the etiology.

As Robin points out in discussing the functional testing in hepatic cirrhosis, neither doctrines, nor the results of some vaguely defined and over inflated test, less of possible reasoning and more of facts observed without prejudice are the guides which should point out the methods employed and the more available they are to the general practitioner, the greater will be our espousal. The poor patient who confides in you his life cares not for theories or cures or even pure science, however brilliant he may be. He only demands that he be cured or at least relieved, and while medical therapeutics is many times impotent when an anatomical lesion obtains, it can profoundly modify the state of affairs in many functional disturbances.

1934 Chestnut Street.

## A REPORT OF 128 CASES OF SCARLATINA TREATED BY VACCINES AND THE METHOD OF MILNE

By ERNEST C. SCHULTZE, M.D.,
NEW YORK,
PHYSICIAN-IN-CHIEF OF THE GOOD SAMARITAN DISPENSARY,
AND
LEWIS A. GOLDBERGER, M.D.,
NEW YORK,
DISTRICT PHYSICIAN OF THE GOOD SAMARITAN DISPENSARY.

It is generally conceded that the organism causing scarlet fever gains entrance into the system through the nose and throat, although formerly and even up to the present date some of the medical profession believe that desquamation plays an important role in the transmission of scarlatina. A great variety of germs found in the nasopharyngeal secretions of scarlet fever patients have been described by various writers and investigators but their claims to specificity have not been substantiated. However, etiological significance must be attached to the large coccus described in the Medical Record of December 10, 1910, by E. C. Schultze and found in the throats of nearly all our scarlet fever patients, many times in almost pure culture, generally far outnumbering all other organisms present except a streptococcus. In speaking of this coccus in the future it will be referred to as *Micrococcus "S."*

To determine the value of Dr. Schultze's discovery therapeutically, we decided to treat all our scarlet fever cases with a vaccine prepared from the *Micrococcus "S"* through the kindness of N. S. Ferry, M.D., and beginning March, 1911, to the present date, one hundred and twenty-eight cases were so treated. These patients were treated at their homes. They were of the very poorest classes living in the most thickly populated corner of the globe, the lower east side of New York City, where strict isolation, dietary precautions, etc., were impossible, many of our patients being up and about on a general diet, at the end of four or five days (not with our approval, however). In addition to the vaccine injection all our patients received a preliminary course of eight or ten doses of calomel, 1/10 to ¼ gram and castor oil or citrate of magnesia, and also had their throats swabbed with a 10 per cent. solution of carbolic acid in oil, and their bodies rubbed with a 10 per cent. solution of eucalyptus in oil, as advocated by Robert Milne in his article on the "Home Treatment of Scarlet Fever" in the *British Medical Journal,* October 31, 1908.

A few patients after having been subjected to Milne's treatment passed smoky urine, an evidence of too great absorption of carbolic acid. We therefore temporarily discontinued the use of carbolic acid and the urine promptly cleared. We then diminished the strength of the carbolic acid solution to 5 per cent. and have been using the 5 per cent. strength ever since, with no untoward effects. Milne advises painting the tonsils with carbolic acid solution every two hours for the first twenty-

four hours, later diminishing the frequency according to the appearance of the throat. We would suggest, painting the posterior pharyngeal wall, as well as the tonsils, and continue painting until cultures from the throat show no more "S" cocci. The eucalyptus oil, Milne advises should be rubbed in thoroughly "all over the body from the crown of the head to the soles of the feet, at first twice a day, thence once a day until the tenth day of disease." The rubbing in of the eucalyptus oil, we found was very soothing, and in many cases relieved the intense itching which accompanied desquamation. The carbolic acid swabbing of the throats and the rubbing in of eucalyptus oil in the bodies were continued throughout the course of the disease and in a few cases were also used as a prophylactic measure on some of the healthy members of the family with very good result. However, due to the ignorance of the foreign mothers and lack of understanding, it is a question how thoroughly this treatment was followed.

The vaccines used were three in number, composed of the following organisms: (1) *Micrococcus "S,"* 400 million per c.c.; (2) streptococcus, 400 million per c.c.; (3) *Micrococcus "S"* and Streptococcus (combined), 400 million per c.c. In one hundred and three of the cases only culture "S" vaccine was injected. The other twenty-five cases received the *Micrococcus "S"* and streptococcus vaccine (combined), but as the results obtained by the use of the combined vaccine did not seem to be any better than with the culture "S" vaccine alone, the use of the combined vaccine was discontinued. The dosage of each injection was estimated according to the age of the patient and the severity of the disease.

Of the one hundred and three cases that were given only "S" vaccine, fifty-five received 1 c.c., forty-one received 2 c.c., five received 3 c.c., and two received 4 c.c. Of the twenty-five cases that were given the combined vaccine, ten received 1 c.c., ten received 2 c.c., two received 3 c.c., two received 4 c.c., and one received 7 c.c. In one hundred and twenty-one of the whole series of one hundred and twenty-eight cases only one injection was found necessary. Of the other seven cases, three cases received two injections, two cases received three injections, and two cases received four injections. The necessity for reinjecting a patient was judged by the reaction obtained from previous injections.

In most of the cases the reaction was rather striking. The temperature fell by crisis, and not as described in the textbooks by lysis, reaching normal in from 24 to 72 hours, the general condition of the patient improved markedly; whereas, before injection, many of these patients "looked sick," soon after the injection, however, their general mental and physical conditions showed such improvement that their facial expressions were those of well-being rather than of severe sickness; usually they felt hungry and cried for food, although in some cases the rectal temperature registered 104 or 105 degrees.

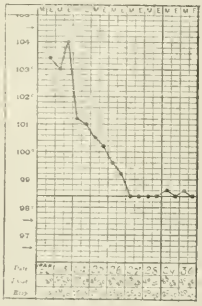
A few case histories may be of interest.

Case I.—M. W. (Case 2), male, three years old; history of one day's illness, fever, vomited, and appearance of eruption. Physical examination showed patient suffering from a typically severe case of scarlet fever; temperature 103, pulse 134, marked cervical adenitis forming a "collar" around the neck and dark-gray membranous patches covering hypertrophied tonsils which meet in the center of the throat. Injected 1c.c. culture "S" vaccine. Temperature the next day 101°, the third day 100°, the fourth day 99°, fifth day 101°, sixth day 100°, the seventh day 99°, eighth day 100°, ninth day 98°, after which the temperature remained normal. The swollen glands subsided rapidly, the throat cleared, desquamation followed, and the child made a complete recovery. Culture showed no Klebs-Loeffler bacilli. The chief interest in this case was the rapid disappearance of the membrance and of the extensive adenopathy, possibly in part due to the swabbing of the throat.

Case II.—M. G. (Case 3), male, two and one-half years old. History of having had a suppurating gland on side of neck incised one week previous to present illness. Present illness is of one day's duration; patient vomited, had fever, and eruption appeared. Diagnosis, scarlet fever. Temperature, 103°. Injected 1 c.c. "S" vaccine; next day, temperature 101°, rash fading; third day, temperature 98°, remaining normal after this day. On the sixteenth day of his disease both ears began discharging. (Culture taken from the pus showed only ordinary pyogenic organisms.)

Case III.—E. M. (Case 4), female, eight years old; ill one day, vomited, marked angina, pseudo-membrane covering both tonsils, punctate rash extending down to the knees. Temperature 103°, pulse 120, respiration 26. Child looked very sick. Injected 1 c.c. "S" vaccine and Milne treatment instituted. Following day, temperature 104, pulse 130, respiration 30. Notwithstanding the high temperature we found the child was sitting up in bed when we entered the tenement in which she lived and the child stated that she felt "all right." Physical examination showed rash covering the entire body, throat improved, membrane a whitish color, less anenopathy. Report of culture from the Health Department showed no Klebs-Loeffler bacilli.

The following chart shows the course of the temperature:



This is a fairly typical chart of nearly all the cases. First, a slight rise of temperature following an injection, then a rapid fall, usually of two or three degrees, with a rapid amelioration of all symptoms.

In connection with this case, we wish to state, that on account of the severity of the weather and the poverty of the family, they had no fuel to make a fire and as the entire family occupied only one small room with a single bed, the mother, the sick child and a younger sister age 3, shared the same bed throughout the illness; notwithstanding the contact the younger member did not contract the disease, probably due to the care that the mother took of the discharge from the nose and throat of the sick child.

Case IV.—E. U. (Case 28), female, nine years old. Five days' illness, fever, vomited first day of her illness. Physical examination, punctate erythema covering the entire body, dry, strawberry tongue, edges covered with sordes, tonsils meet and covered with pseudomembrane, cervical glands size of walnuts, child very ill, septic. Temperature 104°, pulse 124, respiration 26. Injected 3 c.c. "S" vaccine and Milne treatment instituted. The next morning (twelve hours later), temperature 100°, pulse 96, respiration 20. Evening of the same day, temperature 102, pulse 104, respiration 24. This continued for twenty-four hours, after which the highest temperature recorded in the evening was 99°, pulse 96, all symptoms abating. Child up and about on

the fifth day on a full diet (against our advice). Urine examination throughout the course of the disease showed no albumen.

Case V.—W. McE. (Case 41), male, four years old. Two weeks previous to present illness was in a contagious disease hospital for diphtheria; history of three days' illness, initial vomiting, fever, and sore throat. Physical examination showed a punctate erythema covering the entire body, marked cervical adenitis, congestion of throat but no visible membrane, strawberry tongue. Temperature 104°, pulse 136, respiration 20. Injected 2 c.c. "S" vaccine and Milne treatment given. The following day, temperature 102°, pulse 134, respiration 32; rash faint. Third day, temperature 102°, pulse 120, respiration 24; catarrhal symptoms and few macules appeared; throat clear. Evening of same day, temperature 103, pulse 130, respiration 28; macules more numerous (measles). Fourth day, temperature 103°, pulse 134, respiration 30; whitish exudate on tonsils; P.M., temperature 102° pulse 140, respiration 30. Fifth day, A.M., temperature 102°, pulse 140, respiration 34; P.M., temperature 103°, pulse 136, respiration 32; desquamating profusely. Sixth day, A.M., temperature 104°, pulse 140, respiration 38; P.M., temperature 104°, pulse 120, respiration 32; exudate in throat still present (culture showed no Klebs-Loeffler bacilli). Seventh day, A.M., temperature 100°, pulse 120, respiration 28; P.M., temperature 101°, pulse 120, respiration 28. Eighth day, temperature 99°, pulse 120, respiration 28. Ninth day, temperature 99°, pulse 120, respiration 28. Tenth day, temperature 98°, pulse 104, respiration 24. After this day temperature remained normal; no further complications developed. Urinary examinations normal throughout.

Case VI.—H. S. (Case 70), male, three years old. Typical scarlet fever with dark-gray membrane on tonsils, glands of neck about the size of walnuts, temperature 103°. Injected 1 c.c. vaccine "S"; temperature fell steadily until it reached normal on the sixth day, the glands on the right side of neck rapidly subsiding, but not on the left side; temperature fluctuating between 99° and 101°. On the thirty-fifth day of disease, injected 1 c.c. streptococcus vaccine with no apparent effect. Abscess developed on left side of neck, which was incised on the forty-third day of illness, after which the patient made an uneventful recovery. (Pus examined and contained only pyogenic organisms.)

Case VII.—O. T. (Case 89), male, eleven years old. This patient was first seen late in the evening on the fifth day of his illness. His attending physician told the family there was no hope for the child. He thought that the child could linger only a little while longer. History of initial vomiting, sore throat, and appearance of eruption. Had been delirious almost from the very onset of his illness. Temperature ranged between 103° and 104°. Physical examination: Semicomatose, delirious, profuse scarlatinal form eruption all over body, marked cervical adenitis and dark-gray patches on tonsils; temperature 103° to 104°, pulse 134, respiration 28. Injected 4 c.c. combined "S" and streptococcus vaccine. The next morning, temperature 102°, pulse 128, respiration 26. Patient rational. Temperature dropped steadily reaching 100° on the third day (eighth day of disease), then fluctuating between 99° and 100°, until the twelfth day (seventeenth day of disease) when it reached 98° and remained normal after that. Desquamation, which was profuse, was first noticed on the fifth day (tenth day of disease). After that the patient made a complete and uneventful recovery.

To cite more cases would only lengthen this paper unnecessarily. The cases treated were not selected; they were taken at random without any exceptions; every case that presented itself, mild or severe, complicated or uncomplicated was injected and results watched. Of the one hundred and twenty-eight cases treated the following three died:

Case VIII.—R. L., female, two years old; when first seen was moribund, in deep coma, with symptoms of meningeal involvement. Two injections of 2 c.c. "S" vaccine each were given; no change noted; child lingered for three days when she passed away. (A brother who had been a patient in the Willard Parker Hospital for three weeks suffering from the same illness also died that same night.)

Case IX.—W. B., male, aged four years. First seen on the fourth day of his illness. For three days previous temperature ranged from 103° to 104°. At the time of the examination, temperature 104°, pulse 140, respiration 30, bright scarlet eruption, marked cervical adenitis, dirty looking patches on tonsils. Injected 1 c.c. "S" vaccine. The next day, temperature 103°, pulse 134, respiration 28, nasal diphtheria complicating (culture showed Klebs-Loeffler bacilli). Diphtheria antitoxin administered. For the next eight days temperature ranged from 101° to 104°. On the ninth day 2 c.c. combined "S" and streptococcus vaccine injected; temperature dropped and on twelfth day reached 99°, at which figure it remained for two days. The patient's general condition was fair. On the fourteenth day, temperature rose to 100° and the right knee and ankle joints became slightly swollen and painful. Condition unchanged the next four days. Eighteenth day again injected 2 c.c. combined "S" and streptococcus vaccine. Nineteenth day left wrist swollen and endocarditis developed; 3 c.c. combined "S" and streptococcus vaccine injected. Twentieth day patient died, so that this case, which was very severe from the onset, did fairly well until the complicating scarlatinal rheumatism and endocarditis developed which rapidly proved fatal.

Case X.—S. S., female, four years old, a severe septic case of scarlet fever; temperature ranging from 104° to 106°. Extraordinarily large glands of neck and very dirty looking gray membranous patches in throat. On fourth day of illness injected 2 c.c. combined "S" and streptococcus vaccine without any apparent or appreciable effect. Fifth day injected 1 c.c. more of the combined vaccine, still no reaction. Owing to the severe sepsis, due probably to complicating streptococcus infection, on the seventh day we injected 2 c.c. of streptococcus vaccine; repeated the same dose two days later without change in objective or subjective symptoms. The patient died on the eleventh day of disease. This case, however, was the only one of a number of severe septic cases that did not seem to respond to the vaccine treatment.

At the same time that our cases were under observation, there were treated by private physicians in the same district three hundred and fifty-four cases of scarlet fever, which were looked after by the nurses of the Henry Street Settlement, to whom we must express our thanks and appreciation for their kind assistance in our work. These three hundred and fifty-four patients were treated by the usual expectant or symptomatic methods in vogue. Inasmuch as these families were able to pay for their medical services, we must assume that all other conditions which may have exerted any influence upon the course of scarlet fever, must have been more favorable; whereas, in our cases, because of the extreme poverty, ignorance, etc., the difficulties we had to contend with were, innumerable. Of the three hundred and fifty-four cases, there were eleven deaths (3.1 per cent.). Of our one hundred and twenty-eight cases, there were two deaths (1.5 per cent.). (The case cited, R. L., age 2 years, is not included, as this patient was moribund when the treatment was begun, besides having a complicating meningitis which really caused the death of the child.) Of the one hundred and twenty-eight cases, seven were complicated with diphtheria, cultures having shown Klobs-Loeffler bacilli; diphtheria antitoxin in addition to the vaccine and Milne treatment was administered. All of these cases recovered except case W. B., which died of complicating endocarditis. Other complications were: Adenitis, 7 (5.46 per cent.); nephritis, 7 (5.46 per cent.); otitis media, 3 (2.34 per cent.); arthritis, 3 (2.34 per cent.); pneumonia, 1 (0.86 per cent.); measles, 1 (0.86 per cent.); arthritis and endocarditis, 1 (0.86 per cent.); total, 20 (15.62 per cent.).

An analysis of these results reveals certain facts worthy of special note, such as: (1) The rapid improvement in most of the cases treated, the temperature falling by crisis and not by lysis as de-

scribed in the textbooks. (2) Notwithstanding the fact that many of our patients were out of bed and on a full diet early in the course of their disease, there were comparatively few complications. (3) Very few secondary contact cases developed, possibly due to the swabbing of the throats of the healthy members of the family as well as of the diseased. (4) The spread of scarlet fever could probably be kept under better control and the number of cases greatly reduced if all school children were examined by the proper health authorities at the beginning of each school term and in relays during the school year. Cultures should be taken from their throats and examined for *Micrococcus "S"* as well as Klebs-Loeffler bacilli; all suspicious cases to be excluded and isolated until further cultures show no more *Micrococci "S"* or Klebs-Loeffler bacilli present.

In conclusion, we would say that our experience with the use of the *Micrococcus "S"* vaccine and the Milne treatment warrants us in continuing their use in the treatment of scarlet fever; the results obtained compare very favorably with those obtained from other methods of treatment and perhaps, after further studies as to dosage, etc., in the not too distant future, the *Micrococcus "S"* vaccine will prove its value in reducing the all too great mortality percentage of scarlet fever.

Before closing, we wish to state that this paper was not written with the idea of exploiting any vaccine or of endorsing the Milne treatment, but merely to record our observations as they presented themselves to us in our case histories.

## STUDY OF BACTERIOLOGY OF THE POSTERIOR NASOPHARYNX IN SCARLATINA.*

By N. S. FERRY, M.D.,
DETROIT, MICH.

Late in 1909, at the request of Dr. E. C. Schultze, Director of the Good Samaritan Dispensary of New York, the study of the bacteriology of the posterior nasopharynx in scarlatina was undertaken by the writer. He endeavored to isolate, if possible, and determine the rôle of a certain micrococcus found in this region and briefly described by Dr. Schultze in a preliminary report in the Medical Record, New York, Dec. 10, 1910. This organism was seen by Dr. Schultze in smears from 459 out of 555 cultures taken from the throats of patients suffering with typical symptoms of the disease.

After the writer became interested in the work, cultures were obtained, through the kindness of Dr. Schultze, from patients of the Good Samaritan Dispensary, and through the kindness of Dr. Guy L. Kiefer, of Detroit, from patients of the Herman Kiefer Hospital. On account of certain peculiarities of the organism in question, it early became evident that there were difficulties in the way of isolating and growing it in pure culture, although the organism could be seen in a large majority of cases in smears from cultures taken early in the disease. The greatest number of positive findings have been obtained by swabbing the posterior pharyngeal wall and allowing the swab to stand in a test tube of bouillon a few hours. The entire amount of bouillon is then plated in the usual manner.

The organism was not isolated in the later stages of the disease and was not found in any of the purulent discharges nor in the blood, which seems very significant, considering the fact that it appears to coincide with the contention of the majority of observers that the disease is contagious only in its early stages. All previous observations have been corroborated to the extent of finding a streptococcus predominating on the plates, while the organism next in order, with the exception perhaps of the staphylococcus, is the one fulfilling the description given by Dr. Schultze. For convenience in nomenclature this organism was called by the writer *Micrococcus "S,"* and, for the present, it will continue to be designated by that term.

The *Mic. "S"* is a large coccus usually found in pairs and often in tetrads, which grows luxuriantly on all culture media after the first few generations. While the writer believes it to be a distinct species, it is distinguished at times with difficulty, morphologically, from other cocci found in the buccal cavity, both in health and disease. There is no doubt that this identical organism has been seen by other observers, yet a detailed description of an organism of a like nature has not been found in the literature. Whether the *Mic. "S"* has or has not any specific clinical or pathological significance, for the purpose of placing it on record, a detailed description of the organism will be given, followed by a brief review of the experimental work carried out with it.

*Morphology.—Mic. "S"* is a large, clearly defined, biscuit-shaped diplococcus, sometimes appearing in tetrads, measuring about the size of the meningococcus and gonococcus. It is non-spore-bearing, non-motile, non-capsulated, stains deeply with all aniline dyes and is positive to Gram Cultural Reactions—Agar slant: Abundant, smooth, grayish-white, glistening, opaque, filiform or slightly beaded raised growth, becoming somewhat viscid within a few days. Agar deep: Abundant, filiform growth, usually in one plane, with a slightly spreading surface growth. Agar colony: Slow growing, round, smooth, convex, entire, coarsely granular colony. Bouillon: Slight growth, clear with sediment. Potato: Very slight, colorless growth. Litmus milk: No change. Koch's serum: Slight, filiform, white growth. Loeffler's serum: Abundant, filiform, smooth, glistening, pinkish white growth. Gelatin stab: Gradual stratiform liquefaction. In about five days a cup forms at the surface and as liquefaction increases it reaches the sides of the tube and then proceeds downwards. At the end of six weeks the medium is liquefied about half way down. Indol negative. Litmus sugars: Glucose, maltose, and saccharose gave an acid reaction; galactose, levulose and lactose, no change. Pathogenic powers: While extensive inoculation experiments were carried out with this organism, nothing of any special specific significance could be gleaned from the work. Whether the organism soon loses its virulence on artificial culture media, or whether it is devoid of all pathogenic properties for the animals used, is a question which was undecided.

The following experiments were undertaken: (1) Four monkeys were inoculated subcutaneously with as many strains of *Mic. "S."* (2) Throats of four monkeys ewre smeared with *Mic. "S."* (3)

*Read before the Society of American Bacteriologists, Montreal, January 2, 1914.

Throats of three monkeys were swabbed with *Mic. "S."* (4) Control. Two monkeys were inoculated (Nos. 1 and 2) with streptococci taken from scarlatina throats. (5) Four monkeys were inoculated with *Mic. "S"* grown in monkey blood culture. (6) *Mic. "S"* was inoculated into mucous membrane of pharynx and also into glands of neck. These monkeys were previously given morphine subcutaneously, as a means of lowering their resistance.

In all of the experiments, with the exception of a slight rise of temperature on the fifth day, followed by a swelling of the nearest lymph glands, accompanied by a general indisposition, there were no symptoms indicative of an infection, and no signs or symptoms, whatever, simulating or approaching those of scarlatina as it is recognized clinically to-day. Believing, nevertheless, that this organism was found in a large enough proportion of cases to warrant further work, irrespective of the apparently negative pathogenicity, several vaccines were prepared with it which have been fairly tested out, both prophylactically and therapeutically under the supervision of Dr. Schultze in New York and Dr. Kiefer in Detroit, which work will be reported in later communications by them.

The finding of a diplococcus in such a large proportion of cases of scarlatina is suggestive of the work of Class, who, a few years ago, believed that he had discovered the cause of the disease. Class, in his original article,* described his organism as a "diplococcus, polymorphous in character, but resembling, as ordinarily seen on slides made from fresh cultures grown on any medium, a very large gonococcus." Other observers have, from time to time, noted the presence of a large diplococcus in cultures and smears from the throats of scarlatina cases, and yet no one has succeeded in proving that it has any part to play in the disease, and, therefore, very little stress has been laid on the findings. The organism described by these writers is so varied in its morphology and cultural characteristics that one is inclined to one of two suppositions. Either it is extremely polymorphous, as was claimed by Class, or else they were dealing with cultures containing streptococci, which organism may often be seen, in smears from the throat directly or from cultures, as large diplococci.

It is very evident, from the work of Class at any rate, that he did not always take the utmost pains to assure himself of pure cultures. He says: "I wish to state that the cultures used in these animal experiments were not isolated by means of 'Platten giessen,' but I am quite certain that they were not contaminated by other germs as repeated careful examinations showed. The reason why I did not isolate the germs by means of the process mentioned was on account of the fact that their vitality is easily destroyed by heating, the cultures obtained by isolating the germs by means of the plate method growing very poorly."

From the experience of the writer with the organism he has isolated and named *Mic. "S,"* which tallies with the general descriptions given by Schultze, Class, and others, as seen in smears, it is quite essential not only to plate the cultures but to be absolutely certain that the colonies from which the cultures are taken have no small colonies of streptococci, either deep or superficial, adjacent to or near them. This can be ascertained only by examining the field with a lens. The writer employed for this work a Zeiss binocular dissecting microscope. This precaution was deemed necessary, as it was found that there appeared to be some sort of a symbiotic relationship between this organism and the streptococcus, as was evidenced by the fact that whenever this organism appeared associated with the streptococcus individual organisms were invariably seen surrounded by numerous streptococci hanging close to it.

In attempting to isolate the organism by the plate method, these streptococci are seen to have a tendency to remain in this relationship, and individual colonies of the *Mic. "S"* are seen surrounded in extremely close proximity by minute colonies of streptococci, some so small as not to be recognized by the unaided eye. With this experience at hand, and considering the viscid character of the growth, the writer can very readily imagine how the streptococci, unless great care was taken to avoid them, could and probably would be carried along with cultures of the micrococcus. The streptococci then would be overshadowed by the heavy growth of the organism in question, which might cause it to assume a polymorphous as well as a pathogenic character.

In pure culture, taken very carefully from single colonies some distance from colonies of streptococci, the writer has found the organism isolated by him to be extremely constant morphologically and culturally, appearing only as a large diplococcus. While Class may have had in mind this same organism, especially as seen by him in smears taken from throat cultures, the description of the strains isolated by the writer and identified by their morphology by Schultze, do not correspond with those given by Class, irrespective of the streptococcic forms mentioned by him which the writer has never seen with the *Mic. "S."* According to Class, his organism decolorized by Gram's stain, while the *Mic. "S"* retains the stain. While Class found that his organism grew sparingly on many of the ordinary culture media, necessitating the use of a special garden earth media of his own, and not at all on gelatin, the *Mic. "S"* grows fairly luxuriantly on all ordinary media, including gelatin, in which it gives a typical liquefaction. Inasmuch as it is not a certainty that Class' cultures were pure in his animal experiments, it is impossible to compare results along that line.

Among the several known organisms found in the throat, from which the *Mic. "S"* should be differentiated, the following are the most important: *Micrococcus catarrhalis, Micrococcus tetragenus, Micrococcus pharyngis siccus, Diplococcus intracellularis meningitidis.* Inasmuch as the *Micrococcus "S"* is Gram positive and at the same time liquefies gelatin, it will be seen that these two reactions are all that are necessary to differentiate it from any of the organisms mentioned, including the organism of Class.

The *Micrococcus catarrhalis* is Gram negative and does not liquefy gelatin, and as a rule is a much smaller organism. The *Micrococcus tetragenus* does not liquefy gelatin and is usually found in tetrads. The *Micrococcus pharyngis siccus* is Gram negative and gives also a dry growth. The *Diplococcus intracellularis meningitidis* is both Gram negative and non-liquefying, and also gives a scanty growth on all media. The *Mic. scarlatinæ* of Class is Gram negative, does not liquefy gelatin and grows very sparingly on all ordinary media.

*Medical Record, 1899, Vol. LVI, p. 330.

# SOME EXPERIENCES WITH BACTERIAL VACCINES IN SCARLATINA.

By GUY L. KIEFER, M.D., D.P.H.,

AND

N. S. FERRY, M.D.,

DETROIT, MICHIGAN.

THE bacterial vaccines employed in this work, which was carried on at the Herman Kiefer Hospital, Detroit, were as follows: A vaccine composed of streptococci isolated from the nasopharynx of individuals suffering with typical symptoms of scarlatina; a vaccine composed of an organism isolated from the same situation, called for the present *Micrococcus "S,"* and described by one of us; and a vaccine composed of a mixture of the two. These vaccines which were polyvalent, being composed of several strains of each organism, contained 400 million organisms per c.c. each. Two lines of treatment were undertaken; prophylactic and curative, the nurses receiving the prophylactic treatment and the patients the curative. For curative purposes the three vaccines were used as described, while, for prophylactic purposes, the *Mic. "S"* vaccine alone was tested.

*Curative tests.* In order to avoid any chance of a personal factor entering into the work, the streptococcus vaccine was administered to the girls, the *Mic. "S"* vaccine to the boys and the combined to the adults. The vaccines were given a very fair trial, extending over a period of seven months, during which time one hundred and six patients received treatment. The patients treated were proportioned as follows: Those receiving the streptococcus vaccine, twenty-nine; the *Mic. "S"* vaccine, forty-four; and the combined vaccine, thirty-three. The vaccines were given about every two or three days, starting with one-half a cubic centimeter and increasing the dose as the symptoms warranted; and the treatment, as a rule, was continued until the termination of the case. No set rules for the course of treatment were adhered to; this was left entirely to the judgment of the physician in charge. The results of the treatment will be seen in the following tabulated reports made out from the history charts:

Treated with *Mic. "S"* Vaccine.
Number of cases, 44.
Uncomplicated, 34 (77.25 per cent.)
Complicated, 10 (22.72 per cent.).
Adenitis, 3.
Adenitis and Otitis media, 3.
Purpura hemorrhagica, 1.
Adenitis, otitis and purpura, 1.
Total.
Adenitis, 10 (22 per cent.).
Otitis, 4 (9 per cent.).
Purpura, 2 (4.5 per cent.).
Deaths, 2 (4.5 per cent.).

Treated with streptococcus vaccine.
Number of cases, 29.
Uncomplicated, 25 (86.2 per cent.)
Complicated, 4 (13.8 per cent.).
Otitis and adenitis, 2.
Otitis, 2.
Total.
Adenitis, 2 (6.8 per cent.)
Otitis, 4 (12.7 per cent.).

Treated with combined vaccine
Number of cases, 33.
Uncomplicated, 28 (84.8 per cent.)
Complicated, 5 (15.15 per cent.)
Adenitis, 1.
Otitis, 1.
Otitis and adenitis, 3.
Total.
Adenitis, 4 (12 per cent.)
Otitis, 4 (12 per cent.).

Cases treated the preceding year at the hospital, without vaccines.
Number of cases, 318.
Uncomplicated, 255 (80.19 per cent.)
Complicated, 63 (19.81 per cent.)
Otitis media, 21 (6.6 per cent.)
Adenitis, 26 (8.1 per cent.).
Nephritis, 10 (3.1 per cent.).
Pneumonia, 3.
Mastoid, 2.
Arthritis, 1.
Deaths, 14.

Comparison of the cases treated with the vaccine with cases treated according to the usual expectant methods.

| Cases | Untreated, 381, per Cent | Mic. "S" 44, per Cent | Streptococcus 29, per Cent | Combined 33, per Cent |
|---|---|---|---|---|
| Uncomplicated | 80.19 | 77.25 | 86.2 | 84.84 |
| Complicated | 19.81 | 22.72 | 13.8 | 15.15 |
| Adenitis | 8.1 | 22 | 6.8 | 12 |
| Otitis media | 6.6 | 9 | 13.7 | 12 |
| Deaths | 4.4 | 4.45 | 0 | 0 |

From the above résumé it would appear that the vaccines which contained the streptococci had an advantage over the ones containing the *Mic. "S"* alone, as well as over the usual expectant treatment which was previously carried on in the institution. This is what might have been expected in view of our present knowledge of the disease and experience with other diseases. Irrespective of the primary cause of the disease, it is practically conceded by all authorities that the streptococcus is a large factor in the cause of the complications, sequelæ and fatalities and, therefore, if a vaccine has any specific action, the most favorable results would be expected with one containing this streptococcus.

Whether the *Mic. "S"* bears any relation to the disease, it would appear from the study of these few cases that, as a curative agent, a vaccine composed of this organism, alone, would not be indicated. This is also partly borne out by the fact, as pointed out by one of us in another paper, that the *Mic. "S"* is more easily isolated and is found in larger numbers in the early stages of the disease, and has not been isolated from any of the discharges.

*Prophylactic tests.* For prophylactic purposes the *Mic. "S"* vaccine was given in three doses of increasing strength with three to five day intervals between doses. The doses contained two hundred, four hundred, and eight hundred million bacteria respectively. Up to the time of starting this work six nurses out of about one hundred had contracted the disease. However, since the introduction of this vaccine as a prophylactic measure among all nurses who had not already had the disease, not a case has been reported. It is interesting and rather significant, also, that during a period of three months when the prophylactic treatments were discontinued, four out of about twenty nurses became infected. The apparently favorable results following the prophylactic injections may be a coincidence, but whether they are or not, the treatment is being continued and will probably be tried in other institutions in order to test further and more conclusively the value of the vaccine.

*Conclusion.* It would seem from the results of the prophylactic tests with the *Mic. "S,"* together with the frequency with which this organism has been found in cultures from the nasopharynx in scarlatina, that one would be warranted in giving more serious thought to it whether it has or has not up to the present given any evidence of possessing pathogenic properties of a specific nature.

287 WOODWARD AVENUE.

# RETROPERITONEAL HERNIA OF THE APPENDIX INTO THE ILEOAPPENDICULAR FOSSA.*

BY ISADORE SEFF, M.D.,

NEW YORK.

ADJUNCT ATTENDING SURGEON, BETH ISRAEL HOSPITAL.

THE usual herniæ of the viscera of the abdominal cavity through the various openings in its parietes are well understood, and do not as a rule give rise to much difficulty in their diagnosis and the method of operative procedure. But when an internal hernia of the intestine or appendix into one of the various fossæ of the peritoneum is encountered, it immediately creates an interest, not only because of its rare occurrence, but also because of the pathological conditions and the surgical features such herniæ present.

For a better understanding of the form of hernia of the appendix, to which the title of this paper refers, a review of the anatomy and location of the pericecal folds and fossæ will be of interest, particularly the ileoappendicular, with which we are most concerned. The same name has by various authors been applied to entirely different fossæ in the pericecal region, and in order to avoid this confusion in the nomenclature we will adopt the classification of Moynihan[1] as given in his most thorough survey of the anatomy and surgery of the pericecal fossæ.

The existence of the fossæ of the ileocecal region depends upon the formation and the presence of the primary and secondary folds. The primary folds are:

1. The Anterior Ileocolic, or anterior vascular, which is produced by the raising of the peritoneum by a branch of the ileocolic artery, which runs over the anterior aspect of the ileocecal junction.

2. The Ileoappendicular, or intermediate, is primarily non-vascular. There are many views, though no agreement as to its mode of origin. Many names have been given to this fold, and that suggested by Jonnesco most suitably and definitely describes its point of origin and attachment.

3. The Mesoappendix, or posterior vascular, is produced by the raising of the peritoneum by the appendicular branch of the ileocolic artery, which runs behind the ileocecal junction.

4. The Accessory Ileocolic, which is not always present, is produced by an additional branch of the anterior ileocolic artery which raises the peritoneum.

These folds are best seen in their typical form in early life, and with increasing years they become modified from one cause or another.

The fossæ formed by these folds are:

1. The Ileocolic, which is situated anteriorly and above the ileocecal junction, between the anterior and the accessory ileocolic folds.

2. The Accessory Ileocolic is not always present, and when it exists its upper and outer border is formed by the accessory ileocolic fold.

These fossæ are of anatomical interest only.

3. The Ileoappendicular fossa lies behind the ileocecal junction, between the mesentery of the appendix and the ileoappendicular fold. A more detailed description of this fossa, which is of interest both anatomically and pathologically, will be given later.

The secondary folds are formed by secondary physiological adhesions between the ascending colon and the posterior abdominal wall. They are the Mesentericoparietal and the Parietocolic folds, between which is found the retrocecal fossa. At times there may be a third fold between these two, forming an outer and inner retrocecal fossa.

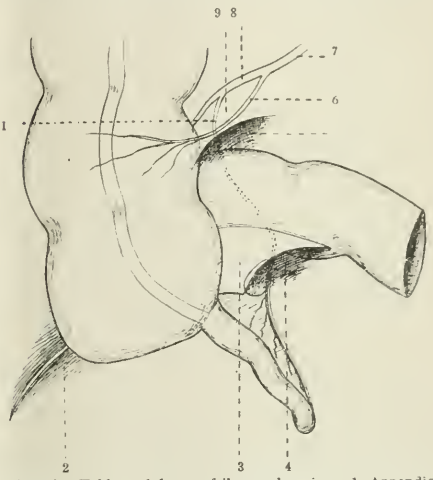

FIG. 1.—Folds and fossæ of ileocecal region. 1, Appendicular artery; 2, subcecal fossa; 3, ileoappendicular fold; 4, ileoappendicular fossa; 5, anterior ileocolic fossa; 6, anterior ileocolic artery; 7, ileocolic artery; 8, posterior ileocolic artery; 9, anterior ileocolic fold.

The *Ileoappendicular fold* (superior ileocecal fold of Waldeyer, bloodless fold of Treves, ileocecal of Lockwood and Rolleston, ileoappendicular of Jonnesco), is described by Moynihan as follows: "The fold extends from the lower border of the ileum—that directly opposite the line of the mesenteric attachment—to the anterior surface of the mesoappendix. It is quadrilateral in outline. The upper border is attached to the ileum for an extent which is extremely variable. An average length will be between 1½ to 2½ inches. The lower border extends from an angle formed by the appendix with the cecum, inward on the anterior surface of the mesoappendix, along a line parallel to the upper border, when the appendix is straightened out. Sometimes this line of attachment is shifted to the appendix itself. Its outer or right border is attached to the inner aspect of the cecum, as far down as the root of the appendix. Its left or inner border is concave to the left and free. This edge contains the recurrent or ileoappendicular artery, given off from the main appendicular, just above the level of the ileum."

The *Ileoappendicular fossa* (recessus ileocæcalis, Luschka; fossa ileocæcalis media, Hartmann; fossa ileocæcalis inferior, Waldeyer) is present in almost all subjects, and depends for its formation upon the ileoappendicular fold and the mesoappendix. The size of the fossa depends mainly upon the size of the former of these two folds. It is triangular in shape. Above it is bounded by the posterior surface of the ileum, and the mesentery immediately adjacent to it; in front and below by the ileoappendicular fold; behind by the upper part of the mesoappendix. The orifice looks downward and to the left. It may be quite large, admitting the tips of one or two fingers for half an inch.

The Ileoappendicular fossa is subject to two

*Read at a meeting of the Eastern Medical Society, February 14, 1914.

pathological conditions. By closure of the mouth of the fossa, a cyst may be formed. Hernia of the small intestine or vermiform appendix may occur into it.

It has been stated that retroperitoneal hernia of the appendix probably exists in 8 to 10 per cent. of

FIG. 2.—Partial hernia of the appendix into the ileoappendicular fossa.

all subjects. An exhaustive search of the literature reveals but few cases of retroperitoneal hernia of the appendix into the ileoappendicular fossa found at autopsy or at operation.

Moynihan, up to 1906, reported seven cases of retroperitoneal hernia of the small intestines into the ileoappendicular fossa, but in this list there were none of the appendix itself.

Murphy[3] in his contribution to the surgery of the vermiform appendix describes the possibility of retroperitoneal hernia into either the ileoappendicular or retrocecal fossæ. He states it is more frequent into the former, but does not cite a case of hernia of the appendix into either.

A. V. Moschcowitz stated in a personal communication to the writer that in a series of 2,000 cases of appendicitis operated upon at Mt. Sinai Hospital, he could not remember a single case of hernia of the appendix into the ileoappendicular fossa.

In a series of 450 cases of appendicitis operated within the last three years at Beth Israel Hospital, I am unable to find a record of any case of hernia of the appendix into the ileoappendicular fossa.

The subject of retroperitoneal hernia of the appendix from a surgical point of view was first studied by Lockwood,[2] who in 1890 reported two cases of hernia of the appendix into the ileoappendicular fossa, which apparently did not give symptoms during life and were found at autopsy. The appendix in each case was thought to be absent. However on close inspection of the ileocecal region the appendix was revealed in one case imbedded in a pouch running behind and parallel to the ileum. In the other it was found partially herniated in a similar fossa.

Elliot[4] in his report of a case of a diseased appendix found in the ileocecal fossa, mentions a nonpathological internal hernia of the appendix shown to him by Mixter in a dissecting room subject, in which the appendix was actually lying in an ileocecal (ileoappendicular) fossa, as described by Treves.

The small number of cases that have been reported of hernia of the appendix into the ileoappendicular fossa have not been diagnosed as such, but have been found at the time of operation. It necessarily follows that from the complicated anatomy more or less difficulty would be encountered not only in locating but also in removing the diseased appendix.

In the following case the above conditions have been observed:

H. S., male, age 32, tailor, was admitted to my service at Beth Israel Hospital on August 17, 1913; has had attacks similar to the present one, nine, and five months ago. Present attack began three days before admission, with severe abdominal pain, accompanied by nausea, vomiting, and fever; bowels constipated. Pain became localized in right iliac region. Physical examination revealed a poorly nourished individual; tongue slightly coated and moist; abdomen not distended; slight rigidity of the right rectus muscle; tenderness over right lower abdomen, most marked over McBurney's point. A small tender mass was felt, which from its position and indefinite outline indicated that it was behind and to the inner side of the cecum. On admission, temperature 101.8° F., pulse 96, respiration 24. Blood count: white blood cells 11,400, polynuclear 68 per cent., lymphocytes 32 per cent. After the patient received his admission treatment, the temperature dropped to 100° F. and the tenderness over the mass was markedly diminished. The case was considered one of appendicitis, passing from the acute to the interval stage. Therefore, he was not operated upon until three days after admission. Anociassociation anesthesia, as recommended by Crile, was given; Kammerer incision three inches long. Peritoneum opened and found normal; no free fluid; cecum freely movable. On palpating for the appendix it could not be felt. On replacing the cecum into its normal position a small mass could be felt through the cecum near its inner border, which was thought to be the appendix hidden away in some recess. Abdominal incision was enlarged. Cecum was pushed up toward the liver, and ileum drawn over to the left. Just below the ileocecal junction on the smooth peritoneum, there was seen an area of fibrinous exudate the size of a quarter. This was easily removed, revealing an opening into a small fossa, having a free margin concave to the left. The appendix was seen to pass over this edge. Beneath the fold, which was undoubtedly the ileoappendicular, the handle of a scalpel was passed into the fossa, upward and somewhat to the right, for a distance of three-fourths of an inch. Beneath this fold, the small mass heretofore described, could be felt. It could not be disengaged. The appendix was ligated at its base, and the stump buried, after it was treated with carbolic acid and alcohol. In order to deliver the appendix, it was necessary to incise the fold from the middle of its concave border over the handle of a scalpel as a guide for a distance of three-fourths of an inch. Then using the ligature on the distal end of the appendix as a retractor, the adherent appendix was brought into view. It was congested. It was stripped out of its serous coat for a distance of 1½ inches. The tip was bent upon itself, club-shaped, and free, except that it was attached to a portion of the mesoappendix. This was ligated, and the appendix was removed. No bleeding was seen. The cut edge of the fold was sutured together with the serous covering of the appendix, thereby obliterating the fossa. A small rubber tissue drain was inserted to the orifice of the fossa, and was removed at the end of 48 hours. Postoperative course was uneventful. The patient did not have any pain in wound, or gas pains, nor did he require any hypnotic. This can undoubtedly be ascribed to the method of anesthesia.

Specimen.—Appendix three inches long, consisting of three portions. First portion three-fourths of an inch long from base to the point where it passed over the free edge of the ileoappendicular fold. This portion was apparently normal. The second portion was firmly adherent to the fossa for a distance of 1½ inches. It was congested, and when removed from its serous coat appeared mottled and as if it was gangrenous. The third portion, the tip of the appendix, was club-shaped, bent upon itself, and lay free in the fossa. Although thickened, it appeared normal.

Pathological report.—Acute suppurative appendicitis.

A careful analysis of the cases of hernia of the

appendix into the ileoappendicular fossa shows that they may be classified in the same manner as the diseased appendix found in its usual situations. These herniæ may be complete or partial, depending upon whether the entire appendix or portion of it is found in the fossa.

A complete hernia of the appendix into the ileoappendicular fossa is described by Lockwood,[5] in one of two cases reported by him. "A delicate streak was observed running across the peritoneum of the iliac fossa close to the attachment of the ascending colon. A little pulling apart with dissecting forceps showed that this was the mouth of the ileoappendicular fossa, within which the appendix lay concealed." This very well demonstrates the possibility of how an appendix might be overlooked, and no doubt accounts for some of the cases giving symptoms of appendicitis and no appendix or abscess being found at operation.

In the other case, Lockwood described a partial hernia into the fossa, in which the appendix was free for about 2 cm. before it bent at an acute angle over the free edge of the ileoappendicular fold, and disappeared into the fossa from which it was easily removed. This was the condition observed in my own case, but in addition the first portion of the appendix and orifice of the fossa was covered by a fibrinous exudate, and the second portion was adherent to the posterior wall of the ileoappendicular fossa.

Belonging to the same class of cases is the one described by Mr. Heaton,[6] in which only the tip of the appendix was strangulated in the ileocecal (ileoappendicular) fossa, giving rise to acute abdominal symptoms, with recurring attacks of severe colic and vomiting.

Elliot,[4] in 1891, reported a case of recurrent attacks of appendicitis extending over a period of two years, which was operated in the interval. His findings are those of a herniated appendix, imbedded in firm adhesions in a fold of the peritoneum, which Treves described as an ileocecal fossa. He substantiates the diagnosis by referring to the case of Mixter, shown to him ten days before. It can be readily seen that as a result of the formation of such adhesions, marked difficulties may be encountered in the search for and the removal of such an appendix.

As the result of strangulation of a herniated appendix, suppuration with abscess formation may occur in the fossa and involve the structures in close proximity. Allen[7] reports such a case. An abstract of his findings will be of interest. A circumscribed mass the size of a small lime, freely moveable, was felt and observed to be on the inner side of what was considered to be the cecum. The mass was incised close to the bowel wall, and pus was evacuated. What was thought to be the appendix was ligated, and proved to be the dividend ureter. The appendix was found closer to the bowel wall, and in order to invert the stump into the cecum, it was necessary to pass it through the mesentery of the ileum. An analysis of this case impresses one with the fact that not only must we have a thorough knowledge of the complications of hernia of the appendix, but also of the anatomy of the ileocecal region and of the folds and fossa situated here.

The case of "transmesenteric hernia of the appendix" described by Wood[8] in 1905 is somewhat similar to Allen's case. From his description it is very difficult to determine whether the appendix had been herniated into a preexisting fossa, or through some defect in the mesentery of the appendix. It is possible that the appendix may find its way into the ileoappendicular fossa, and pass through the mesentery of the ileum, which forms part of its upper boundary; but then the appendix could not be seen, as is described in this case, but would be above and behind the ileum. If there existed some congenital opening in the mesoappendix through which the appendix passed and was strangulated, then this case must be excluded from our list.

After a careful search of the literature at hand I was unable to find any cases other than those herein cited.

*Summary.*—1. Although retroperitoneal hernia of the appendix, and the possibility of their occurrence, especially into the ileoappendicular fossa, is mentioned in most of the works on surgery, it is rather surprising to note how few cases have been reported. It seems that either the condition has not been observed at the time of operation (especially in the cases where the appendix may be dislodged easily) or it is really one of rare occurrence.

2. The diagnosis of appendicitis is established as in the ordinary case, but the malposition of the appendix is discovered at the time of operation.

3. A knowledge of the anatomy of the pericecal folds and fossæ is absolutely necessary in order to locate the supposedly absent appendix, and to employ the proper operative measures.

4. Complications involving important structures in close proximity to the ileocecal junction occur and must be borne in mind.

5. Retroperitoneal hernia of the appendix into the ileoappendicular fossa may be complete or partial.

**New Studies of the Pathology of Trichinosis.**—Gruber sums up his article as follows: The presence of trichina cells in the muscles conditions a toxic action on the infected organism. The toxins proceed both from the disintegration products of the muscles, and from the secretions of the parasite and are doubtless distinct substances. As a result of the entrance into the blood of the secretions of the parasite a blood eosinophilia develops and a tissue eosinophilia follows. The eosinophile cells are formed by preference in the bone marrow. The claim that the serum of infected animals is toxic cannot be confirmed, and another assertion that trichinosis in the intestines can give rise to a bacteriemia is highly improbable. The furuncles seen in trichinosis subjects are due to the ordinary local causes. The phenomena seen in the liver and kidneys in acute trichonosis require further study. The entire subject, much as it has been and is being studied, is still obscure in many respects.—*Münchener medizinische Wochenschrift.*

## STUDIES ON ERYTHROCYTIC RESISTANCE.

AN important field of clinical research is that which is concerned with the study of the resistance of the red blood cells to the hemolyzing action of various substances. Étienne May* has written an important monograph on this subject. He notes that Malassez was the first to study the clinical significance of the erythrocytic resistance. In 1873 he investigated the action on red blood cells of saline solutions in cancerous patients and in those suffering from chronic lead poisoning. Since that time these studies have been continued by Mosso, Viola, Hamburger, and Vaquez and Ribierre.

Étienne May studied the resistance of the red blood cells in various pathological conditions. He classified the results in two groups. The first includes all those facts pertaining to the erythrocytic resistance with reference to hypotonic saline solutions and saponin. The second group includes all instances in which the red blood cells are not affected by hypotonic solutions. The first group includes cases of hepatic icterus, various forms of tuberculosis in the course of evolution, typhoid fever, and certain cases of saturnism and Bright's disease. It is pointed out that in all of these affections there are modifications in the lipoid content of the blood, which modifications have the effect of altering the resistance of the red blood cells to hypotonic saline solutions and to saponin. The cholesterin in the red blood cells increases their resistance to saponin and diminishes it toward hypotonic solutions. The fatty acids increase the resistance of the red blood cells to saline solutions. Lecithin seems to diminish the resistance of the red blood cells to saponin.

As an example of the diseases accompanied by a diminished content of cholesterin in the blood, the author mentions typhoid fever and tuberculosis. The studies of Chauffard and his pupils have shown that the cholesterin of the blood serum is constantly diminished in these affections. These studies are entirely in accord with the facts concerning the resistance of the red blood cells in these diseases. In severe cases of typhoid fever as well as in developing cases of pulmonary tuberculosis there is a persistent diminution of the resistance of the red blood cells to saponin and an increased resistance of these cells to saline solutions. From this fact it is concluded that in typhoid fever and in tuberculosis the content of cholesterin is diminished in the red blood cells as well as in the blood serum. The cellular disturbance is much more pronounced than that of the serum. The globular fragility with reference to saponin is proportionate to the gravity of the disease. In mild cases there are a few fragile red blood cells while the remainder have a normal or an increased resistance.

In pernicious anemia the globular resistance to hypotonic solutions is habitually diminished, but to saponin it is, on the contrary, normal. The anemias on the whole are characterized by a more or less marked diminution of resistance to hypotonic solutions, without any change of resistance to solutions of saponin. In the anemia of Bright's disease the resistance is variable, sometimes with reference to the saline solutions, sometimes with reference to saponin. It is probable that the variations are dependent upon the variations in the substances retained in the blood at different stages of the malady. In saturnism the results are similarly variable. Of particular clinical importance are the comparative studies of the behavior of hypotonic solutions and of saponin in the course of various forms of jaundice. In hepatic icterus there is an increased fragility of the red blood cells under the influence of saponin, whereas in hemolytic icterus there is a diminished resistance to salines and a normal resistance to saponin. It is possible that there are mixed forms of icterus in which there is a double globular fragility. The icterus produced by toluylenediamine appears to be a type of the latter.

In classifying the changes in the blood produced by various morbid conditions May distinguishes two types of globular changes. The first is of a chemical nature, dependent upon the relative proportions of the lipoids in the red blood cells. The second is of a physical nature and depends upon a modification of the coloidal state of the globular constituents.

*"Études sur les Résistances Globulaires. Courbes de Résistances aux Solutions Salines. Résistances Globulaires à la Saponine." Par le Dr. Étienne May, Ancien Interne des Hôpitaux de Paris. Paris: Felix Alcan. 1914.

## A NEW THEORY OF FUNDAMENTAL NERVOUS ACTIVITY.

THERE have been two stages in the interpretation of the real unit of nervous activity. At one time this unit was regarded as the neuron. This conception held sway until Sherrington, in 1906, enlarged the conception of the functional unit in the nervous system, and defined the reflex as the functional unit. This idea was elaborated in his work on the "Integrative Action of the Nervous System." According to this view, nervous activity is conducted from periphery to periphery through a nervous arc consisting of an afferent neuron, an efferent neuron, and one or more interposed neurons. Sherrington's theory sought to establish a morphological basis for the physiological conception that all nervous activity originates primarily at the periphery; in other words, that the nervous system is but a specialized organ which takes over the function of response of the organism to external irritation.

A third conception of the fundamental unit of the nervous system has just been advanced. T. Graham Brown in the *Journal of Physiology*, March 31, 1914, protests against the undisputed sway of the spinal reflex as the original unit and believes that the time has arrived when one should regard the efferent neuron as the functional unit. His theory is based upon a number of his own experimental studies and those of others. These studies were concerned with the act of progression in animals in which the spinal cord had been cut. In studying the act of progression in the decerebrate cat, which progression may be evoked under narcosis even after section of the spinal cord, Brown concluded that the rhythmic alternation of activities is not conditioned by afferent self-generated stimuli proceeding from any of the limbs. The phenomena that followed rapid division of the lower thoracic spinal cord entered with a state of maintained flexion and ended in a state of maintained extension. In the intermediate phase where both activities are balanced the rhythmic act of progression occurs. It is this balance of two antagonistic activities that constitutes, according to Brown, the basis of progression. He next inquired whether this rhythmic phenomenon is the result of peripheral causes. He performed a series of experiments the details of which are too complicated to be alluded to in this place, which experiments seemed to show that a certain complex rhythmic movement may occur at a depth of narcosis at which the peripheral reflexes are abolished and therefore that the spinal efferent neurons may show some degree of independence of the afferent neurons and some of the phenomena of reciprocal innervation when functionally separated from them. This theory tends to displace the reflex as the unit of activity in the spinal centers and put in its stead a mechanism composed of efferent neurons. Brown regards the rhythmic phenomenon of progression as fundamentally conditioned by the balanced activation of antagonistic and linked efferent centers (or "half-centers"), but this activation is not necessarily of peripheral origin. It may be produced by conditions similar to those of the blood-stimulus in respiration. The so-called "half-centers" have mutual interconnections the properties of which seem to condition the rhythm which occurs during the equal activation of the interconnections. The essence of Brown's theory is therefore the independence of the efferent neuron. The mutually conditioned activities of the linked antagonistic efferent neurons together form the "center." The primitive activity of the nervous system is seen in such rhythmic acts as progression and respiration.

In addition to this novel and ingenious hypothesis of the fundamental nature of nervous activity, Brown proposes a theory of the manner of the evolution of function in the nervous system. He assumes that at first the "half-center" is directly exposed to the environment and that a state of "local asphyxia" then acts as the equivalent of the "blood-stimulus" in activating it and thus producing movements of the effector. Such rough movements might serve to change the immediate surroundings of the animal. Then a primitive coordination arises in the appearance of a system of mutual inhibition between "half-centers" which innervate antagonistic effectors. At this stage rhythmic activity becomes possible, and with it a more efficient locomotion of the animal. With the unfolding of the nervous system the primitive environmental direct stimulus is replaced by the indirect "blood-stimulus," and a peripheral afferent nerve mechanism, the function of which is to perfect the movements of progression and to give reflex movements of attack and defense, arises.

## THE DANGER OF PYELOGRAPHY.

THE first radiogram of the injected renal pelvis in the living subject was obtained by Voelcker, of Heidelberg, about eight years ago. The great value of this procedure was not at first recognized and, in fact, very little attention was paid to it until several years later when Braasch recognized its possibilities in the diagnosis of obscure ureteral and renal conditions, began the systematic use of pyelography at the Mayo Clinic, and, after a considerable experience, made an enthusiastic report (*Annals of Surgery*, Nov., 1910) based upon his observations. This seemed to be the signal for the universal acceptance of the method and numerous articles soon appeared confirming essentially all that Braasch had written as to the value of the procedure and the indications for its use. Naturally details in technique, the limitations, and the dangers of its employment still remained to be determined; and of these latter forcible injection of the opaque fluid was found to be the greatest. Accordingly, the technique adopted by most operators has eliminated hand pressure injection and substituted mild hydrostatic pressure obtained by raising the container six to twelve inches above the level of the body, the flow to be stopped at the first complaint of discomfort from renal distension.

It has been demonstrated experimentally that in normal kidneys, so long as the capacity of the pelvis is not overstepped, infiltration of collargol into the kidney substance does not take place. Upon exceeding this capacity, however, collargol is demonstrable in the interstitial tissues; while with still larger amounts injected the silver may be found not only in the interstitial tissue but also in the secreting structure, permeating even into the glomeruli and subcapsular spaces, infiltrating the connective tissue at the uretero-pelvic junction and structures at the hilus of the kidney. When there is a nephritis permeation may take place still more readily and there is thus an added danger of embarrassing an already impaired kidney by even slight overdistention of the pelvis. This has been demonstrated on several occasions when accidents have followed pyelography.

These facts are now so generally known that it would seem unnecessary to emphasize these points editorially but for the fact that new operators are constantly entering the field who do not seem to realize the dangers as well as the virtues of the method. That this warning is necessary is attested by the fact that there have been reported recently a number of avoidable accidents due to too

strenuous injection. The solution should be allowed to run in under a hydrostatic pressure generated by an elevation of certainly not over twelve inches, and not only should the flow be stopped but a little should be allowed to flow back at the first complaint of pain from renal distention; there will thus be little chance of damage to the kidney. Absolute adherence to these rules is, however, essential if one would avoid the occurrence of wholly unnecessary complications.

## HEAT AND INFANT MORTALITY.

That there is a direct and indirect relationship between a high temperature and infant mortality is obvious. The question is how to apportion the causative factors. There is no need to dilate upon the fact that the hotter the summer the greater the mortality rate among infants, for the matter has already been exhaustively dealt with. Views as to ventilation have changed considerably in recent years, and Flügge, Hill, and others have shown that movement of the air is of great assistance in eliminating heat from the body by accelerating evaporation. Moreover, as infants, especially of the poorer classes, spend a great deal of their time indoors, it might be expected that infants living in houses or in parts of cities unfavorable to a free circulation of air would be injuriously affected by such conditions. This has been found to be the case, and consequently it would appear that heat bulks somewhat largely as a direct factor in the causation of summer infant mortality, and further that it is an indoor temperature rather than an outdoor temperature to which infants are exposed.

J. W. Schereschewsky, Surgeon U. S. Public Health Service, in Public Health Reports for Dec. 5, 1913, discussed this relation of heat and infant mortality. He points out that the hypothesis held in this country 35 years ago and advanced anew by Meinert in 1884, that heat itself, by its various effects upon the infant organism, must be regarded as the chief factor in the summer mortality of infants, is once again attracting attention. Schereschewsky concludes as follows: (1) The action of heat as a direct cause in the summer mortality of infants has been greatly underestimated in the last 25 years. In the future much more weight should be given to its influence. (2) The lethal action of heat is a function not so much of the maximum and mean temperatures of the external air as of the indoor temperatures, which, in the late summer may continue to be high, in spite of remissions in temperature of the external air. (3) The action of stale and dirty milk in causing the death of infants has been given a significance which has overshadowed other factors of equal or possibly greater importance. (4) There is evidence to show that a certain proportion of infant deaths are due to specific infections in the dissemination of which contact infection and flies doubtless play a part. (5) As a result, future activities for the prevention of infant mortality must concentrate themselves to a greater extent on the question of housing, especially on the conditions productive of high indoor temperatures, such as overcrowded, narrow streets, and the absence of thorough ventilation. (6) Poor housing conditions can be partially neutralized by the proper care of babies in summer. The general public should be educated as to the importance of high indoor temperature in causing the death of infants, and especially as to measures which prevent babies from suffering from the heat. (7) Breast feeding must still be regarded as a most, if not the most, important preventive of the summer death of infants.

## Comfort Stations in New York.

The Bureau of Public Health and Hygiene of the Department of Social Welfare of the New York Association for Improving the Condition of the Poor has published recently a pamphlet showing what has been done in the direction of providing comfort stations in New York and what remains to be done. The sins of omission as regards this matter are greater by far in New York than the sins of commission, for there are few European or British cities which do not provide better public toilet facilities than New York. In the pamphlet referred to are several recommendations as to the provision of new public comfort stations and the better equipment of some of those now in use, and the general insanitary conditions of the subway and elevated comfort stations is commented on. In London and in practically all the large British cities excellent and adequate toilets are provided in which for a small fee persons are supplied with the conveniences of what are known here as comfort stations. Each station has its attendant or attendants whose duty it is to keep the place scrupulously clean. A sanitary educational campaign under the direction of the Bureau of Public Health and Hygiene would not be amiss in New York and in some other American cities. By this means civic pride might be aroused and efforts would consequently be made to place them at least abreast of European cities from the standpoint of municipal hygiene.

## How the Farmer Can Prevent Malaria

In Supplement No. 11 to Public Health Reports, published Feb. 13, 1914, R. H. von Ezdorf, surgeon U. S. Public Health Service, points out measures that farmers can take to prevent malaria. It is only, however, by understanding the manner in which malaria is contracted and spread and acting upon this knowledge that the disease can be prevented. The farmer must therefore comprehend that (1) malaria is contracted only through the bite of a special mosquito; (2) man infects the mosquito, and the mosquito in turn infects man. In order to prevent malaria the chain must be broken somewhere and the means for effecting this object may be summarized as follows: Houses to be screened and rendered mosquito proof. Mosquito bars to be used over beds if the house is not well screened. Quinine to be taken to keep the system free from the malaria germ. The breeding of mosquitos to be prevented by clearing ditches of grass and weeds and doing way with stagnant water. Von Ezdorf gives a number of instructive examples of how farmers by following these methods have abolished malaria from their immediate neighborhood.

## News of the Week.

**Plague in Colombia.**—The health authorities of the Canal Zone have declared a seven-day quarantine against all ports of Colombia, owing to reports which indicate that the situation there in regard to bubonic plague has become serious. Cases have been reported from Barranquilla, Cartagena, and Calamar on the Magdalena River, about sixty-five miles inland.

**Centenarian Dead.**—Mrs. Bridget D. Curran, said to have been the oldest person in the State of Pennsylvania, died at her home in South Bethlehem on May 15, at the age of 107 years. She came of a long lived family, her mother living to be 102 years old and her grandfather 108.

**Bronx Hospital Assured.**—The protests of persons living in the Seton Falls Park neighborhood of the Bronx, New York, against the construction of a hospital in the district for the treatment of contagious diseases, failed to move the Board of Estimate, which on May 15 authorized the Comptroller to buy a site of thirty-two acres in the park at a price not to exceed $32,000.

**Cancer Conference.**—The American Society for the Control of Cancer held a public meeting in Boston on May 19, under the auspices of the Boston Federation of Women's Clubs. The speakers were Frederick L. Hoffman of the Prudential Life Insurance Company, Dr. F. F. Simpson of Pittsburgh, and Dr. J. Collins Warren of Harvard University.

**Coroners Move.**—The offices of the Coroners of New York County were removed on May 16 to the new quarters in the Municipal building. The Coroners are now housed on the second floor of the building, while the court is held on the fifth floor. The rooms were opened to the public on May 18.

**Montefiore Home.**—A special meeting of the subscribers to this institution was held on May 17, to authorize a change of name from the Montefiore Home and Hospital for Chronic Invalids and Country Sanitarium for Consumptives to the Montefiore Hospital for Chronic Diseases and Country Sanitarium.

**Turtle Serum Suit.**—Basing her action on the contention that the so-called Friedmann turtle cure for tuberculosis was worthless, the widow of a patient treated with the serum recently secured a verdict of $225 against a former assistant to Dr. Friedmann while he was in this country, this being the amount which had been accepted in payment for the treatment. The patient died seven days after its administration.

**Beth Israel's New Site.**—The Beth Israel Hospital Association of New York has announced its plans for what will be one of the largest private hospitals in the city. For the new site land has been acquired on Livingston place between Sixteenth and Seventeenth streets, facing Stuyvesant square, as well as the property at 322 and 324 East Seventeenth street, forming an L with the plot on Livingston place. The site contains 14,000 square feet. On this it is planned to erect a sixteen-story hospital, at a cost of about $1,000,000, giving accommodations to 500 patients. The present hospital at Jefferson and Cherry streets has provision for 150 patients and a dispensary in which hundreds of patients are treated daily. It is probable that this hospital will be maintained, even after the completion of the new building, for emergency work.

**Movies in Health Work.**—Following a conference with Deputy Commissioner Emerson and Dr. Bolduan of the Department of Health, the Motion Picture Exhibitors Association of Greater New York has volunteered the services of more than 800 moving picture theaters for the educational work of the Department. The work began on May 11 when hundreds of theaters in New York displayed slides calling attention to the "clean-up" campaign inaugurated by Commissioner Goldwater.

**Personals.**—Dr. SIMON BARUCH of New York was elected president of the American Association for Promoting Hygiene and Public Baths at the annual meeting in Newark on May 12 and 13.

Dr. JOSEPH S. NEFF has resigned as director of public health and charities in Philadelphia, because of continued ill-health, and Dr. Richard H. Harte has been appointed to the office.

Dr. THEOBALD SMITH of Harvard University has accepted the appointment of director of the new department of animal pathology at the Rockefeller Institute. Mr. John D. Rockefeller recently added $1,000,000 to the endowment of the Institute in order to make possible the foundation of this department. To Dr. Smith's researches are largely due the doctrine of anaphylaxis, the institution of vaccine therapy, the distinction between bovine and human tuberculosis, our knowledge of "carriers," and that of the rôle of insects in the transmission of disease.

Dr. OTTO GLOGAU of New York has been appointed by Governor Glynn to represent the State of New York at the third International Congress of Occupational Diseases, which will be held in Vienna in September, 1914.

Dr. S. A. KNOPF of this city has been invited to give the opening clinic, on June 2, for a postgraduate course to be inaugurated by the Bruchesi Tuberculosis Institute of Montreal.

**Charitable Gifts.**—Beth Israel Hospital, New York, receives a bequest of $1,000 by the will of Mrs. Esther Geloski of Newark, N. J., who died on April 24.

Mr. George W. Nevil of Philadelphia has made a gift of $5,000 to the Jewish Hospital for the endowment of a free bed in memory of the family of Joseph and Amelia Nevil.

The Massachusetts General Hospital, Boston, receives $10,000 by the will of the late Francis Skinner of that city.

Among the residuary legatees of the estate of Miss Mary Guerin of New York are the New York Foundling Hospital and St. Vincent's Hospital, each of which has received $2,160.

The sum of $2,500 each was bequeathed to the Brooklyn Eye and Ear Hospital and the House of St. Giles the Cripple, by the will of Carl H. De Silver of Brooklyn.

By the will of the late Mrs. Francis K. Harlow, widow of Dr. John M. Harlow of Woburn, Mass., the sum of $20,000 was left to the Woburn Charitable Association for the purpose of establishing a surgical building as an addition to the Choate Memorial Hospital, which is to be known as the John M. Harlow Surgery.

**Medical Society Elections.**—MEDICAL ASSOCIATION OF THE STATE OF ALABAMA: Annual meeting at Montgomery, April 23 and 24. Officers elected: *President*, Dr. Benjamin B. Simms, Talladega; *Vice-Presidents*, Dr. Francis A. Webb, Calvert, and Dr. Jacob U. Ray, Woodstock; *Secretary*, Dr. James

N. Baker, Montgomery; *Treasurer*, Dr. Henry Gaither Perry, Montgomery.

TOLLAND COUNTY (CONN.) MEDICAL SOCIETY: Annual meeting at Rockville on April 21. Officers elected: *President*, Dr. Cyrus B. Newton, Stafford; *Vice-President*, Dr. Thomas F. Rockville, Rockville; *Secretary-Treasurer*, Dr. Eli Percival Flint, Rockville.

WORCESTER NORTH DISTRICT (MASS.) MEDICAL SOCIETY: Annual meeting at Leominster on April 28. Officers elected: *President*, Dr. H. W. Page, Baldwinsville; *Vice-President*, Dr. John B. Donnelly, Gardner; *Secretary*, Dr. Curtis H. Jennings, Fitchburg; *Treasurer*, Dr. F. H. Thompson, Jr., Fitchburg.

ESSEX NORTH DISTRICT (MASS.) MEDICAL SOCIETY: Annual meeting at Lawrence on May 6. Officers elected: *President*, Dr. I. J. Clarke, Haverhill; *Vice-President*, Dr. Victor A. Reed, Lawrence; *Secretary*, Dr. Jos. F. Burnham, Lawrence; *Corresponding Secretary*, Dr. Thomas M. Stone, Haverhill.

**Association of American Physicians.**—At the twenty-ninth meeting of the Association of American Physicians, which was held at Atlantic City on May 12 and 13, the following officers were elected for the ensuing year: *President*, Dr. S. J. Meltzer, Rockefeller Institute, New York; *Vice-President*, Dr. Henry Sewall, Denver; *Secretary*, Dr. George M. Kober, Washington; *Recorder*, Dr. Thomas McCrae, Philadelphia; *Treasurer*, Dr. J. P. Crozer Griffith, Philadelphia; *Councillor*, Dr. W. S. Thayer, Baltimore; *Representative on Executive Committee of Congress of American Physicians and Surgeons*, Dr. Theodore C. Janeway; *Alternate*, Dr. Richard P. Strong.

**American Dermatological Association.**—At the thirty-eighth annual meeting of this association, held in Chicago, May 14-16, 1914, the following officers were elected for the ensuing year: *President*, Dr. S. Pollitzer of New York; *Vice-President*, Dr. Martin F. Engman of St. Louis; *Secretary and Treasurer*, Dr. Oliver S. Ormsby of Chicago. It was decided to hold the next meeting in New York City in May, 1915.

**American Pediatric Society.**—The twenty-sixth annual meeting of this society will be held at the Red Lion Inn, Stockbridge, Mass., on May 26, 27, and 28, 1914, Dr. Samuel McC. Hamill of Philadelphia presiding. The secretary of the association, from whom further details as to the program may be procured, is Dr. Samuel S. Adams, 1801 Connecticut avenue, Washington, D. C.

**Canadian Tuberculosis Society.**—The fourteenth annual meeting of the Canadian Association for the Prevention of Tuberculosis will be held at Halifax, N. S., on July 13 and 14, 1914. Dr. S. Adolphus Knopf of New York has been invited to deliver the oration on that occasion, and has chosen for his title: "The Modern Warfare Against Tuberculosis as a Disease of the Masses." His Royal Highness, the Governor-General of Canada, is the Honorary President of the Association.

**American Medical Editors' Association.**—The annual meeting of this Association will be held on June 22 at the Marlborough-Blenheim Hotel, Atlantic City, N. J., under the presidency of Dr. E. A. VanderVeer of Albany, N. Y. The following papers will be read: "President's Address," by E. A. VanderVeer, Albany, N. Y.; "Relation of the Medical Press to the Cancer Problem," by Frederick L. Hoffman, Newark, N. J.; "The Things that Count in Medical Practice," by H. Edwin Lewis, New York; "Ideal National Medical Journal: What It Should Be and What It Should Not Be," by W. J. Robinson, New York; "Two Problems of the Organization Journal: The Mediocre Paper and the Editorial Department," by Sarah M. Hobson, Chicago, Ill.; "Medical Journalism as a Local and as a National Proposition," by Thomas S. Blair, Harrisburg, Pa.; "Medical Books and Journals," by T. D. Crothers, Hartford, Conn.; "The Medical Periodical and the Scientific Society," by F. H. Garrison, Washington, D. C.; "Editorial Experiences," by A. L. Benedict, Buffalo, N. Y.; "The Special Medical Journal," by A. Bassler, New York; "The Medical Profession and Its Influence from a Buying Standpoint," by Joseph MacDonald, Jr., New York; "The Preparation of the Original Article and the Editors' Latitude," by E. Franklin Smith, New York; "He Among You Who Is Without Sin Shall Cast the First Stone," by Erwin Reissmann, Newark, N. J.

**American Medico-Psychological Association.**—The seventieth annual meeting of this Association will be held at Baltimore on May 26-29, 1914, under the presidency of Dr. Carlos F. MacDonald. The secretary is Dr. Charles G. Wagner of Binghamton, N. Y. The recently revised program of the meeting contains an excellent photograph of the president.

**Brooklyn Pediatric Society.**—At a meeting of this society, to be held May 27, in the building of the Medical Society of the County of Kings, 1313 Bedford Avenue, the subject of discussion will be "The Limitation of Offspring by the Artificial Prevention of Conception, from the Individual, Social, and Eugenic Standpoints." The speakers will be Drs. Wm. J. Robinson, William F. Campbell, J. Richard Kevin, Robert L. Dickinson, and James W. Fleming.

**Obituary Notes.**—Dr. JOHN WILLIAM DOWLING of New York, secretary and professor of medicine of the New York Homeopathic Medical College and Hospital, from which institution he was graduated in 1886, and a member of the New York Academy of Pathological Science, the American Institute of Homeopathy, and the State Homeopathic Medical Society, died at Middletown, N. Y., after a lingering illness, on May 11, aged 48 years.

Dr. NEWTON F. CURTIS, of Milton, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1874, and until recently a resident of White Plains, N. Y., died at his home after a long illness, on April 30, aged 64 years.

Dr. OLIVER N. WOLCOTT, of Columbus, O., a graduate of the Starling Medical College, Columbus, in 1875, and a member of the Ohio State Medical Association and the Columbus Academy of Medicine, died at his home, from paralysis, on April 25, aged 64 years.

Dr. PATRICK MCKEOWN of Long Island City, N. Y., a graduate of the Bellevue Hospital Medical College, New York, in 1890, a member of the American Medical Association, the Medical Society of the State of New York, and the Queens-Nassau County Medical Society, and formerly health officer of Long Island City, died at his home on May 3, aged fifty-three years.

Dr. LOUIS PEALE LAMPEN of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1883, and a member of the Medical Society of the State of Pennsylvania and the Philadelphia County Medical Society, died at his home on May 1, aged fifty-four years.

Dr. SAMUEL G. GRAY of Landisville, Pa., a gradu-

ate of the medical department of the University of Pennsylvania, Philadelphia, in 1863, a surgeon in the United States Army during the Civil War, and a member of the Medical Society of the State of Pennsylvania and the Lancaster County Medical Society, died at his home on May 2, aged seventy-six years.

Dr. WILLIAM FRANCIS GLEASON of Providence, R. I., a graduate of the Harvard Medical School, Boston, in 1886, for three years a member of the school committee of Providence, visiting physician to St. Joseph's Hospital, of which institution he was formerly medical superintendent, consulting physician to the City Hospital and the St. Vincent de Paul Infant Asylum, and a member of the American Medical Association and the Rhode Island and Providence District Medical Societies, died at his home, from nephritis, on April 27, aged fifty-three years.

Dr. THOMAS TRENAMAN of Halifax, N. S., a graduate of the College of Physicians and Surgeons, New York, in 1869, for many years president of King's College, Windsor, N. S., and health officer of Halifax, died at his home, on April 27, aged seventy years.

Dr. IRBY WYNNE HAMIL of Goshen, Ala., a graduate of the Louisville, Ky., Medical College in 1867, and a member of the Medical Association of the State of Alabama and the Pike County Medical Societies, did at his home, on April 25, aged sixty-one years.

Dr. WILLIAM EDMUND WEBER of New York a graduate of the College of Physicians and Surgeons, New York, in 1894, for many years chief medical inspector of the milk department of the New York City Department of Health and in charge of the infants' milk stations, attending physician to the German Hospital Out-Patient Department, and a member of the American Medical Association and the New York State and County Medical Societies, died suddenly, on May 7, aged forty-five years.

Dr. JOHN MCCROSKERY of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1887, and a member of the American Medical Association, the New York State and County Medical Societies, and the Alumni Association of the Kings County Hospital, died suddenly, from heart disease, on May 9, aged forty-nine years.

Dr. MARY C. FARNHAM of Denver, Col., a graduate of the Chicago Homeopathic Medical College in 1881, died at her home, from pleuropneumonia, on May 2, aged 72 years.

Dr. ROBERT KING of Emporia, Kan., a graduate of the New York Homeopathic Medical College and Hospital in 1863, died at his home, from cancer, on May 2, aged 75 years.

Dr. IRA YOUNG KEZARTEE of Battle Creek, Mich., a graduate of the University of Michigan, Department of Medicine and Surgery, in 1867, died at his home, after a long illness, on May 4, aged 70 years.

Dr. WILLIAM H. KERR of Falls City, Neb., a graduate of the College of Physicians and Surgeons, Kekuk, in 1867, and a veteran of the Civil War, died at the home of his son in Minneapolis, Minn., on May 1, aged 75 years.

Dr. DAVID WILLIAM BULLOCK of Wilmington, N. C., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1873, and a member of the Medical Society of the State of North Carolina and the New Hanover County Medical Society, died at his home, from typhoid fever, on May 6, aged 60 years.

## Correspondence.

### THE TYPHUS GERM.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Few readers of your valued journal could have felt the same interest in the reported isolation of the causative organism of typhus fever as the undersigned who has watched through several large epidemics of the disease in Russia and who knows what ravages are caused by this scourge among the poorer classes of Russia as well as such members of the upper classes as are compelled to dwell in the military barracks or in the prison pens of that unhappy land. For the discovery of a causative organism means progress toward the discovery of a specific treatment. In this connection it is of interest to trace in a few words the history of typhus fever in this vicinity during recent years, especially as your correspondent was active in determining the nature of the disease as it appeared here. As is well known, Dr. Brill had for many years observed that certain cases of sickness usually classified with typhoid fever did not answer the description of that disease in many important characteristics and he separated this group of cases to which the name of "Brill's disease" was not infrequently applied. It has been my fortune to prove that modern typhus answers all the conditions stipulated by Dr. Brill and that in short Brill's disease is nothing more or less than typhus fever as it develops under the hygienic and social conditions of our city. These facts I supported in several meetings when speaking in discussion of Dr. Brill's papers and finally in a paper read before the Academy of Medicine, May 16, 1911, and reported in your valued journal on September 16. These discussions aroused great interest in the whole question and finally led to the well-known research of Anderson and Goldberger (first reported in February, 1912), who, with the transmission of typhus fever to monkeys, gave laboratory proof of the truth of my contention. The crowning achievement, the discovery of the cause of typhus, is now reported by Dr. Plotz of Mt. Sinai Hospital in this city, and I close by expressing the hope that the report may find corroboration so that another scourge of humanity may be checked in its devastating course.

G. A. FRIEDMAN, M.D.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

COLLEGE OF PHYSICIANS' REPORT ON TUBERCULOSIS—CAMPAIGN AGAINST FLIES—ELECTRIFIED MILK—MEDICAL MISSIONS—NURSING CONFERENCE.

LONDON, May 1, 1914.

THE Royal College of Physicians has thought well at the present time to issue a statement on the nature and infectivity of tuberculosis. It embraces those points which are of the greatest importance for the consideration of the public and which will, no doubt, be regarded as authoritative.

Tuberculosis is stated to be an acquired disease but certain constitutional types may be inherited, rendering a person specially susceptible to infection and there is reason to think that such susceptibility is an inherited character. The bacillus may be contained in the various discharges and excreta, especially the sputa, but these are not infective unless the bacillus is contained, so that tubercu-

losis from internal organs from which no excretion is furnished, even cases of arrested pulmonary phthisis, have never been proved to be infectious. But here it is to be noted that by "arrest" is meant that all symptoms and physical signs of activity have disappeared and the sputum has ceased or contains no bacilli.

The next point considered is the way in which tubercle may find entrance into the body: (*a*) through a wound or abrasion of the skin, which has sometimes happened to those engaged in post mortems or laboratories or working with tuberculous material and the report says this is presumably the way in which lupus is contracted. (*b*) by inhalation of air containing bacilli, either in droplets or as fine dust. Sputum and other discharges on soiled linen or other articles soon dries and is easily converted into fine dust and as such dispensed about rooms or any enclosed spaces. It is suggested that droplets are the less important form because nurses and others engaged in hospitals where the discharges are, of course, carefully disposed of, do not suffer from tubercle above the average. (*c*) by swallowing food on which infected dust has settled, so carrying the bacillus directly into the alimentary canal. Again, it is suggested that direct transmission may occur in the act of kissing or by the use of food utensils which have been used by consumptives and not been adequately cleansed. It is estimated that some 10 per cent. of milk supplied to large cities contains tubercle derived from tuberculous cows and this is a special danger to young children for the bovine bacillus is more commonly found in them than in adults. It is affirmed that there is no evidence that tubercle can be conveyed to others by the breath alone, or by emanations from the patients, or by their garments, unless they have become soiled as mentioned above and the dried discharges become pulverized and so distributed.

The precautionary measures that should be taken in all cases are obvious from the considerations already reported and, no doubt, the intelligent members of the public will to some extent adopt them; especially will they be welcome to the families who have been or are afflicted by this scourge. It may be added, however, that the spread of tuberculosis is favored by overcrowding, defective ventilation, and all forms of uncleanliness. Experience in hospitals and institutions shows that the risk of infection can be reduced to a minimum. The means they employ to secure this reduction are not those named or indicated above, such as the disinfection or destruction of soiled articles, removal of dust by frequent moist cleansing of floors, walls, etc., with full and free ventilation. The report declares that no risk is incurred by living in the immediate neighborhood of properly conducted institutions for the treatment of tuberculosis. One might add that there appears no risk from residence within such institutions looking at what has been shown to be the average mortality of those engaged in them.

The campaign against houseflies which I mentioned on the 10th ult., as opened by the Medical Officers of Health, has continued in a desultory sort of a way—not so actively perhaps in London as in various country places where the pests have hatched out in the warm spring we have enjoyed. At Tunbridge Wells swarms of flies have taken possession of one of the churches and caused so much annoyance to the congregation that the building has been closed to fumigate it in the hope of destroying the pests. It seems a case for minute inspection of the building and all around to find the breeding places.

Lecturing on flies and disease at the Royal Sanitary Institution the other evening Dr. Graham-Smith said there was great need for more careful study of the habits of flies and of their various enemies. If, for instance, one could discover how to propagate the fungus which attacks them in the autumn it would help us to get rid of their attentions. Failing that he emphasized the importance of destroying their breeding places which are always insanitary.

In reply to questions he said flies were in the habit of drinking in the early morning and if some drops of milk and water containing 1 per cent. of formalin were left on plates in a room for the night, they would drink and be found dead in the morning, within a few inches of the plates.

Professor J. M. Beattie has reported on some experiments carried out at a Liverpool milk depot with a view of determining whether the electrical treatment of milk destroys pathological bacteria. Sterilization is not in the strict sense of the word brought about but a great reduction in the total number of bacteria and after treatment the milk keeps sweet for three or four days, no chemical change taking place in that time and no alteration in taste. In two cases the electrified milk was non-tuberculous though the controls yielded tubercle, so that it seems the milk treated by electricity is a satisfactory food for infants.

At the annual meeting of the Medical Missions of the Society for the Propagation of the Gospel, Lord Sydenham, presiding, commented on the terrible loss of life in India from preventible causes. But he said research was being carried on not only in the great epidemics but in all directions by an able and diligent board of medical and scientific accomplished observers. Personally he thought there was an excellent sphere for lady doctors to go out and take a share in the work of medical missions which gave to the people the best service they could give in a spirit of love which was truly Christian.

The Seventh Annual Nursing Conference has been held this week when a resolution was carried by a large majority calling on the government to accept the bill for the state registration of nurses introduced by Dr. Chapple. An exhibition in connection with the conference was held in the Royal Horticultural Hall and was well attended. In the discussion on ambulance work the lady superintendent of St. John's Brigade described the origin of the association and said improvement in quality not quantity was needed. She had seen any number of half-trained people rushing off to Ulster who would be useless in case their services were needed.

Mrs. J. Cantlie said Red Cross work lay along lines of communication and a separate body was required for it. First aid was outside doctoring and hospital training. Almost everything had to be improvised and this was the charm of the Voluntary Aid Association work. Ambulances and stretchers would be taken for the front and the "Volunteer Aid Detachments" had to learn how first rate dressings for wounds could be made of burnt leaves, sticks, hay, or straw; that straw ropes could serve as bandages; that stretchers could be constructed out of pitchforks, cross sticks, and straw rope. Some protests were made against the disregard of the trained nurses by the Red

Cross Society. It was also objected that this society should not undertake ambulance work but leave it to the St. John's Brigade. A suggestion was put forward to incorporate nurses into a supplementary division of the Army Medical Corps.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

"BUYO" CHEEK CANCER—EPIDEMIOLOGY OF ASIATIC CHOLERA IN THE PHILIPPINES—FACTORS OF THE SPREAD OF CHOLERA—TREATMENT OF CHOLERA—SANITATION IN THE PHILIPPINE LEGISLATURE.

MANILA, P. I., March 7, 1914.

THE regular monthly meeting of the Manila Medical Society was held at 8.30 P. M., March 2, in the amphitheater of the College of Medicine and Surgery of the University of the Philippines. There was a large attendance.

The first paper read was entitled "'Buyo' Cheek Cancer: A Study of 65 Cases of Oral Cancer With Special Reference to Cheek Cancer and Its Etiology," by Dr. Geo. G. Davis. The author gave a history of a number of cheek cancers which seemed to be very closely associated with the chewing of betel nut and the buyo leaf. This habit is very common in the Philippines, especially among the lower classes. A slice of betel nut is placed upon a buyo leaf, ordinary lime is sprinkled upon it, and then it is wrapped up in the leaf and this whole morsel is placed in the mouth and chewed. The teeth of betel nut chewers gradually become discolored to a brownish black. It is assumed that the irritation which is set up by the chewing of this substance has an intimate relationship with cancer. In the discussion which followed, Dr. Heiser pointed out that the more scientific study of diseases in the Philippine Islands showed more and more conclusively that cancer apparently prevails in the Philippine Islands just as extensively as in other countries. He drew special attention to the fact that prior to 1905, or before the time that careful and extensive studies were made of the diseases which afflicted Filipinos, it was frequently stated by writers that cancer was very rare in the Philippines. He also inferred that the alleged infrequency of cancer in the tropics, mentioned by many authorities, would in all probability be found erroneous if a more careful study of the disease were made.

The next paper was entitled "Some Recent Developments With Regard to the Epidemiology of Asiatic Cholera in the Philippines," by Dr. Victor G. Heiser. The writer stated that in accordance with the best information available, prior to August, 1912, cholera had been absent from the Philippines for the two preceding years. In the present outbreak the first cases occurred among permanent residents and no infection could be traced to foreign sources. The disease appeared often simultaneously in widely separated sections without its being possible to trace any connection between them. There is now much evidence available to show that cholera carriers probably were present in the Philippines at all times and that possibly they were not recognized because the cholera organism might perhaps pass through a cycle during certain stages of which it might not be possible to identify it by present laboratory methods. He dwelt particularly upon the fact that the disease had not become epidemic and that this was perhaps due to the fact that the cases were quickly discovered, so that there had not been an opportunity for many passages from one human intestine to another, thereby keeping the virulency low. Greater cooperation was had than in previous outbreaks, and that was probably due to the fact that the masses are rapidly gaining confidence in modern health methods. The measures employed to combat the disease were also less irksome than heretofore. Briefly, they consisted only of the quarantining of the sick person. The stools of the sick and of the contacts were passed into receptacles which contained a disinfecting fluid. At the door of each house in which a case of cholera occurred there was placed a bowl of disinfecting solution and each person who desired to leave the house, whether it was the sanitary inspector, guard, nurse, or doctor was required to immerse his hands therein. In stricken towns the stools of the whole population and the water supplies were safeguarded. There was no other quarantine nor were there any restrictions placed upon the sale of foodstuffs. This did much to remove friction. Greater success was had in combating this outbreak than any which occurred heretofore of which there was any record.

The next paper was entitled "Observations on Some Factors Responsible for Spreading of Asiatic Cholera; Vitality of the Cholera Vibrio in (1) Cholera Carriers, and (2) Water," by Dr. Otto Schöbl. The author briefly reviewed the laboratory history of the cholera organism and stated that the behavior of the cholera vibrio in this outbreak was much the same as that which had heretofore been reported. He drew especial attention to the fact that he had been able to keep the cholera organism alive in sea water for a period of 106 days and at this writing the organism still continued to grow in that medium. In ordinary Manila tap water he kept it alive for 50 days.

The next paper was entitled "Treatment of Asiatic Cholera at San Lazaro Hospital," by Dr. A. C. Garton. The author stated that the intravenous transfusion of calcium permanganate and sodium chloride as recommended by Rogers of India had produced most excellent results and that in a series of 116 cases he had attained the mortality of 35 (30 per cent.), which is a lower mortality than has heretofore been reported in any Philippine outbreak. The last 57 cases treated gave a mortality of 10 (17.5 per cent.).

The Philippine Legislature held its last session on February 28 and will not convene again until next October. The Council of Hygiene Bill, which provided for a Board of Health or Council instead of a Director of Health, as at present, failed of passage in the Upper House of the Legislature. The bill to transfer the Philippine General Hospital to the College of Medicine and Surgery of the University of the Philippines met a similar fate. A bill recommended by the Director of Health for the more central control of sanitation in the provinces also failed of passage. The intention of this law was to make the health service in the Philippines much the same as that of Cuba during the last temporary occupation by the United States. Briefly, more central control was aimed at. Politics have interfered so much with the municipal control of sanitation that in many instances effective work is not possible, and it was therefore the desire to remove the control of sanitation in the provinces from the influence of politics in order that more efficiency might be obtained. The Legislature passed a model bill directed against misleading advertise-

ments, which has recently become a law in Minnesota and a number of other States. Possibly the most drastic measure affecting patent and proprietary medicines that has ever been enacted by any Legislature became a law on February 27. This law provides that no medicinal preparation, except that of a licensed physician, may be sold without the qualitative and quantitative formula being given on the label and also in any advertisement of it which may be published, whether by circular, handbill, newspaper, or periodical. There is also a severe penalty for false, misleading, or exaggerated claims or statements. The law was considered necessary because the patent medicine evil has not yet seriously spread in the Philippine Islands, and by placing rigorous restrictions upon it now it is thought that the Filipinos might be protected against acquiring the habit of using them or at least only those that have real merit.

1. Results of the Swift-Ellis Intradural Method of Treatmeint in General Paresis. A. Myerson.
2. Hip Fractures and Their Treatment. F. J. Cotton.
3. The Experimental Method as Utilized in the Clinico-Pathological Conference. H. T. Karsner.
4. The The Vesalianum Mistaken for a Fracture of the Fifth Metatarsal. W. P. Coues.

**1. The Swift-Ellis Treatment in General Paresis.**—A. Myerson concludes that patients receiving this form of treatment show changes mostly limited to the disappearance of the Wassermann reaction and alterations in the chemical and cytological composition of the spinal fluid. The order of changes is somewhat as follows: The Wassermann reaction seems to be the most variable—the first to disappear and the least stable. The cell count seems to be the next most variable constituent. It seems to be profoundly affected by the treatment, but a reduction must not be taken too optimistically. The globulin is perhaps a little less variable than the cell count; it does not diminish much under treatment, and it rarely completely disappears. Finally, the albumin content is the most constant of all and is least affected by treatment. The Wassermann reaction is not nearly as important a criterion of improvement or recovery as it is frequently held to be. This applies in a lesser degree to the chemical and cytological changes. It is probably true that the criterion of recovery or progress at present must be in the field of the clinical manifestations. The author believes that the theoretical grounds upon which the Swift-Ellis treatment is based do not seem to be valid. It is assumed that because the Wassermann reaction is most constant an hour after the administration of salvarsan, therefore the body at that time contains more antibodies. This is by no means certain, for the meaning of the Wassermann reaction is unknown. Furthermore, it seems to be the opinion shared by Swift and Ellis that the nervous system is inaccessible to medicaments administered in the usual channels. One hears the term "inaccessibility of the nervous system" quite frequently, yet there is really no such thing. The effects of opium, chloral, bromides, alcohol, strychnine, and certain of the toxins of the infectious diseases seem notably to affect the brain and nervous system, and to do this through the blood stream. There seems to be another reason for the failure of salvarsanized serum in this method of treatment. Granted that its theoretical basis be correct, and that the introduction into the intradural spaces can locally and favorably influence general paresis, the amount introduced seems utterly insufficient. Of all the blood in the body, 50 c.c. are removed one hour after salvarsan has been administered. Such an insignificant fraction of the total amount of the blood present can contain only a small amount of salvarsan. Its introduction seems *a priori* to be adding but little of local treatment to that of the salvarsanized blood stream itself.

**4. The Vesalianum Mistaken for a Fracture of the Fifth Metatarsal.**—W. P. Coues notes that the occurrence of the Vesalianum in the foot is so unusual that no reference is made to it in such modern anatomies as Sobotta, Piersol, Gerrish, Morris, Macalister and Gray. A few *x*-ray experts and surgeons are familiar with its occurrence, although the modern books on fractures are silent on its relation to fracture of the base of the fifth metatarsal. The author reports the case of a girl aged 12 years in whom the Vesalianum was mistaken for a fracture of the fifth metatarsal bone. The importance of the recognition of this rare abnormality is obvious. Its relation to the cases of fracture of the base of the fifth metatarsal bone by inversion of the foot needs further study and elucidation. It is possible that some of the reported cases of this lesion have been this rare anatomical variant, and that others may have been fractures through the line of union of the Vesalianum with the metatarsal. A radiograph of both feet with a good view of each fifth metatarsal bone should be taken in all cases in which the diagnosis of fracture of the base of the fifth metatarsal bone has been made.

1. The Relation of Aphasia to Mental Disease from the Medicolegal Point of View. C. W. Burr.
2. Sensorimotor Aphasia. J. H. Lloyd.
3. Some Observations on the Child of Today. T. S. Southworth.
4. Psychoanalysis. M. Solomon.
5. The Psychological Effect of the Fairy Story. A. L. Benedict.
6. Rectal Cases under Local Anesthesia. J. F. Saphir.
7. Why Electrotherapy Cures. H. H. Seelye.
8. Brachial Neuritis. J. F. Harris.
9. Acute Dilatation of the Stomach Complicating Pregnancy. N. P. Thompson.
10. In Memoriam, Dr. Edward Charles Spitzka. N. E. Brill.

**1. The Relation of Aphasia to Mental Disease.**—C. W. Burr concludes that motor aphasia in and by itself does not affect mentality. When dementia is present it is due to widespread cerebral arterial disease. In aphasia due to destruction of the auditory speech center there is always dementia. When the amnesic aphasia is only partial, dementia may or may not be present, depending upon the amount of speech disorder. Isolated word blindness may occur without mental defect. Aphasia of any kind may be a mere incident in the course of paresis or senile dementia. If it is sensory the dementia is thereby increased. The true essential insanities, paranoia, manic depressive insanity, and dementia præcox are never caused by aphasia.

**2. Sensorimotor Aphasia.**—J. H. Lloyd admits that Broca's convolution is the motor center of speech, but believes that this motor center represents only one part of the speech zone, and without a study of the great primary auditory or sensory zone, by means of which the mother tongue is learned, one is likely to make grave mistakes in studying this obscure subject. There are hardly two cases of aphasia that are alike. The attempt to localize language in the brain cortex any more accurately than one is now able to do, is destined to be futile. It looks as though one is simply threshing over the old straw in trying to make an anatomical dissection of a complicated psychological process. Language, in its very nature, has a sensory as well as a motor element, and to attempt to separate these two is something like an attempt to separate

force from matter, or form from substance. The idea is metaphysical, not practical. There are two sides to the shield, and it depends upon which side the observer is looking at, whether he calls it the one thing or the other.

**6. Rectal Cases Under Local Anesthesia.**—J. F. Saphir prefers the use of quinine and urea hydrochloride as a local anesthetic. This is not followed by the toxic symptoms, the cold sweat, the feeling of faintness, and the excruciating after-pains that usually follow the use of cocaine or beta-eucaine. The anesthesia produced by quinine and urea hydrochloride solution takes place within three to twenty minutes, and lasts for a period of three to ten days after the operation, a sufficient time to allow the wounds produced by an ordinary rectal operation to heal. Even the distention pain caused by sterile water or saline solution is avoided when quinine and urea hydrochloride solution is used. Rectal cases in which local anesthesia is feasible are: (1) Thrombotic hemorrhoids, (2) skin tags, (3) external hemorrhoids, (5) fissure ani, (6) ulcers of the anus, (7) dermoid cysts, (8) rectal polypi, (9) tight sphincter ani, (10) some cases of fistula ani, and (11) some cases of prolapsus ani. Rectal cases in which local anesthesia should be preferred are: (1) Patients who refuse to be operated on under general anesthesia, (2) patients who cannot afford to absent themselves from their place of business or from their social duties for one or two weeks, (3) patients who are sufferers from some cardiac, nephritic, or pulmonary affection.

**8. Brachial Neuritis.**—J. F. Harris states that the best results in the treatment of this condition are obtained with the high frequency current. All the author's cases treated in the dispensary were given applications of the Oudin current by means of a glass vacuum electrode. These treatments were of ten minutes' duration and were given three times a week. The electrode was passed slowly from the plexus to the finger tips and back again for the period of time stated. No internal medication was advised, with the possible exception of a mild tonic laxative. The results were astonishing. Relief was obtained in many cases at the end of the first week and in the majority of cases a complete cure was established in one month. The patients often remarked after the first application of the current that the arm felt "looser," that the sense of tightness had been relieved. The only form of the disease which failed to yield to the current was one of diabetic origin, and here one was able merely to alleviate the pain for a short time following each treatment. It was found that if the electrode was held in one position for any length of time, the skin became extremely sensitive, so much so that the next application became very painful, hence the employment of the slow massaging application of the entire arm. Treatment should never be given through an intervening garment, but always upon the bare skin, for burns may result, and in one instance reported to the author, a lady's silk waist was destroyed by a circular piece of sleeve dropping out. In private practice the author has found that the use of wet hot applications for one hour, following the high frequency treatment, has been quite advantageous, but only when used within a few hours. The duration of this disease in private practice in which the high frequency current is used is even shorter than in the dispensary, for in the former case patients are able to receive daily application of electricity which after all is the most desirable method of treatment. The author cites the case of a dentist who was suffering intense pain and difficulty in raising the arm, and who, as the result of a daily treatment with the current, was able to continue his work until a cure was effected.

**3. Radium Treatment of Cutaneous Epitheliomas by Single or Massive Doses.**—A. S. Clark concludes that radium if used in sufficient quantity is an efficient and satisfactory means of attacking these lesions. The single or massive dose method will probably prove to be the method of choice. It is easier to estimate this single or massive dose because one is dealing with a stable remedy emitting a constant amount of rays, which is not the case with the Röntgen rays, even with the pastiles now at one's disposal. The cosmetic results are at least equal to those of any other form of treatment of these lesions. Its ease of application, comparative painlessness, even in the inflammatory stage, and harmless appearance recommend it to patients. The length of exposures can be practically determined and depends on the amount of radium and the character of its container; its distance from the lesion; the character of the lesion, whether superficial or deep, and the age, state of health, and susceptibility of the patient to other rays, such as the sun's. Its two disadvantages are its high cost and the length of time of exposure in the single-dose method. This latter, however, is indirectly in proportion to the amount of radium employed.

**4. Cholesterinized Antigen.**—L. Thompson concludes that owing to the ease of preparation of this antigen it is to be recommended. It is slightly more delicate than other antigens, and is especially valuable in determining when a cure has been effected, as a positive reaction with its use persists after treatment for a longer time than with other antigens. If the reagents are titrated properly, non-syphilitics will not give positive results.

**7. Antigonococcic Serum in Gonorrhea.**—B. C. Corbus comes to the following conclusions: The complement-fixation test is a reliable guide in the administration of the serum. When the test is negative, the serum should not be used. The intensity of the positive complement-fixation test offers a reliable guide as to whether or not the serum will be efficient, as the efficiency and intensity are in direct proportion. The amount injected should be at least from 36 to 45 c.c., administered intramuscularly, from 12 to 15 c.c. a day, for three days. Serum-sickness, if distressing, should not be alarming. A negative complement-fixation test after two or three months shows a complete cure.

**8. Cowpox Vaccination.**—J. N. Force states that any one of the typical reactions against vaccine virus must be regarded as an evidence of immunity. If antibodies against virus are present in the blood of the individual the immediate reaction occurs, characterized by the formation of an areola around the vaccinated spot usually within the twenty-four hours succeeding the vaccination. If antibodies are not present but the

power of forming them exists through previous vaccinations, the growing vesicle is aborted sooner than in a previously unvaccinated person, which accounts for the small size of the vesicle and the early appearance of an areola larger than in the case of a vesicle of the same age. The author has evolved a special technique as an aid to exact observation subsequent to revaccination. Physicians' certificates of immunity should be based on an observed reaction and not on the failure of two or three vaccinations, unobserved until the fifth day after the insertion. These "failures" may have been due not to immunity but to inert virus.

4. Pain After Operation for Internal Piles and Its Prevention. P. L. Mummery.
5. The Early Detection of Diabetes by a Simple Method of Estimation of the Blood Sugar. Dr. O. K. Carlsbad.

**1. Modern Theories of Hysteria.**—J. A. Ormerod states that the fundamental defect in hysteria, according to Janet, consists in a feebleness of mental synthesis; yet this is a condition that has to be inferred and cannot be directly observed. But there are certain very common mental traits open to observation to which Janet gives the name of mental stigmata, adopting the term used by Charcot for certain common bodily symptoms. Among such mental stigmata are: (1) Suggestibility—not merely that an idea can be easily implanted in a patient's mind, but that it tends to develop there and engross the whole mind. (2) Distractibility—This is merely the obverse of suggestibility, while the patient is occupied with one idea she forgets all others. (3) Feebleness of will—so-called "aboulia." Whatever the will means it implies at the lowest estimate a weighing and comparison of many motives, which is just the sort of thing which the hysterical patient cannot do. (4) Changeability and waywardness, as of symptoms, so of disposition and desires—a trait that has been most unjustly transferred to the whole female sex. (5) Defective memory-amnesia. In addition to a localized amnesia there is a loss of memory which may be called "systematized." The patient forgets everything connected with a particular person, or a particular event, or even a particular conception. It is a class of memories that disappears, not a series of events in time. Hysterical patients are apt to be dominated by fixed ideas. So long as the fixed idea remains buried in the subconsciousness it may give rise to no overt trouble, but should circumstances arise to weaken the grasp of the personal consciousness, so that it vacates its proper dominion, then the subconscious idea may assume command.

**3. Acute Lobar Collopse of the Lung.**—H. L. Tidy and E. Phillips conclude that inaction of the muscles of respiration is a cause of acute lobar collapse. Blockage of the bronchioles from capillary bronchitis may possibly have a similar result. Lobar collapse may explain cases of pleural effusion without corresponding displacement of the mediastinum and heart. In the case described by the authors, acute pleurisy occurred without changes in the lung. Inhibition of the muscles of respiration resulted in acute lobar collapse.

2. On Some Clinical Manifestations of Congenital Syphilis. H. Armstrong.
3. The Clinical Importance of the Cerebrospinal Fluid. W. Boyd.
4. Meningitis in Children. W. M. Smith

**1. Diagnosis and Treatment of Cerebrospinal Syphilis.**—P. Stewart states that before coming to definite conclusions one requires numerous and prolonged observations over a large series of cases. One or two observations are not enough to justify a conclusive opinion in any case. The patients should be repeatedly examined, not only during the progress of the treatment, but at intervals for months and years afterwards. Improvement in the condition of the cerebrospinal fluid is a useful index of arrest of the disease. But one must remember that in general paralysis at least the cell count in the fluid may go down without any corresponding improvement in the mental symptoms. This is readily understood when one bears in mind that, even if the disease process be arrested, those nerve cells and nerve fibers which have been already destroyed, remain destroyed and cannot be regenerated. It is therefore of importance to select only those cases of general paralysis which are in the early or toxic stage of the disease, before the cortex has become profoundly degenerated. The earlier the disease is recognized, the better are the prospects of improvement. Advanced cases with profound cortical degeneration are totally unsuitable. The most thorough method of attacking general paralysis would be to administer the remedies concurrently by all three routes—intravenously, intraspinally, and intracranially. It may be that in the future this combination will be adopted. It is as yet too early to claim that one possesses a cure for tabes or general paralysis, but one can in suitable cases do a good deal toward arresting both diseases. Whether such periods of arrest are permanent time will show.

**4. Meningitis in Children.**—W. M. Smith presents the following table in which he contrasts the different forms of meningitis in children:

| Meningitis | Onset | Initial Symptoms | Cerebrospinal Fluid |
|---|---|---|---|
| Epidemic meningococcal (spotted fever) | Generally sudden | Basal | Polymorphonuclear leucocytes, Weichselbaum's *Diplococcus intracellularis*. |
| Sporadic meningococcal (posterior basal) | Sudden | Basal | Polymorphonuclear leucocytes, non-Gram stained organisms, *Diplococcus intracellularis*. |
| Pneumococcal | Sudden | Cortical | Polymorphonuclear leucocytes, Fränkel's diplococcus. |
| Traumatic | History | | Blood. |
| Pyogenic | Sudden | Cortical | Polymorphonuclear leucocytes, staphylococci or streptococci |
| Rheumatic | During attack of acute rheumatism or history of rheumatism | Cortical | Polymorphonuclear leucocyt s, *Diplococcus rheumaticus*. |
| Other forms of infection (typhoid fever, influenza, etc.) | Sudden | Cortical | Polymorphonuclear leucocytes, infecting organism. |
| Syphilitic | Insidious | Generally basal | Excess of lymphocytes. Wassermann reaction positive. |
| Tuberculous | Generally insidious | Generally cortical | Excess of lymphocytes generally, may be polymorphonuclear leucocytes if acute infection. Tubercle bacilli. |
| Serous | Sudden | Cortical | Excess of lymphocytes, no organisms. Fluid at increased pressure |
| Meningism | Generally insidious | Cortical | Normal fluid generally at increased pressure. |

The initial symptoms when the cortex is first invaded are intense pain, headache, convulsions, and mental symptoms. When the base is first invaded the initial symptoms are tonic muscular spasm, paralysis, constant vomiting, and optic neuritis.

**Theories Concerning the Thyroid.**—Grumme considers Graves' disease, myxedema, cretinism, goiter, hyper- and hypothyroidism. From his speculations he seeks to draw some practical conclusions, such as: Cretinism, myxedema and endemic goiter are all benefited by organic (thyroid) iodine. In the endemic goiter of mountainous countries, which is to be regarded as an incomplete cretinism, inorganic iodine acts more intensively than organic iodine, causing improvement, *i.e.*, reduction in size of the goiter. In Graves' disease all iodine is harmful, even foods which are rich in iodine (marine fish). Apparently simple goiter of the plain and lowlands, since it often represents a step toward Graves' disease, is also aggravated by iodine. Naturally cases arise of simple goiter in which the crucial factor of altitude is in abeyance—for example, after a migration from low to high lands. In such cases to give iodine would be a blunder. The history, therefore, must be investigated in cases of plain goiter, and with added reference to previous treatment. Several blood tests are also available to distinguish an incipient goiter from incipient Graves' disease. These concern both the blood count and coagulability (Kocher, Kottmann). Other differential tests are found in special works.

**Studies of Mummies and Frozen Mammals.**—Heller studied the mummies of both Egypt and Peru, and the Siberian mammoth as preserved in ice. While the finds interest chiefly the pure scientists, since they consist of minute anatomical finds, there is much of collateral interest to the general reader. The mammoths found were not victims of any cataclysm, but simply fell into holes which had been hidden by an artificial soil of débris. Multiple fractures give proof of this statement. The animals were not killed outright, for they made attempts to raise themselves and to eat. Death, however, occurred quickly, from whatever cause, and the cadavers were soon covered with ice and preserved, until at some later period during the subsidence of glacial ice, a river washed away the latter and exposed the monsters. As the mammoth was preserved by ice, the Peruvian mummy was kept intact primarily by heat. Peruvian mummies may be traced back to 1100 B. C. Preservation was due solely to burial in a hot, dry soil. The Egyptian mummies, in addition to the action of the hot, dry climate, went through a process of embalming, but only in relatively modern times. Natural mummies occupy the interval between 4000 and 2000 B. C. The embalming technique shows variations from century to century.

*April* 27, 1914.

**Causation of Landry's Paralysis.**—Leschke has been at work upon this subject, in common with his superior, Saenger, for some months. After describing a typical case in a 16-year-old girl, he sums it up as follows: paralysis ascendens acuta with complete absence of fever—an ascending flaccid palsy, causing death by finally involving the medulla. Autopsy showed no naked eye alterations in the brain and cord. The latter to the microscope showed severe recent lesions in the ganglion cells; more or less complete plasmolysis and chromolysis of the cells of the anterior horns. On the other hand there were absolutely no inflammatory changes and nowhere any infiltrative interstitial process —which distinguishes this form of paralysis from the epidemic infantile type. After a description of the so-called Landry corpuscles found in the spine the author relates the results of inoculation experiments on animals. He was able to inoculate apes with the disease, and to propagate it from ape to ape, but no positive results were obtained from small laboratory animals. The virus is filtrable and the period of incubation varies from 7 to 23 days. Clinically the affection often results from exposure, or the grip, after a latent period of about two weeks. Attempts to cultivate the germ have as yet met with but doubtful success. All alleged Landry bacilli have thus far been shown to be non-pathogenic. The author's virus seems a marked advance.

**Investigations into Abderhalden's Dialysis Procedure in Pregnancy.**—Lange has studied 170 sera with several hundred single determinations, the chief value being based on double determinations and other controls. In regard to the claim that placenta substance is not broken down by the sera of subjects with cancer and salpingitis, the author found that in not a few placentas there was a positive reaction with such sera. Proceeding with control subjects the author tested cases of febrile diseases, lues, tuberculosis, etc., and in from 30 to 65 cases obtained the "pregnancy reaction"—results which cannot be set down to technical errors alone. The specific character of these reactions seems much in doubt.

**What Kind of Cancers Are Best Suited for Treatment with Radioactive Substances?**—Koblanck lays special emphasis on the following: superficial chancroids of the face; carcinoma of the uterus, vagina and vulva; cancer of the tonsil; cancer of the parotid. Facial chancroids heal with surprising rapidity if the treatment is supported by high frequency. Surprising facts come to light in the treatment of the portio vaginalis. Thus after the latter had been destroyed by the disease it underwent regeneration through treatment. Not a single operable case is included in the author's material. Various forms of cancer and sarcoma readily accessible to the treatment do not benefit by it at all. Here belong advanced, deeply eroding cancers of the face, cancerous ulceration in the scalp, ovarian cancer, and bone sarcoma. The preceding make up the "unfavorable" group. Between this and the "favorable" group lies a stretch of intermediate territory, occupied by tumors of the breast, respiratory and digestive tracts. The prognosis here is doubtful.

*April* 7, 1914.

**Silicic Acid in Cancer and Tuberculosis.**—This number of the Wochenschrift has two articles on these subjects. Kahle, who has studied both the metabolism of silica and the latter's relation to tuberculosis, makes some important announcements with especial reference to the pancreas. 1. There is an intimate association between the pancreas and the silica metabolism of the organism. The metabolism of this acid is changed in the tuberculous and cancerous subjects. In both less of the acid is eliminated by the kidneys than is the rule in health. 2. In the pancreas of tuberculous subjects there is a deficiency of silicic acid. Therefore the patient should not only injest a sufficient quantity of this chemical, but it may also be used to advantage as a local cicatrizant which inclines wounds to heal, but causes granulation tissue to cicatrize. The tuberculous subject should freely injest silicates, etc. In the pancreas of cancerous subjects but little silicic acid is found, and there is no rationale for this deficit. The use of silica preparations in tuberculosis of all kinds lies in the production of new connective tissue which may encapsule the tuberculous lesions and lead to a cicatrization of the latter. The second article is by Roessle, who supervised the work of Kahle. He states

that he has yet to see a case of "incoercible phthisis" associated with cancer. In his silica treatment of tuberculosis he is guided largely by the control of the intracutaneous reaction, repeatedly applied.

**Diagnosis of Cerebral Apoplexy.**—Mendel refers here to the condition which precedes the stroke. A search for prodromes has as a rule yielded the knowledge that such occur in but 1 or 2 per cent. The author has noted a symptom which while evidently rare is none the less dependable, and moreover portends a fatal hemorrhage. A unilateral congestion of the scalp is accompanied by seborrhea on the side of the future focus. In rare exceptions the entire scalp is involved. Following the seborrhea is a contraction of the arrectores pilorum muscles which causes the hair to stand on end, just as in case of profound fright. The face, after a brief congestive stage becomes pale and sunken, with an anxious expression and there is precordial anxiety. Some hours may elapse before the stroke. The nature of the phenomenon is obscure, although the author cites some plausible views.

**Gorky's Recovery from Pulmonary Consumption.**—Gorky himself contributed an article on this subject in the lay press, a résumé of which is as follows: The distinguished author's left apex was in the first stage, the right apex in the second stage. The abundant purulent sputum contained Koch's bacillus in abundance. There was frequent hemoptysis, profuse night sweats, a high degree of emaciation and weakness. In August, 1913, a profuse hemorrhage occurred. For a number of years past the author had lived at Capri, without apparent benefit. In October of the same year the author, while at his worst, submitted to Röntgen radiation of the spleen for a period of several months. The improvement was pronounced from the start. The severe symptoms ceased and there was a gain in weight of 20 pounds. At present the author, in St. Petersburg, feels well and is under no special regimen.

## Münchener medizinische Wochenschrift.

*April* 14, 1914.

**Nature of the So-called Defensive Ferments.**—Stephan refers to the slenderness of our knowledge of these bodies. The word "ferment" and the word "defensive" may alike have been prematurely chosen. The bodies appear to be of the nature of Ehrlich's amboceptors. The author has made many researches into the numerous forms of Abderhalden's seroreaction, and learned that in all cases the addition of the so-called "complement" greatly intensified the reaction. Under this term in this connection we are to understand the following: Fresh guinea pig serum 0.1 ccm. diluted in the proportion of 1:2 with physiological saline solution. Starting with this discovery he continued his research until the following conclusion was reached: The so-called defensive ferments are of complex nature, of the nature of the amboceptor bodies of Ehrlich. They do not differ from the various bodies of immunity research—hemolysins, bacteriolysins, cytolysins. The author uses a term "albumin reagins" to comprise all of these bodies. "Reagins" are always strictly specific. The complement, on the other hand, contains a proteolytic enzyme which is not specific.

**"Combined" Treatment of Syphilis.**—Klausner refers to a mixture used by a colleague to abort syphilis. The chief active constituent is colloidal, molecular mercury, and with it are combined salicyl, quinin, sublimate, arsenic, phosphorus and an iodine compound. The formula is not new, for it has been tested for over two years. From all indications it is intended for the market. The author would term it an excellent mercurial, the role of the combined substances not being specifically apparent. It is injected intramuscularly. In no sense is it advocated as a substitute for salvarsan, for a combination of the two is advocated. The combined remedies appear to be intended, at least in part, to offset mercurialism, so that a good dosage is practicable. Attempts have long been made to modify the action of mercurials in such manner that they may be given safely—for Hg. is a much stronger spirocheticide than salvarsan, and although it causes high morbidity it does not menace life.

**Tuberculin Cures in a Sanatorium.**—Ponndorf, who is at the head of a large public institute for inoculation treatment, gives some statistics of results during 1913. His patients received one to six or seven inoculations with tuberculin, chiefly "new." The number treated was 134, and during this period 44 were pronounced cured, 37 greatly improved and 28 somewhat improved. Twelve disappeared and the remaining 13, who did not react to tuberculin (clinical diagnosis positive?) were not treated. All ages, and all forms and stages of the disease were represented. Since some of the cures cannot have been in clinically tuberculous subjects—they are recorded as asthma, anemia, etc.—the inference is that there was a laboratory diagnosis. Of much interest is the fact that tuberculous subjects, especially those under 25 years of age, have a very marked tendency to enlarged thyroid as evidence of tuberculous toxicosis. This is readily determined by neck measurements. Not infrequently the latter show a decline after a few inoculations.

## Münchener medizinische Wochenschrift.

*April* 21, 1914

**Two Cases of Nutmeg Poisoning.**—Beck relates the following: two servant girls partook of a mixture made up of two ground nutmegs, a small quantity of powdered cinnamon and half a liter of hot wine. One girl, M. U., drank the greater part, the other, M. H., receiving but a small portion. Both were brought to the hospital unconscious. M. U., a strong girl of 20, could not be aroused by speaking. Her respiration was 20, even. Pupils reacted to light. Pulse small, 95. Heart and lungs normal, also urine and temperature. Reflexes all normal. In sum, with the exception of the stupor and pulse, nothing abnormal was found save a divergent strabismus and slight meteorism. The stomach was washed out and analeptics were given. Although much of the ingested nutmeg was removed patient became restless, while her pulse and temperature rose. She was not aroused from stupor until the third day. The fifth day found her nearly well, some headache persisting. The other patient had a similar experience but less pronounced, and recovered more promptly. Both girls stated that after taking the mixture they developed consecutively dyspnea, failure of memory, vertigo, and somnolence. The purpose of the draught was to bring on delayed menses. The toxicity is probably due to ethereal oils and their terpenes.

**Peculiar State of Narcosis after Industrial Work with Methyl Chloride.**—Gerbis relates an episode of this sort, which occurred after this chemical had by oversight been eliminated from the industrial poisons, and indeed from the general list of poisons. Those who work industrially with methyl chloride handle the latter in closed vessels, since it is highly volatile. As a rule, therefore, the worker is not exposed to danger. It had been noted incidentally that while the employees led a very active life, they nevertheless quickly became fat, but aside from this there was nothing to suggest an occupational affection. However, when the gasometers

are cleaned, it appears that unless due precautions are used fumes of the methyl chloride may be inhaled and cause peculiar disturbances of vision, along with a cerebral state not unlike alcoholic intoxication, initial excitation being followed by prolonged somnolence. The author believed at first that he had made a new contribution to industrial poisonings, but after the completion of his report learned that over ten years ago methyl bromide was placed among these poisons in Switzerland as the handling of it by workmen caused a high degree of weakened vision, disturbances of memory, and somnolence. This intoxication was chronic in type. When large amounts were inhaled convulsions and coma developed with persistent delirium, ending in cachexia and dementia. The author sees sufficient difference between these types of intoxication to entitle him to some priority, the difference being more than one of degree.

### Deutsche medizinische Wochenschrift.

*April* 9, 1914.

**Familial Syphilis and Keratitis Parenchymatosa.**—Lesser and Carsten emphasize the fact that the newer seropathology has made many changes in our ancient empirical knowledge of lues. This is nowhere more apparent than in the congenital form, and all our old ideas of familial syphilis must require overhauling. We can no longer depend on indirect clinical evidence in such cases, for serological tests must be applied. In order to secure an entering wedge the authors began to study the families in which one or more cases of keratitis parenchymatosa exist. While we know but little of the intimate nature of this affection, few will deny that it is typically syphilitic—although in about 10 per cent. of cases this connection had not been demonstrated. This was originally true also of tabes before the introduction of the Wa R. The authors hope that they have raised the percentage to 100. Thus of 38 children with keratitis, 35 gave outright the positive Wa R. The other three were tested with lüetin with two positive results. Thus but one case remained unaccounted for. To explain its existence by the presence of some other constitutional disease was merely begging the question. Tuberculosis naturally coexists to some extent with keratitis parenchymatosa. Thus in five cases a positive von Pirquet was obtainable. Yet how does syphilis produce this lesion? No spirochetes have been found in the former, nor does inoculation of the latter cause keratitis. We can only accuse the blood vessels. The phenomenon is almost universally bilateral, the sequence being akin to that of sympathetic ophthalmia; so that the mechanisms in the two affections should be closely related. In regard to the success of treatment all agree that after one eye is attacked nothing can prevent the development of the affection in its fellow. To come to the heredity of the cases 20 fathers of 38 children admitted infection and four of these had metasyphilis (a shocking percentage). The problem with the mothers was singularly complicated. The latent syphilis, Colles cases, etc., naturally caused much confusion. As a rule the mother of a syphilitic child gives at first a positive Wa R, ranging from 90 per cent. to 100 per cent. The negative cases coincide in part with the Colles law women, but this as a rule is apparent only after the first few years, when the number of negative finds attest that the so-called Colles mothers tend to recover spontaneously. In further labors these negative Wa R women tend to bear healthy children. The highly interesting work must be summed up as follows: Keratitis parenchymatosa is doubtless purely syphilitic in character, results of medication are uncertain, but it is a practical certainty that if one eye is affected the participation of the other cannot be prevented. The clinically intact mother of a congenitally syphilitic child almost unvariably shows a positive Wa R. The so-called "Colles mother" suffers from latent syphilis. The new serology throws no light on the old alternative of "infection of the mother vs. infection of the ovum." At least two "serologically syphilitic" children are born to every clinically syphilitic child. These data open up endless possibilities for new medicolegal problems.

### Deutsche medizinische Wochenschrift.

*April* 16, 1914.

**Etiology of Acute Articular Rheumatism.**—Singer reviews all the recent speculations on the nature of this affection, with special reference to the septic rheumatoids. The occurrence of acute phenomena in a chronic rheumatic subject naturally suggests anaphylaxis. Despite the great number of affections in which the joints participate, generalizations seem out of the question. We can only speak of arthrotropic toxins or bacteria, and of arthrotropic medicaments which are of more or less value in treatment. The author goes no further than the statement that we cannot escape the streptococcus as an arthrotropic disease exciter. This seems assured for all secondary articular rheumatism, and the author is convinced that streptococci will be recognized eventually as the essential exciter of the acute type. Singer announces his adhesion to the opinion which was advanced many years ago that acute articular rheumatism belongs to the large family of pyemias.

**Functional Testing of the Liver with Levulose.**—Arai of Tokio sums up his personal experience of this subject as follows: 50 grams levulose suffice to test the function of the gland. If a healthy subject ingests this quantity a positive result is almost never obtained. For testing in levulosuria a simple Nylander reaction suffices, provided that the fasting urine is exactly controlled. The color reactions of Pinoff or Selivanoff is quite uncertain. In different affections of the liver we see the strongest depression of the tolerance for levulose in cirrhosis, high degrees of syphilis of the liver, marked atrophic processes in the liver from various causes, and in general marked injury of the liver parenchyma. As for catarrhal jaundice a decision here has not been reached. In primary and secondary tumors of the liver, in parasitic diseases of the same, in stasis, in gallstones (especially in cysticus obstruction) in the swollen liver of leucemia or pseudoleucemia the tolerance for levulose is not at all reduced, or barely so at most. As far as he has gone the author finds the test a simple and trustworthy one.

**The Iodotherapy of Arteriosclerosis.**—Schwalbe concludes a serial article on this subject as follows: But one thing seems assured, to wit, that iodine can influence favorably syphilitic arteriosclerosis. Where improvement follows in cases which occur in non-syphilitics we may, of course, suspect that the disease is latent (no mention of the Wassermann reaction). In the other types of the disease the iodine is given quite empirically—there is no theory yet devised to explain the merchanism of a cure, just as there is no proof in a given case that the disease is not due to suggestion or other factor. An iodine cure should be given with intermissions, and may be prolonged for years. Failure of improvement after a reasonable time, say 4 months, should lead to permanent discontinuance. There is always a possibility that iodine will cause unpleasant symptoms in overlooked goitre, and it is then contraindicated. This also holds good if iodism goes beyond a certain point.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### CAUSES OF DEATH AMONG WOMEN.

THE Medico-Actuarial Investigation Committee has tabulated the following comparison of the causes of death among men and women for twelve of the most common diseases:

MEN AND WOMEN—DEATHS BY CAUSE.
PERCENTAGES OF TOTAL DEATHS.

| Cause of Death | AGES AT ENTRY, 15-29 | | AGES AT ENTRY, 30-44 | | AGES AT ENTRY, 45 AND OVER | |
|---|---|---|---|---|---|---|
| | Men | Women | Men | Women | Men | Women |
| Typhoid fever | 14 2 | 6 3 | 6 8 | 4 3 | 2 0 | 1.3 |
| Tuberculosis of the lungs | 22 5 | 27 2 | 12 3 | 13 9 | 4 5 | 4.0 |
| Cancer and other malignant tumors | 2 1 | 2 7 | 4 8 | 11 8 | 7.7 | 13 3 |
| Diabetes | 1 2 | 7 | 1 7 | 9 | 1.5 | 1 8 |
| Cerebral hemorrhage and apoplexy | 2 1 | 1 5 | 6 2 | 3 9 | 11 3 | 10 3 |
| Organic disease of the heart | 3 0 | 3 3 | 5 9 | 5.3 | 10 6 | 10 7 |
| Pneumonia | 7 6 | 6.1 | 9 4 | 7 5 | 8 4 | 10 7 |
| Appendicitis and typhlitis | 3 3 | 2 3 | 2 1 | 1.5 | 1 0 | .3 |
| Cirrhosis of the liver | .7 | .4 | 1 4 | .8 | 1 7 | 1 0 |
| Nephritis and Bright's disease | 4 1 | 4 2 | 7 3 | 6 4 | 9 6 | 7 4 |
| Suicide | 3 1 | 2 1 | 4 1 | 1 4 | 2 5 | .5 |
| Accident | 12 1 | 3.7 | 8 2 | 4 0 | 4 8 | 2 6 |
| All other causes | 24 0 | 39.5 | 29.8 | 38.3 | 34 4 | 26.1 |

RATIOS PER 10,000 EXPOSED TO RISK.

| Cause of Death | AGES AT ENTRY, 15-29 | | AGES AT ENTRY, 30-44 | | AGES AT ENTRY 45 AND OVER, | |
|---|---|---|---|---|---|---|
| | Men | Women | Men | Women | Men | Women |
| Typhoid fever | 6.7 | 3 3 | 4 6 | 2.7 | 3 7 | 2.3 |
| Tuberculosis of the lungs | 10.6 | 14 1 | 8 2 | 8 6 | 8.4 | 7.3 |
| Cancer and other malignant tumors | 1.0 | 1 4 | 3.2 | 7.3 | 14 4 | 24.3 |
| Diabetes | .6 | .4 | 1.2 | .6 | 2.8 | 3.3 |
| Cerebral hemorrhage and apoplexy | 1 0 | .8 | 4 1 | 2.4 | 21.2 | 18 7 |
| Organic disease of the heart | 1.4 | 1.7 | 4 0 | 3.3 | 19.9 | 19.6 |
| Pneumonia | 3.6 | 3 2 | 6.3 | 4 7 | 15 8 | 19.5 |
| Appendicitis and typhlitis | 1.6 | 1.2 | 1 4 | 1.0 | 1 9 | .6 |
| Cirrhosis of the liver | .3 | .2 | 1 0 | .5 | 3.3 | 1.8 |
| Nephritis and Bright's disease | 1 9 | 2 2 | 4.9 | 4 0 | 17.9 | 13.6 |
| Suicide | 1 5 | 1 1 | 2.8 | .9 | 4 8 | 1.0 |
| Accident | 5 7 | 2.0 | 5.5 | 2 4 | 8 9 | 4 8 |
| All other causes | 11.3 | 20.5 | 20.0 | 23.7 | 64 2 | 66.0 |

It is seen from a comparison of these tables that typhoid fever, appendicitis, cirrhosis of liver, suicide, and accident cause the death of a larger number of men, and that cancer and malignant tumors are the causes of a greater proportion of deaths among women.

The death rate among insured women may be studied under four classes: 1. Spinsters. 2. Married women with husband beneficiary. 3. Married women with beneficiary other than husband. 4. Widows and divorced. It is found that spinsters show a much lower mortality than any of the other classes from tuberculosis of lungs, pneumonia, disease of the kidneys, cancer, apoplexy, and cardiac diseases.

A comparison of the death rates of men and women with tuberculosis as the cause show that the mortality from this disease among women, even spinsters, is considerably higher than that among men at the early ages. This, however, may be accounted for to some degree by laxity in the medical examination.

It is interesting to note the effect of marriage on female life during and after the period of childbearing. The result of most observations have been that the high mortality among women is limited to the child-bearing ages, 15 to 45, whereas a lower rate is found above those ages. This is brought out by the following Medico-Actuarial table:

DISEASES OF PREGNANCY AND THE PUERPERAL STATE.

| Class | AGES AT ENTRY, 15-29 | | AGES AT ENTRY 30-44 | |
|---|---|---|---|---|
| | Percentage of Total Deaths | Ratio per 10,000 Exposed to Risk | Percentage of Total Deaths | Ratio per 10,000 Exposed to Risk |
| Spinsters | 8 6 | 3.5 | 3.8 | 1.6 |
| Married women, beneficiary husband | 18 8 | 12.5 | 8.8 | 6.3 |
| Married women, beneficiary other than husband | 14 7 | 10.1 | 6.3 | 4 7 |
| Widows and divorced | 6.2 | 4.0 | 1 8 | 1.2 |

The foregoing table indicates that many who insure as spinsters marry afterwards and that childbirth has an important influence on the mortality among married women.

This influence of build on the mortality of women is of some importance, as seen in the following table:

WOMEN.
Height 4 Feet 11 Inches to 5 Feet 10 Inches Inclusive.
ALL POLICY YEARS COMBINED.

| Variation From Average Weight in Pounds | AGES AT ENTRY, 20 TO 39 INCLUSIVE | AGES AT ENTRY, 40 TO 62 INCLUSIVE |
|---|---|---|
| | Ratio of Actual to Expected Deaths, Per Cent | Ratio of Actual to Expected Deaths, Per Cent |
| −25 to −30 | 101 | 87 |
| −15 to −20 | 111 | 96 |
| −10 to +10 | 105 | 101 |
| +15 to +30 | 105 | 119 |
| +35 to +60 | 117 | 124 |
| Total | 107 | 101 |

The foregoing table emphasizes the distinctly better quality of the underweight risks at the older ages.

If these results are compared to those found among men, it is found that the effect of underweight or overweight, particularly at the younger ages, is less than among men, though exhibiting the same general tendencies. At the older ages, underweight to the extent of at least 30 pounds is an advantage and overweight is a disadvantage, increasing with the degree of overweight.

---

**Ever-Increasing Interdependence Between Life Insurance and the State.**—The growth of life insurance and State supervision have kept pace with each other. The people now call for and demand strict supervision of all classes of business, but especially of the insurance business. They are entitled to it, and the viewpoint of the Hon. James R. Young, president, National Convention of Insurance Commissioners, Raleigh, N. C., is to make it a help and not a hindrance to the business. Supervision, as now conducted, has helped the growth of the companies, and produced a better feeling among them. They have learned to know each other better and to distrust each other less, to feel that the success of one, instead of hurting, is a decided advantage to the other. There in no question as to the progress and splendid results in the life insurance business. From a mere wager, or a desire to protect one's family, the business has advanced to the protection of our business and business associates. The business no longer moves or evolves its work without the Government and its laws. The State, in its onward progress and wonderful industrial development, can no longer neglect or do without life insurance and its support and aid to business.—Association of Life Insurance Presidents, December, 1913.

# Book Reviews.

MENTAL DISEASES—A Textbook of Psychiatry for Medical Students and Practitioners. By R. H. COLE, M.D. (London), M.R.C.P., Physician for Mental Diseases to St. Mary's Hospital; Lecturer on Mental Diseases to St. Mary's Hospital Medical School, and at the West London Hospital Postgraduate College. With 52 Illustrations and Plates. London: Published for the University of London Press by Hodder & Stoughton, 1913.

THIS small volume is one of the London Medical Publications series. It purports to delineate in a concise manner the salient features of present day psychiatry. This is an interesting statement in itself as latter-day advance in psychiatry represents both a continually developing evolution and a decided revolution in the entire subject. The Kraepelin classification was a wonderful advance over the old psychiatry and, as the author says, "the teaching of Kraepelin is tending to dominate psychiatry in England." But there are even later teachings, of the Freudian school, and other workers, which are molding even a newer psychiatry in this country. However, while we do not find in it much about Freud or even about Kraepelin, we recognize in this book a step in the right direction in English psychiatry. The subject-matter is set forth very clearly and the book ought to be of service to those for whom it was especially written. The illustrations are also good, for the most part. The plan and scope of this work are as follows: In the first chapter are given, very briefly, the incidence and history of insanity. In the next four chapters we find a very elementary description of mental mechanisms in health, with their disorders in abnormal mental conditions, and reference to the structure and vascular supply of the brain. The next chapter is entitled "The Diagnosis of Insanity." The next two chapters are on general causation and classification. Then follow condensed descriptions of the psychoses in ten chapters, and chapters on "General Diseases and Insanity," the "Pathology of Insanity," "Prognosis," "The Legal Relations of Insanity and Mental Deficiency," and "General Treatment."

OUR NATION'S HEALTH ENDANGERED BY POISONOUS INFECTION through the Social Malady: The Protective Work of the Municipal Clinic of San Francisco and Its Fight for Existence. By Dr. JULIUS ROSENSTIRN, Chief of Staff and Attending Surgeon Mount Zion Hospital; Chairman Advisory Committee Municipal Clinic. Price 25 cents. San Francisco, 1913.

THIS publication is a denouncement of what is claimed to be a great wrong done in San Francisco by the suppression of an institution that has been most active for the benefit and preservation of the public health. It divulges the plan of attack of the opponents of sanitary reforms regarding venereal diseases. A brief description of the Municipal Clinic of San Francisco is given and its aims and work are discussed.

BURDETT'S HOSPITALS AND CHARITIES, 1914. Being the Year Book of Philanthropy and the Hospital Annual. Containing a Review of the Position and Requirements, and Chapters on the Management, Revenue, and Cost of the Charities. An Exhaustive Record of Hospital Work for the Year. It will also be found to be the most useful and reliable guide to British, American, and Colonial hospitals, and asylums, medical schools and colleges, nursing and convalescent institutions, consumption sanatoria, religious and benevolent institutions, and dispensaries. By Sir HENRY BURDETT, K.C.B., K.C.U.O.; Editor of *The Hospital*. Twenty-fifth year. London: The Scientific Press, Limited, 1914.

BURDETT'S Hospitals and Charities is too well known throughout the English-speaking medical world to require eulogy. It stands alone. This issue, however, is the jubilee issue and it is instructive to note the manner in which each new edition has been an improvement on the previous one. The feature of the present volume is its special chapters, which, with the exception of one chapter, deals with hospital and charitable affairs in Great Britain. The last special chapter but one discusses the hospitals of the United States, Canada, Australasia, and India. Again the author calls attention to the difficulties which beset the compilers of information concerning hospitals and other charitable institutions of the United States, and he criticizes the somewhat chaotic condition of hospital accounts in this country. He recommends to a limited extent the adoption in Great Britain of the American system of paying wards. With regard to the vexed question as to what effect the national insurance act of Great Britain is likely to have on the voluntary hospital system the author is silent. Burdett's Hospitals and Charities is a rich mine of valuable information and is almost as necessary to the physician as the medical directory. Sir Henry has performed a public service in gathering information concerning hospitals and charities during the period of twenty-five years.

DISEASES OF THE DIGESTIVE CANAL—Esophagus, Stomach, and Intestines. By Dr. PAUL COHNHEIM, Specialist in Diseases of the Stomach and Intestines in Berlin. From the Second German Edition. Edited and Translated by DUDLEY FULTON, M.D., Assistant Professor of Principles and Practice of Medicine, University of California College of Medicine, Los Angeles Department; Attending Physician, Los Angeles County Hospital. Illustrated. Third Edition. Price $4.00. Philadelphia and London: J. B. Lippincott & Co., 1913.

THE third English edition of this work speaks for the continued popularity which it enjoys. The most distinctive feature of the present volume, as of the previous ones, is the discussion of the subject matter purely from the clinical point of view, and is thus written especially for the physician in general practice. The author considers the anamesis the most important part of the examination in arriving at a diagnosis of the condition of the gastrointestinal tract and throughout the volume he so defines the significance of the subjective symptoms that the reader will scarcely fail to be impressed with the value of the art of interpreting these rather than applying himself to complicated details of laboratory work. The author frankly disclaims any attempt to review the literature or to compile views of other authors or to present any pathological details or theoretical discussions. Every subject is attacked with directness and all non-essentials are ignored. The volume is a succinct record of the author's daily experiences with gastrointestinal diseases of every kind and this is perhaps the most valuable asset of the book. Only a few changes and additions have seemed necessary. New matter pertaining to the medical treatment of gastric and duodenal ulcer have been added. The general section deals with taking history, physical examination, laboratory methods of examination. The special section deals with the diseases of the stomach and intestines. Increasing value is attached to skiagraphy, recent improvements in the diagnosis of lesions of the esophagus, acute dilatation of the stomach, treatment of gastric and duodenal hemorrhage, and technique of sigmoidoscopy.

LEITFADEN DER SÄUGLINGSKRANKHEITEN für Studierende und Ärzte. Von Dr. WALTER BIRK, Privatdozenten für Kinderheilkunde, an der Universität Kiel. Mit 25 Abbildungen im Text. Price 4.80 marks. Bonn: A. Marcus & E. Webers Verlag, Dr. jur. Albert Ahn, 1914.

THIS book, which is termed the "Essentials of Diseases of Children," is more than a mere synopsis of pediatric science. It is a succinct account of pediatrics from the viewpoint of the latest German theory and practice. This modern presentation of the subject is clearly indicated in the chapter on the nutritional disturbances of infancy. The classification of these as adopted by the author is the one introduced by Czerny and Keller and is as follows: (1) Nutritional disturbances *ex alimentatione*, (2) nutritional disturbances *ex infectione*, (3) nutritional disturbances *ex constitutione*, and (4) nutritional disturbances from congenital difficiencies. In discussing the alimentary types of nutritional disturbances the author takes up in order those caused by deficient or disturbed lactation, those caused by disturbances of lactation in children suffering from the exudative diathesis, and those arising in artificially fed infants. The last group is of particular interest inasmuch as the author describes in detail the latest methods of managing those difficult cases of malnutrition in which cow's milk disagrees either in whole or in part. The malnutrition associated with an excessive cereal diet is sharply delineated. The method of managing cases of alimentary intoxication according to the teachings of Finkelstein is presented in full. This summary of part of the section dealing with infant feeding may serve to illustrate the up-to-date manner in which the principles of pediatrics are handled by the author. This book, which in its 256 pages epitomizes the practice of pediatrics in the leading German clinics, may be recommended to all those who would obtain a brief survey of this fertile domain.

MANUAL OF SURGERY. By ALEXIS THOMSON, Professor of Surgery, University of Edinburgh; Surgeon Edinburgh Royal Infirmary; and ALEXANDER MILES, Surgeon Edinburgh Royal Infirmary. Vol. III—Operative Surgery. Second Edition, 620 pages, with 255 illustrations. Price $3.50. Edinburgh, Glasgow, and London: Henry Frowde, Hodder & Stoughton; New York: Oxford University Press, 1913.

THE first edition of this surgery received a very flattering reception on this side of the Atlantic, and deserved it. The work has been most thoroughly revised and brought up to date and is one of the best of the smaller operative surgeries. The assignment of space to the various subjects is, however, open to criticism. Why give 60 pages to the time honored repetition of ligature of arteries and only two each to the operations on the pancreas and spleen and a trifle over five to the kidneys? But four pages are allowed for operations on the liver, while the gall-bladder is disposed of in 11, and much of the space assigned to the consideration of operations on these vitally important organs is taken up by illustrations. With these exceptions, and the fact that the use of the Basle nomenclature makes some of the descriptions rather difficult to follow, one can but feel that criticism is unwarranted, while much praise should be given the authors for crowding so much of true value into a book of this size. The choice of operations is almost invariably good, the descriptions are remarkably clear, and the illustrations, which are found in great profusion, are of unusual excellence. The latest advances in the way of surgical technique are to be found almost without exception; and American surgeons have certainly fared well at the hands of the authors. The work of Murphy in the treatment of ankylosed joints, of Cushing, Elsberg, Frazier, and Hartley in the development of the surgery of the brain and spinal cord, of the Mayos in the surgery of the stomach and thyroid, of Young on the prostate, the work of C. L. Gibson, Halstead, Crile, Whitman, and many others has received recognition and often especial prominence. Any surgeon's library will be enriched by the acquisition of this volume.

PRACTICAL PATHOLOGY, INCLUDING MORBID ANATOMY AND POST-MORTEM TECHNIQUE. By JAMES MILLER, M.D., D.Sc., F.R.C.P.E., Lecturer on Pathology and Bacteriology, School of Medicine of the Royal Colleges, Edinburgh, and Edinburgh School of Medicine for Women; Examiner in Pathology, University of Aberdeen and Royal College of Physicians, Edinburgh; Pathologist, Royal Victoria Hospital, Royal Hospital for Incurables, and Deaconess Hospital, Edinburgh; Assistant Pathologist, Royal Infirmary and Royal Maternity Hospital, Edinburgh; late Visiting Pathologist, General Hospital, Birmingham; Lecturer, Birmingham University; Examiner in Pathology, University of St. Andrews. Price, $2.50. New York: The Macmillan Company, 1914.

THIS volume is quite evidently intended merely for a student's guide to be used as a current textbook during a course in gross and microscopical pathology. Within these limits the book can be warmly commended, but it is by no means a textbook of pathology for reference. This is best shown by the fact that there are no drawings of histological preparations, but only a series of moderately well-executed plates showing the most important gross lesions. The purely practical portions, such as those on autopsy and section technique, are better than the text descriptive of gross lesions.

SURGICAL DISEASES OF CHILDREN. A Modern Theatise on Pediatric Surgery. By SAMUEL W. KELLEY, M.D., LL.D., Honorary Professor of Surgical Diseases of Children, Medical Department, National University, St. Louis; Pediatrist and Orthopedist, St. Luke's Hospital, Cleveland; Formerly Professor of Diseases of Children, Cleveland College of Physicians and Surgeons, Medical Department, Ohio Wesleyan University. Illustrated. Second Edition, Revised and Enlarged. Price $5.00. New York: E. B. Treat & Co., 1914.

THIS volume admirably covers the ground of pediatric surgery. The author has shown in the first edition of this work a sympathetic interest in the problems and special technique of the surgery of children. In the second edition he has maintained this attitude and has made notable additions to the text. Among these additions may be mentioned transfusion by means of Brewer's tubes, arthroplasty, motion after dislocation and other joint injuries, anomalies and deformities of the skull, Abbott's method for scoliosis, tonsillectomy, fistulæ and cysts of the neck, and Cook's operation for relapsed clubfoot. The general practitioner will find in this work detailed instructions as to the simple operative procedures which he may attempt while the general surgeon who would gain an insight into the special needs of the surgery of children will be greatly assisted by this volume. Such subjects as appendicitis in children, the indications and technique of intubation, the operations for enlarged tonsils and adenoids, the treatment of bony deformities and of the various forms of bone and joint tuberculosis in children, etc., are all fully described. Exception may be taken to the use of the word "tubercular" instead of "tuberculous," when the author wishes to convey the meaning that the condition pertains to tuberculosis rather than that the lesion is one having a nodular conformation, as in the case of the cutaneous lesions of leprosy and syphilis. On the whole this volume may be commended for its happy planning and complete execution. It is in every respect a treatise on the surgical diseases of children.

A MANUAL OF MEDICAL TREATMENT OR CLINICAL THERAPEUTICS. By I. BURNEY YEO, M.D., F.R.C.P., Emeritus Professor of Medicine in King's College, London; Consulting Physician to King's College Hospital; Honorable Fellow of King's College. Fifth Edition. By RAYMOND CRAWFORD, M.A., M.D. (Oxon.), F.R.C.P.; Physician and Lecturer on Clinical Medicine to King's College Hospital; Fellow of King's College, London; Examiner in Medicine, Royal College of Physicians; late Examiner in Materia Medica and Pharmacology, University of London, etc., and E. FARQUHAR BUZZARD, M.A., M.D. (Oxon), F.R.C.P.; Physician for Out-Patients to St. Thomas's Hospital and to the National Hospital for the Paralyzed and Epileptic, Queen Square; Consulting Neurologist to the Royal Free Hospital and to the Hospital for Diseases of the Throat, Golden Square; late Physician to the Belgrave Hospital for Children, and Goulstonian Lecturer, Royal College of Physicians, etc. In Two Volumes. Price $6.00 net. New York: William Wood & Company, 1913.

THE fourth edition of this work appeared in 1909 and the advances made since that time have called for a revising and enlargement of this fifth edition, particularly in the fields of physical therapy, use of the *x*-ray in diagnosis, and serviceability of various physical methods of treatment. The study of disease from the point of view of treatment is the object of this work. The teaching of therapeutics is here approached from the side of the drug or remedy. No attempt is made to discuss questions of treatment apart from considerations of the clinical history, course, and pathological characters of the disease. Rational indications for treatment are arrived at by examining the mode of causation of disease. The aim has been to deduce rational indications for treatment from an examination of the pathological nature and the clinical course and characters of the disease under discussion. Selections of formulas are added to most of the chapters. Vol. I deals with chapters on Diseases of the Organs of Digestion, Heart and Blood Vessels, and the Blood and Ductless Glands, Diseases of the Organs of Respiration, and Phthisis. Vol. II treats of Diseases of the Liver, Kidneys, Nervous System, Constitutional Disease, Specific and Infective Diseases.

ANATOMY AND PHYSIOLOGY. A Textbook for Nurses. By JOHN FORSYTH LITTLE, M.D., Assistant Demonstrator of Anatomy, Jefferson Medical College, Philadelphia. Illustrated with 149 engravings and 4 plates; price $1.75. Philadelphia and New York: Lea & Febiger, 1914.

DR. LITTLE has presented in this textbook for nurses a work which may be considered an intermediate between a compend and the larger standard works on the same subjects. No space has been wasted, and every line in the book contains well arranged, clearly thought-out facts. The illustrations, which are many for a book of this size, are the classic ones usually found in the large works on anatomy and physiology and have been both faithfully and beautifully reproduced. The preface states that "emphasis has been placed on the description of organs and their functions which are of fundamental importance in the practical work of the nurse." The book shows that the author has fully succeeded in his efforts. As an additional aid to the course of lectures given in the training schools this little work should prove invaluable.

### SECTION ON SURGERY.

*Thursday, April 30—Third Day.*

**The Surgical Treatment of Empyema.**—Dr. CHARLES N. DOWD of New York read this paper. He said that anatomy must be the basis of surgery, but lately there had been the tendency to use physiological and pathological knowledge to conserve the strength of the patient. Surgeons were more careful of interfering with processes tending to repair. The surgical treatment of empyema was directed toward the drainage of pus. The frequency of pus pockets had been exaggerated, while the frequency of pneumonia had not been appreciated. Pneumonia was the cause of death in most cases; empyema was only incidental. Aspiration was used for diagnosis, but it was not without danger, because when one lung was incapacitated pneumothorax might result from puncture, with fatal result. As regard thoracotomy ether inhalation was not good for pneumonia patients. Local anesthesia was sufficient for resecting a piece of rib. The introduction of the finger was necessary to determine whether there was lung compression. The patient must be made to cough, and if he coughed and expanded lung, lung compression need not be feared. It was important not to cut below the diaphragm. It was better to cut above the eighth rib. The treatment in babies was very discouraging. There were very seldom good results in these cases. The after treatment of thoracotomy was important. Rubber spools maintained satisfactory drainage. Suction apparatus gave little help. The lung should expand at the time of operation, and if adhesions were present blowing exercises should be used. The X-ray should be taken after thoracotomy. The lung would sometimes remain compressed for months. Thoracotomy with decortication of the lung sometimes was of use in these cases, in others not. When the compression was extreme permanent expansion could not be maintained. The procedure was to resect two ribs under ether; the pleura was divided and a longitudinal incision made. The patient was allowed to emerge from anesthesia to cough so that the lung bulged into the wound. The chest wall was brought together with sutures.

Dr. H. LILIENTHAL of New York agreed with Dr. Dowd that empyema was a complication and not a disease. The primary condition should be looked for in order to treat the complication as much or as little as necessary. In the majority of cases the pneumococcus was the infecting agent. Local anesthesia was of utmost importance. The shock and pain were not great if the intercostal nerve was anesthetized, although the crunching of bone frightened the patient. It was dangerous to aspirate for emptying the cavity in cases in which the heart had been swung very much to the side, particularly in left-sided empyema. With the great suction pulling the heart too suddenly back, sudden death might occur. Aspiration was not a simple operation; it was dangerous and free opening was preferable. The patient should have time to get over pneumonia before resection of the ribs was attempted.

Dr. E. W. PETERSON of New York said that very young subjects were not successfully treated no matter how managed. Most cases were due to pneumococcus infection, but if from streptococcus the prognosis was very bad.

Dr. WALLACE of Syracuse said that an *x*-ray was important to keep track of the fluid in the chest and if fluid were present, early aspiration was indicated.

Dr. DAWBARN of New York said that in cases of thickened pleura where the patient's condition was desperate, an Estlander incision or decortication of the lung were not well borne. He used instead a third method which consisted in making long cuts from top to bottom of the pleura, binding down the lung. The lung could be seen expanding. To do this he advocated a long-handled knife, called a "pleura knife," in which a cross bar on the back of the blade controlled the depth of the cut, thus avoiding too deep a cut and the possibility of pulmonary hemorrhage. The knife could be made in three sizes with a malleable handle to be bent as the surgeon required.

**The Surgery of Acute Osteomyelitis.**—Dr. WILLIAM L. WALLACE of Syracuse said that osteomyelitis had been described and treated for many years. Before bacteria were recognized the cause was supposed to be trauma. Pyemia was early recognized. The treatment was procrastination, in the hope that part of the limb might be saved. Later some bold surgeons amputated, and, as the medullary cavity was infected, death resultcd. Next they amputated at the joint above. This also usually meant death. Later discoveries showed that the staphylococcus was the cause of osteomyelitis. Osteomyelitis was a secondary pyemic infection of bone, starting in the epiphyseal cartilage, generally from trauma. The damage was rapid and extensive necrosis with severe symptoms needing immediate, rapid, surgical care. It came at a very definite time in the course of the primary infection. The source was always a pus focus in some other part of the body. The cause was bacteriemia, which was often so mild as to be overlooked. It was an infection of early life, most frequent between 8 and 17 years. The child had a throat for scarlet fever. The boy had bones for osteomyelitis. Occasionally it was caused by streptococcus or pneumococcus. The lesions in chronic cases depended more upon the location of the abscess than upon bacteriemia. The symptoms were chills, headache, prostration. Acute osteomyelitis was often called rheumatism. In many cases operation would avoid bone destruction. Tissue should be opened down to the bone two inches above and below the lesion. In many cases this disease was due to infected ears, throats, teeth, etc., perhaps to inhalation of germ laden dust in schools. Perhaps in the future germs would be filtered from the air as typhoid germs had been filtered from drinking water and much disease thus prevented.

Dr. DAWBARN said that much trouble came from lack of thoroughness on the part of the surgeon. Infected bone marrow should be scooped. No bone had ever died for lack of marrow. The cavity should be cleaned and filled.

Dr. LILIENTHAL said that the *x*-ray would not help you in diagnosing osteomyelitis. Nothing could be seen of the site of the inflammation. In a first operation tension should be relieved. In so-called typhoid osteomyelitis it was better to wait, the condition often cleared up.

Dr. LEE of New York, said he had had personal experience of osteomyelitis as a boy, for ten years. He was first treated for "growing pains" and then for rheumatism. Surgeons all over the country tried their hand on him. He had many pieces of bone removed. With modern methods he would not have been a sufferer for so long.

**The Surgery of Acute Suppurative Spreading Infections of the Fingers and Hand.**—Dr. WILLIAM B. BRINSMADE of Brooklyn read this paper. He said that very few persons escaped some infection of the hand, and that certain definite treatment gave the best results. A man worn out with hard labor took infection badly; so did a hard drinker. The worst cases were with tired surgeons, who ran much risk of infection, from contaminated wounds. Infections might cause lymphangitis, tenosynovitis or abscess of the fascial spaces. Treatment was distinct for the three types of processes. Judgment and skill were required here as well as for cancer of the breast, but too often were not given. The causative bacteria were streptococci or staphylococci. The treatment was to put the patient to bed; give saline cathartic; cover lesion with iodine; take pulse and temperature frequently and use large dressings of boric acid. In tenosynovitis drain at once freely, or loss of the tendon would result. In infections of the fascia the spaces must be freely opened. In lymphangitis hot, moist dressings were indicated; the limb must be raised and incisions made under ether. Patient must be treated by rectal saline injections. In cases of infections in a hospital staff, physicians and nurses should be trained to let an infected wound bleed freely and to cover it with tincture of iodine.

Dr. JOHN HARTWELL of New York said that this important paper should have been heard by the Medical Section. Cases in the first stages went to the physician. The surgeon saw them later. It was very hard to make a house staff realize the importance of such cases. The men could not be made to report them. A safeguard for the surgeon was the use of rubber gloves.

which at any rate wiped off some of the poison. A good indication of favorable progress of the patient in these cases was whether he slept well or not. If restless he was not going to do well.

Dr. LEE of New York said he had written a paper on the subject twelve years before, but apparently little attention had been paid to it.

Dr. DAWBARN of New York said that operators could avoid infection by vigorous stripping of the wound. The wound might be deepened with a scalpel to increase outflow of blood.

**The Status of Vaccine Therapy in Acute Suppurative Infections.**—Dr. CHARLES NORRIS of New York presented this subject. He said that some observers had found that immune serum increased the phagocytic power of the blood. This was the basis of Wright's work in immunization against bacterial infection. According to Wright, vaccine injection developed specific opsonins which increased phagocytosis. Many workers, however, had been unable to follow Wright's methods, although some used the opsonic index as a guide to time and amount of vaccine to be given. According to Pearce the enthusiastic advocates of vaccine applied it to every form of bacterial infection. There were three types—production of immunity through development of a mild form of disease; production of immunity after infection; and curative vaccination. Pearce claimed that the latter was doubtful of result. Dr. Norris said that many reports of successful vaccine treatment were based upon faulty reasoning. Any line of treatment in severe infection was given the credit of effecting a cure. Quoting Theobald Smith, he said that an important principle in the process of immunity was that each infection must be studied by itself. The principles of immunity to one infection could not be applied to another. For instance, diphtheria bacilli and tetanus bacilli both produced soluble toxins. One was curative and the other at best prophylactic. Immunology showed that many cooperating and interacting forces were concerned, as antitoxins, bacteriolysins, opsonins, agglutinins and phagocytosis. In no two diseases was the reaction the same. The scientific basis of vaccine therapy could be obtained only through the careful studies of clinical research in the experimental laboratory. Dr. Norris said it was a question whether it was logical to apply the vaccine treatment to such localized lesions such as were caused by staphylococcus. We might ask why introduce more poison in an already overwhelmed organism. The absurdity of giving any doses in acute suppurative conditions was apparent. The great danger of vaccine lay in its effect on local sepsis. The laboratory influence was not altogether wholesome. The surgeon left the risk to the laboratory and it was too easy to put the blame on "the other fellow." The value of vaccine in chronic gonococcus infections and in streptococcus arthritis had been justified by experience. In erysipelas it was useless. The disease was uninfluenced by vaccines. An important question was, was it worth while to raise immunity experimentally and how much energy did it cost the body. Vaccines applied during disease were rarely if ever life saving. They might hurry recovery, however, by bringing into play unused reserves. Future efforts should be directed toward active immunization combined with antiserum.

Dr. L. HOTCHKISS of New York said that Dr. Norris had taken a judicial and sensible view. The indiscriminate use of vaccines was to be deplored.

Dr. DAWBARN of New York said that the streptococcus of erysipelas and that of pus were entirely different, though they looked alike. Results might be obtained by using a strain of streptococcus from an erysipelas patient.

Dr. H. KELLER of New York said that he had had experience with autogenous vaccines in gonococcus infection. Unless the local condition was treated the results were of no use.

**A Consideration of Methods and Results in the Surgery of Rectal Carcinoma.**—Dr. CHARLES H. PECK of New York presented this paper. He said that rectal carcinoma was the *bête noir* of surgeons. The results were far from satisfactory. Symptoms were often passed over as hemorrhoids. If the perirectal tissues were invaded recurrence was almost sure. With secondary involvement in the liver, operation was out of the question. Involvement of the vaginal wall and uterus could often be treated by excision. Over 60 per cent. of cases were unsuitable for operation. Methods and results should be considered and whether there was any hope of reasonably comfortable existence. A fixation of growth contraindicated operation. The abdominal-perineal operation was the ideal anatomical operation. It could be accomplished in one or two stages. The mortality, however, was high. Miles cited 17 deaths of 42 cases; Mayo 5 of 14 cases; of his own cases 2 of 3 died. A preliminary laparotomy would discover metastases and a week or two later the excision of the rectum could be done with removal of anal segment. The two stage operation protected from contamination of the wound. In low operations a posterior incision could be made with preservation of the anal segment. The operation was safer but many died of recurrence. The two stage operation promised to be more popular in the future.

Dr. J. M. LYNCH of New York agreed with Dr. Peck that the combined operation in one or two stages was the preferred one. The greatest shock seemed to be handling the peritoneum round the bladder. The cause of this was unknown. Pressure and handling of the bowel should be avoided. The perineal operation gave least mortality, but recurrence was very great. Mortality would be reduced when better technic was used, with less handling of the gut.

Dr. JOHN HARTWELL said that surgeons tended to go too close to growth above and below in the effort to spare the anus. An artificial anus gave comparatively little trouble.

Dr. S. G. GANT of New York said the surgeon thought too much about the preservation of the anal segment, rather than the life of the patient. Patients would rather have their lives than a good sphincter. The anus with nerves destroyed was of no use and should not be considered.

---

## SECTION ON MEDICINE.

*Tuesday, April 28—First Day.*

DR. CHARLES STOVER OF AMSTERDAM IN THE CHAIR.

**The Pleural Lymph Flow; Causes of Its Increase and Decrease.**—Dr. ALBERT H. GARVIN of Raybrook read this paper and said that the accumulation of fluid within the pleural space was of interest to the clinician in a pathological sense only, as an occurrence and complication in the course of an underlying major illness, or a collection of fluid caused by mechanical obstruction or occurring apparently as an independent local infective manifestation, the portal of the infection not being in evidence at the time. Varying modifications to the standard therapy of pleurisy with effusion arose periodically to be added to the time-honored effective procedures. These modifications ran their course, added but little to the knowledge of the underlying physiology, were then dropped, to be again revived and modified and perhaps perfected. Artificial pneumothorax had gone through such a cycle, and was now laboring under the probable handicap of an insufficient knowledge of the actual physiology involved. The accumulation of fluid within the pleural cavity meant that the secretion of fluid into the pleural cavity was increased or that the elimination was diminished; and further that the increase and the outflow might both be relatively increased above or decreased below the normal rate, or that the outflow might be stopped for all practical purposes for the time being. It was relatively simple to give a correct guess as to which of these factors predominated in a clinical case. Dr. Garvin's review had the purpose of presenting the direction of the pleural lymph flow and of emphasizing some of the factors that varied it as an explanation to this physiological law. The mere approximation of the pulmonic pleura to the parietal was a very important factor in absorption. Numerous experiments had been made to show that absorption was not dependent solely upon mere physical phenomena, such as osmosis and diffusion which played a minor part. Hamburger, Heidenhain, His and others had expressed the opinion that selective cellular activity or some factor other than simple physics entered into the explanation of absorption. In the introduction of air to the extent of half the volume of the pleura, the parietal and visceral pleura remained in contact to an extent greater than half their areas. With the introduction of the same volume of fluid (normal serum) the pleural separation was much greater. What he gave fitted into the previous experimental evidence supporting the fact that the greatest secretion was from the pulmonic area, and the greatest absorption was from the pleural area. The chief present interest in physiology of the pleura ex-

isted in the application of lung collapse or compression in the treatment of pulmonary tuberculosis. Here the so frequent pleuritic inflammatory involvement complicated the clinical picture, and so could interfere frequently with the normal physiology, but in cases where it did not, this factor should be considered. The size of the compression, the extent of the separation of the two pleural surfaces beyond the safe limit might in itself throw out of balance the mechanical factors that regulated and balanced serum flow.

**Clinical Irregularities of the Heart Beat.**—Dr. ALEXANDER LAMBERT of New York presented for discussion the consideration of irregularities of the cardiac rhythm and endeavored to see if the knowledge they possessed of the myocardial degenerations could be correlated with these irregularities. The most common form of the cardiac irregularities was that produced by the so-called auricular fibrillation. In a personal series of 125 hearts showing various forms of cardiac disease in Bellevue Hospital, sphygmographic tracings showed that 46 per cent. gave evidence of some form of irregular heart rhythm. Of these irregularities, 43 per cent. were auricular fibrillation; 26 per cent. showed some form of heart block, either partial or complete; 12 per cent. showed extrasystoles, and 19 per cent. showed various forms of irregularities, such as sinus arrhythmia, tachycardia, and pulsus alternans. To understand these irregularities and their action they must remember the physiological action of the heart and the sequence of its contraction in the normal rhythm. It was of no consequence to them what theory should prove to be the truth provided that they remembered the fact that the contracting impulse started and went in a smooth, uninterrupted wave from a definite position in the upper portion of the sino-auricular junction, passing down from auricle to ventricle, and spread from base to apex of the heart. With this contracting wave then passing definitely from one point to another, it was possible to conceive that pathological lesions injuring or destroying either the muscles or the nerves lying in these tracts could produce irregularity of contraction, irregular forms of cardiac beats and cardiac rhythm. Dr. Lambert then considered each individual form of cardiac irregularity, and asked what the various forms of myocarditis were and how they affected the muscle of the heart. The mildest form of myocardial degeneration was acute albuminous myocarditis which followed all forms of infections and was usually the beginning degeneration in any one of them. The two main diseases which caused destructive lesions in the heart were rheumatism and syphilis. After giving this conception of myocarditis, he asked if they could correlate it with the clinical irregularities of the heart beat. It was evident, therefore, considering the conception that had been given of myocardial degenerations and the occurrence of these degenerations in relation to the various clinical irregularities, that these irregularities were expressions of myocardial degeneration. They were not the expression of normally functionating muscles. It was also evident that at present they could not say that a given irregularity was due to a given definite form of myocardial change. The sinus arrhythmia occurring in the milder forms of myocardial changes was due to the intoxications in the mild forms in which recovery speedily occurred. The severe infections produced the intense acute degenerations which might occur evenly over the heart muscle or might be more intense in one area than in the others, thus producing the same localized intensity of injury that was produced by the chronic forms of myocardial degeneration. These clinical irregularities usually were the expression of the patchy fibroid areas resulting from the morbid processes of rheumatism, syphilis, and arteriosclerosis. They were, therefore, thrown back for their accurate diagnosis on the knowledge of what had gone before, on their knowledge of the diseases from which the individual had suffered. But they were forced to realize that these general diseases of rheumatism, syphilis, sepsis, and the like brought about a change in the heart muscle as they brought about changes in the body, and they must therefore be willing to accept the fact that if these diseases were present, and there were evidences of disturbed cardiac rhythm, the degenerative changes found post-mortem were existing ante-mortem before the pathologist saw them, and that clinically they existed when the heart showed the clinical evidences of this disordered mechanism. The inability, therefore, to diagnosticate myocardial changes was the inability to draw logical deductions from cardiac pain, dyspnea on exertion, and clinical irregularities.

**Pulsus Alternans.**—Dr. HERMON C. GORDINIER of Troy presented this paper. After a careful survey of many observations made by Traube, Sansom, Hering, Volhard, Hoffman, Mackenzie, Windle, Lewis, and others, he said that one was led to the conclusion that both clinical and experimental alternation was the result of varying degrees of impairment from exhaustion of that most important function of the myocardium, contractility, which might be due to temporary exhaustion from the overwork of great rapidity of action, or to permanent exhaustion and early cardiac failure, the result of grave pathological changes in the myocardium. The following were his conclusions: (1) Pulsus alternans, while not common, was certainly not very rare. He agreed with Mackenzie and Windle in giving it the third place among pulse irregularities—extrasystoles being placed first, and the persistent irregularity of auricular fibrillation the second. (2) Clinical alternation was frequently overlooked because it could not be recognized without the graphic registration of the pulse. (3) Its presence was positive evidence of defects of the function of contractility, this in turn being due to temporary or permanent myocardial changes. (4) From a prognostic standpoint, the presence of pulsus alternans, save the temporary form, due to great rapidity of rate, was grave, as it indicated extensive myocardial degeneration—most patients dying from cardiac insufficiency within three years of its onset. (5) Extra-systoles, invariably followed by alternation, also indicated exhaustion of contractility and carried with it a grave prognosis. (6) Persistent false bradycardia, due to feeble systoles, where the deficit between the apex beat and the pulse rate was but little altered by the exhibition of cardiac tonics, such as digitalis or strophanthus, also indicated grave defects of contractility, with extensive myocardial degeneration and unfavorable prognosis.

**The Drop Heart (Heart of Congenital Asthenia); the Hitherto Unrecognized Importance of Its Chronic Dilatations.**—Dr. CHARLES LYMAN GREENE of St. Paul, Minn., read this paper which he illustrated with lantern slides. He said that when insufficient, dilated, and a source of troublesome symptoms, the drop heart was almost invariably overlooked, though readily recognized when undilated and innocuous. It represented ptosis and atony of a hollow muscular viscus, manifestly extraordinarily liable to chronic overstrain and dilatation by reason of enforced constant activity and the imperative and widely varying demands made upon an atonic musculature and subnormal reserve. Despite these facts and despite the knowledge of its known tendency to acute enlargement under severe strain, hitherto its chronic dilatation had been wholly disregarded. The typical pendulous heart, when free from dilatation, was abnormally small, characteristically low and medium in position and peculiarly attenuated and vertical in outline. The domes of the diaphragm itself, unless lifted by intraabdominal pressure, might lie two interspaces below the normal levels, and in certain extreme cases might appear as if actually suspended from the great vessels and cervical fascia. The author summarized as follows: (1) Contrary to current belief both drop heart and its chronic dilatation were extremely common, and indeed should logically be anticipated in view of their present knowledge of the musculature of such hearts. (2) They had been hitherto overlooked, because of the natural tendency to accept as the normal a standard of measurements far in excess of the drop heart normal and a failure to apply the simplest of therapeutic tests. (3) Another cause of general oversight had been the absence of serious symptoms of incompensation, apart from dilatation, and the decided dominance of subjective manifestations. (4) In the absence of proper diagnostic tests, the subjective manifestations were in great measure indistinguishable from those of the so-called neurasthenia and nervous dyspepsia, both of which in most instances were directly associated with chronic congenital asthenia and its visceroptosis. (5) The type of individual case carrying congenital asthenia was easily recognizable and in itself at once suggested the presence of the asthenic for drop heart. (6) Diagnosis must be based upon the basic stigmata, the decided changes wrought by rest, the administration of full therapeutic doses of some standard digitalis preparation, and results of repeated careful percussion with modern technique and a full record of symptoms. (7) In view of the authoritative statement from Cloetta Fraenkel Hansen and others, affirming that therapeutic doses of digitalis failed to affect the normal undilated heart in outline or action the use of this drug as a test measure was not only justified but required, not

only for the recognition of masked dilations of heart drop, but for the silent enlargements of degenerative types as well. (8) The congenitally asthenic heart might initiate symptoms of the most varied character or intensify those originating in other visceroptotic organs or finding expression in the nervous system as a whole. (9) It was therefore a definite and important contributive factor in those morbid states underlying the greater part of our chronic invalidism. (10) A few full doses of digipuratum, rest modified or absolute, and the comparison of carefully determined outlines obtained by modern methods were simple and efficacious means of making a primary diagnosis. (11) Not all drop hearts were symptom-producing, nor did the stigmata of congenital asthenia in general mean necessarily that their possessors must be chronic invalids. (12) Nevertheless, the writer believed that dilated drop hearts, while often borne by well nourished individuals without active symptoms might play a large part in the actual initiation of neurasthenic and dyspeptic symptoms in victims of malnutrition or infections.

**Percussion versus the Röntgen Ray in the Examination of the Heart.**—Dr. GEORGE CHEEVER SHATTUCK of Boston, Mass., read this paper. He said that since Auenbrugger advocated percussion as a means of examining the chest, many different methods and innumerable modifications of technique had been suggested until it would seem that every conceivable procedure had been tried, and yet methods continued to increase. It was many years since a celebrated German professor said that he pitied anyone who had read all that had been written on percussion. Since the invention of radiographic methods of determining cardiac outlines they had been in possession of a new and valuable means of checking and testing the various methods of percussion. Results of this kind in Germany had been important. For example, the combined use of percussion of the phonendoscope in outlining the heart had been shown to be fallacious, and consequently an entire group of percussion methods had been dropped. Two roentgenological methods were of special value in controlling percussion, namely, orthodiagraphy and teleroentgenography. Those who were experienced with the technique in the employment of the former could obtain important information about the heart and neighboring structures, and could make outlines of the sagittal projection of the heart shadow with a high degree of accuracy. The disadvantages of orthodiagraphy were that high skill and patience were required to get accurate pictures, that the method was open to a variety of subjective errors, and that only a small part of the heart shadow could be seen at the moment when a mark was actually being made. To minimize subjectively, Köhler advocated that skiagraphs of the heart be taken from a distance sufficiently great to allow the projection on the plate of a heart shadow practically free from magnification by divergence of rays. This method was called teleroentgenography. Orthodiagraphy and teleroentgenography both were valuable. Three types of percussion had been shown by large numbers of observations (which were checked by roentgenography) to be suitable for obtaining cardiac outlines comparable directly with those of the orthodiagraph; namely, Moritz modification of light, finger percussion, Goldscheider's "threshold percussion" (called by some "orthopercussion"), and Ebstein's "touch percussion." In conclusion Dr. Shattuck said that both orthodiagraphy and teleroentgenography afforded useful means of checking percussion and of bettering its results, but it was essential that they be skilfully handled. Silhouette percussion promised to show smaller amounts of cardiac enlargement than could be detected by ordinary percussion, but the successful application of these methods was difficult. Silhouette percussion should not displace ordinary percussion, but was best used in conjunction with it. Ordinary percussion should be referred to landmarks, but silhouette percussion should be compared with tables of measurement such as were used for the orthodiagram. Measurements implied accuracy, but landmarks did not. When measurements suitable for comparison with normal standards had not been obtained by percussion they should trust to landmarks. Therefore, when measurements suitable for comparison with normal figures had not been obtained it was better to judge by landmarks than to run the risk of being deceived by apparent accuracy which did not exist.

Dr. NEUHOF of New York said that the standpoint he took in regard to arrhythmia differed from that of Dr. Lambert, although he agreed with what he said in general. He had seen one case of auricular fibrillation in which there were no evidences of endocardial, myocardial, or cardiovascular disease. He had seen a number of cases of extrasystole occurring in young people and without any evidences whatever of myocardial, endocardial, or cardiovascular changes. There must be cases which depend upon nonorganic changes, or reflex in character. The study of arrhythmia was very interesting and important. After all it must be stated that arrhythmia arose from some neurogenetic source. It was detrimental to keep such patients in bed. Apropos of sinus arrhythmia it had been his experience to meet with at least two instances which followed severe hemorrhage. He did not think they could rely upon percussion methods, for even the most careful diagnostician would be apt to go astray.

Dr. ROBERT H. HALSEY of New York said that there were certain sounds which should be kept carefully in mind and which would help them in making a probable diagnosis of a great many of those irregularities of the heart. One of the most frequent irregularities was fibrillation, so-called, and a diagnosis could be made without these exact instruments, but there were one or two exceptions even for an exact man. Without these instruments of precision it was often difficult to make a diagnosis such as of flutters, auricular tachycardias, etc. The greatest value in the use of these instruments was that they turned one's attention from the value of the murmurs and made the observer pay more attention to the heart muscle and its functional ability. That was of the greatest value in heart work. With regard to the electrocardiograph it was a very expensive instrument, but did by no means tell them all about the heart. It was specially valuable in summing up what they had found by means of other instruments. He closed by stating that men should be more careful in weighing all the signs at their disposal in looking over cardiac conditions.

Dr. LEO H. NEUMAN of Albany believed that the present meeting was of great value in showing the trend of exact methods in connection with cardiac conditions. The point that Dr. Lambert brought out was a good one—the question of muscular sufficiency of the heart. They had thought about endocarditis, pericarditis, and myocarditis, and they should bear in mind that when there was present an acute affection of the endocardium the affection did not limit itself to the endocardium. The crux of the whole question was in regard to function: was the heart capable of doing the work placed upon it? If not, then there appeared definite symptoms. With regard to the arrhythmias, of course some of them were of great importance from a prognostic standpoint and some were not. As to drop heart the location of the heart itself made it difficult to map out the lower borders. As a matter of fact the low position changed the location of the apex; this was specially so when the patient stood. Buck's instrument was of great aid in locating the apex.

Dr. DE LANCEY ROCHESTER of Buffalo said that when they came to any discussion of the heart from a clinical standpoint they always had before them the condition of the patient, the prognosis and treatment and they wished to use all methods possible. Instruments of precision were very valuable and interesting and would continue to be more and more valuable as time went on. Most of those who practised medicine did not have at hand these instruments and must depend upon the ordinary methods of making physical examinations. In all cases where there was any disturbance in rhythm of the heart they had disturbances of the myocardium which were at the bottom of the condition. As long as forty years ago it was taught by clinicians that the myocardium was the most seriously diseased part of the heart even when there were evidences of endocarditis and pericarditis. In order to get their patients well they must endeavor more to strengthen the heart muscle. In determining the size of the heart he did not think they should limit themselves to percussion, but upon inspection, palpation, auscultation and percussion with the patient in different positions. Then they would get a more exact idea of the edges of the heart.

Dr. MARK I. KNAPP asked what was the normal position of the heart, for they all knew that the position of the heart varied in different individuals, and this was a question that confronted the general practitioner. He had found the normal position of the heart by mapping out by a straight line drawn from the left nipple to the thyroid cartilage. This would map out the absolute

dullness of the heart, but not the relative dullness, which lay from one-half to three-quarters of an inch outside this line.

Dr. Louis Faugeres Bishop believed that the name myocarditis should be discarded from medicine because it was the dumping ground of obscurities. When Mackenzie introduced the term cardiosclerosis he did much for them. He believed that it was to the pathological physiology of the cells of the heart that they should direct their attention. He believed that what they had in these cases was a reaction of the individual cells against some protein to which the cells were sensitive. There was a disturbance of pathological physiology and not of pathological anatomy.

*Wednesday, April 29—Second Day.*

**A Plea for the Diabetic.**—Dr. Douglas C. Moriarta of Saratoga Springs read this paper in which he said that he felt very strongly that he was justified in the position he had taken, that the attention given the diabetic patient by the family physician was often of a very low standard, and that it was not the errors of commission that he would emphasize, but those of omission. Every case of diabetes should be considered of moment by the physician, and every patient should be plainly informed of his condition. The probable satisfactory results of a correct manner of living should be set forth; and, on the other hand, the disaster sure to follow indifference to such advice. The physician must control his patients; if he had their confidence he would be sure of their cooperation. In his early practice carbohydrates were withdrawn from the list until the urine was sugar-free; no importance was attached to the rapidity with which they were withdrawn. Acidosis was not associated as a result of so doing. But, in recent years, much study and experiment on the part of the physiological chemist had given them a mass of clinical information, from which the following points stood out: (1) Acidosis was always a menace to the life of the diabetic, and a factor to be considered in the treatment; (2) ketone bodies, when found in the urine, should always suggest the possibility of supervening acidosis. These bodies appeared when the carbohydrates were diminished to control the secretion of supgar, and were the results of an imperfect oxidation of the fatty acids. (3) The secretion of these bodies in the urine was of more significance, temporarily at least, than that of sugar. (4) It was therefore, apparent that the intake of carbohydrates should never be abruptly withdrawn, and only markedly so when the patient was under personal observation. (5) Various carbohydrates and the alkalies were the most potent prophylactic remedies, as well as the only ones, with which to combat acidosis when it appeared. (6) Tolerance for carbohydrates varied in different individuals and might vary in the same individual at different times. (7) The tolerance in every case, as well as the intake, should be constantly in mind, for occasionally more sugar was secreted than should result from the carbohydrates taken in; and further, with care and attention the tolerance was often increased. (8) A diet low in caloric units, when not contraindicated, was often helpful in relieving obstinate symptoms. (9) Exercise, massage, and a limited amount of alcohol, assisted the oxidization of carbohydrates except in cases which were severe in which exercise increased ketone production. Dr. Moriarta's routine procedure in a case of diabetes was as follows: After the history and diagnosis had been made, he directed the patient to follow his usual diet for forty-eight hours. The urine was collected for examination during the last half of this period. For the following forty-eight hours he gave the patient a definite diet, carefully directing the quantity. The urine was collected during the last half of this period. Each specimen was examined for sugar, acetone, and diacetic acid. From this data, the case was temporarily classified according to the percentage of sugar present, and whether or not this was accompanied by the ketone bodies. The information acquired, when the patient was living on an unmodified diet, as a standard comparison, was useful as the case proceeded. The case might be considered mild if sugar only was present, and serious if, in addition to the sugar, the ketone bodies were found. The urinary findings suggested the immediate procedure. He told the patient very plainly the seriousness of the condition and sought to impress upon him the necessity of following implicitly the directions given (all of which were carefully written down for him) and he tried to enlist the cooperation of his patient. He told him there was no other way; that he had no option if he wished to live comfortably while he did live. He also told him that if he was willing to do as directed and help him, he could probably live many years, though his condition might become anxious at times. For the period of one month the urine was examined daily and he had the patient keep a record of the amount of food taken. The quantity of food was generally estimated, though in some cases he resorted to the scales to determine the quantity which was allowed. He sought to keep the caloric value of the food low when the carbohydrate tolerance was small, unless contraindicated, or in young or growing persons. While all this was simple to describe he assured his hearers that the management of these cases was always a source of anxiety. After a month of such observation he said he had a good clinical idea of the initial peculiarities and carbohydrate tolerance. Some cases yielded almost at once on a restricted diet; others did not and required a great deal of thought. He said he had little or no use for drugs, unless one so characterized the Saratoga mineral waters. In addition to a morning walk to one of the springs before breakfast, where a quantity of the mineral water was taken, he had his patients exercise by further walking, directing a certain distance for each day. A mineral bath was also directed daily at a temperature of 100° F. allowing the patient to remain in the tub for a period of ten minutes; this was followed by a hand rub and a rest. When this régime was followed he had yet to see the first case in which there had not been a general amelioration of the pruritus, thirst, polyuria, constipation, high blood pressure, and fatigue, all of which were distressing symptoms at the commencement of the treatment.

**Some Recent Thoughts on Diabetes and Metabolism.**—Dr. Waldron B. Vanderpoel of New York read this paper. He believed that to the painstaking and widespread labors of the laboratory workers should be attributed much of the medical progress of the present day. Through their efforts with the intelligent cooperation of clinicians, a firmer and more scientific basis had been established for general etiology, pathology, and therapeutics. The result of these labors were manifest in the modern conception of diabetes mellitus, but not in so brilliant a manner as in most other fields of medical research. Diabetes mellitus was classed by many as a symptom complex, and not as a distinct entity and this was because of the number of types with a different etiology for each. The phases and problems presented by this morbid condition were of more than ordinary difficulty of interpretation. The appearance of glucose in the urine was formerly considered diagnostic of diabetes in practically all cases. Later research had revealed that glucose was a not infrequent constituent of the urine. Some eminent observers, notably Pavy, Germain See, Moritz and others came to regard it as a physiological element of the urine. Conceptions of the morbid anatomy of diabetes were still in a transitional stage. As a result of experimental and clinical observations the following tentative propositions might be stated: (1) The liver was closely identified with the morbid process known as diabetes. (2) The nervous system was frequently structurally or functionally involved primarily, but it might only be made manifest by changes in the hepatic circulation. (3) The pancreas was undoubtedly concerned in the production or assimilation of glucose. This gland was supposed to supply a hormone or ferment which stimulated glucose conversion in the muscles. The ductless glands had an undeniable influence over carbohydrate metabolism. These glands were the adrenals, thyroids, parathyroid, pituitary, the island of Langerhans, or the pancreas. To a certain extent confirming the above classification it was usual to recognize clinically three types of the disease: (1) An hepatic type; (2) a nervous one, accompanying lesions of the nervous system; (3) a pancreatic form. It was well known that two opposing factors contributed to produce glycosuria, viz., excessive formation of sugar on the one hand, as against the failure of the muscular tissues to burn it up. The latter was considered as the characteristic feature of diabetes. In like manner glycolysis might prevail in diabetes. Diabetes was to be considered as one of those forms of glycosuria which continued after the elimination of all carbohydrates from the diet. A thorough understanding of the changes and processes was of vast importance in the study of diabetes. As a result of discarding the rigid non-carbohydrate diet, a number of

systems of "cure" had been brought forward, the oatmeal cure of von Noorden, rice cure of von Duhring, potato cure of Mosse, etc. The oatmeal cure had proved the most valuable but it should be modified by limiting to certain periods "carbohydrate days." Whole wheat and barley ground together had been advocated for bread in the diabetic diet.

Dr. N. B. Foster of New York, discussing the two papers relating to the treatment and the pathogenesis of diabetes mellitus, said he wished to transpose the order of presentation so that what he might have to say relating to the metabolism had a bearing upon the treatment. He believed that the last speaker was correct in implying that there was more than a single cause for diabetes. At least there was not a constant pathology. The only organ that was found involved with any degree of constancy was the pancreas; but even here there were exceptions. And it was a striking fact that with young individuals where the disease ran its most rapid and malignant course and where the term "pancreatic diabetes" was often used to designate the severity of the disease, just in these cases they occasionally found at autopsy no significant lesion in the pancreas, no hyaline degeneration of the islets, nor interstitial fibrosis. That the majority of all cases, young and old, did present pancreatic lesions was not disputed; the point was that *all* did not reveal a constant lesion. Their conception that the pancreas was concerned with diabetes was supported not so much from the findings at autopsy as from the experiments on dogs. Removal of the pancreas invariably led to fatal diabetes. Now if they could learn how this occurred they would doubtless learn something of the pathogenesis of the human disease. They knew only that the dog so operated upon could no longer burn sugar; he derived his energy from fat and protein. This was demonstrated by the respiratory quotient which was low. The same was true for severer cases of human diabetes; the quotient showed a fat-protein metabolism. The idea suggested by von Noorden that there was a primary over-production of sugar in the body lacked a vestige of evidence. The trouble was fundamentally that sugar could no longer be utilized. It could not be warehoused as glycogen when it was ingested and the tissues could not utilize it for energy. In what way the pancreas functioned to enable the tissues to use sugar they might only conjecture. An internal secretion was spoken of but the evidence supporting it was of a very dubious character. An hypothesis was permissible but they should not forget that it was purely an hypothesis. They should be content with the fact that with human diabetes there was in some degree a failure to utilize glucose. When this function was but slightly impaired, the disease was mild or early; when gravely impaired no sugar was burned in the body and death quickly followed. Now one new consideration entered at this point and that was that fats were burned normally only when some sugar was being burned also; or as it had been worded "fats are burned in the fire of carbohydrates." From this it followed that when the body consumed but little sugar, about 50 grams per day, the fats were not burned to carbondioxide and water, but only to the ketone stage, oxybutyric and diacetic acids. This was not peculiar to the diabetic; a healthy man might excrete 30 to 40 grams of ketone bodies per day if the diet were suitable for it. Consequently they were confronted therapeutically with this problem—to limit the carbohydrate ingest to the body's capacity, and to increase that capacity to ward off acidosis. Now the principle in treatment was that rest of a diseased function strengthened it and over-use weakened it. It followed that they were not completely successful in treating any case of diabetes so long as glycosuria persisted, simply because the function in question was being overtaxed and weakened. On the other hand they invited disaster if less starch was allowed than could be cared for because this almost surely resulted in acidosis. It was in the early stages of this disease that most could be accomplished and where he was afraid that the least effort was made. The danger of toxemia in younger persons and gangrene in older were not sufficiently appreciated until it was too late.

Dr. William H. Porter believed that the practitioner should make individual examinations, and until this was universally done he did not believe they would make the advancement they were entitled to. It was only when they made their own examinations that they would get at the true inwardness of metabolism. They could get the prognosis by an analysis of the urine. When glucose was found it meant that something was going on in the system, some disturbance in the alimentary canal, or some disturbance of the internal secretions, then an isomer of glucose was produced which gave an instantaneous reaction with Fehling's solution. Every glucose molecule was an oxidation protein product and did not come from fats, sugars, or starches. He thought the whole question of diet had been on a wrong basis.

Dr. Henry S. Stark believed that diabetes was certainly on the increase and that while it was prevalent he did not feel that it was the dangerous disorder today that it was years ago. They did not to-day see those gangrenous processes such as they used to. Why? He did not know. They must confess they were much in the dark as to the history of this disease and even in 1914 the pathology of diabetes had not been discovered. He firmly believed that instead of clothing their investigations with so many mathematical equations they should direct their time more to learning the pathology of the malady. He called attention to the recently formed Life Extension System which had for its object the encouragement of urinary and other examinations. Was diabetes ever cured? There had been cases of glycosuria where the sugar disappeared and never returned again; was that a cure? There evidently was some form in which the patient had diabetes and yet a very careful examination failed to reveal glucose.

Dr. William B. Hanbidge of Ogdensburg called attention to the difficulty of practically managing these cases because of the poverty of the patients in so many instances. In his experience the so-called diabetic foods were the enemies of the diabetic patients. Some diabetic flours had 60 to 80 per cent. of carbohydrates and these foods, too, guaranteed by the pure food law. Another difficulty encountered in treating these patients was that the average man and woman could not restrain from partaking of the sugars and starches.

Dr. Bond Stow of New York said that one must clearly differentiate between a glycosuria which might be but a mere symptom and true diabetes mellitus which represented an organic disease with profound metabolic changes. One of the main causes of glycosuria was an autointoxication from the intestinal tract. This alimentary glycosuria, if left uncorrected, eventually would end in true diabetes. It was in the correction of these cases of alimentary glycosuria that attention was called to the beneficial results from the employment of pure viable cultures of the *Bacillus bulgaricus* grown in a sugar free medium. For the past two years the speaker said he had been much interested in this line of treatment and the causation of unexpected brilliant successes in some cases and failure to succeed in others admitted of plausible explanation. In some cases even a high percentage of sugar in the urine had been reduced to zero in a surprisingly short space of time (two to three weeks); in others more stubborn by nature a longer time was required; in others no reduction whatsoever could be obtained. But in all cases there were improvement in the general health, increase in weight, and raising of the hemoglobin content. These results led to a grouping of cases presenting glucose in the urine clinically as follows: (A) Alimentary glycosuria: (1) Cases controlled simply by the moderate restriction of the carbohydrates and small daily doses of cultures of *B. bulgaricus* grown in a *sugar free medium.* (2) Cases controlled by a restriction of both carbohydrates and albuminates with large daily doses of *B. bulgaricus.* (B) True organic diabetes mellitus: (3) Cases uncontrolled by the complete withdrawal of carbohydrate and a considerable restriction of the albuminates irrespective of the use of *B. bulgaricus.* The ability of diabetics to catabolize sugars exhibited so wide a range that the above clinical grouping of cases afforded an excellent working basis. This lactic bacillary treatment of all cases of alimentary glycosuria when combined with proper dietetics had one decided advantage over the older lines of treatment in that it permitted of a more liberal carbohydrate diet. This Dr. Stow believed was a very essential point. The fundamental experiments of Rosenfeld and Hirschfeld definitely had determined that the complete exclusion of carbohydrates from the metabolism of man (not so in animals) was invariably followed by acetonuria. Excess of acetone and $\beta$-oxybuturic acid in the blood (as is well known) was the direct cause of diabetic coma and death. In all his cases he demanded complete elimination of sugars and sweets, but under the lactic bacillary treatment a lim-

ited amount of starchy foods, as potatoes, cereals (especially oatmeal), green vegetables, and fresh fruits, was found to be well tolerated and a benefit. In all cases short periods of rigid dietetic measures were exacted in the very beginning of treatment. After the sugar had disappeared entirely for some length of time the physician should begin experimenting with small quantities of the heavier starchy foods, especially potatoes and oatmeal. There was but one rational explanation of the successful treatment of glycosuria by lactic acid bacilli. The cases were due to some form of toxemia that directly interfered with the glycogenic function of the liver cells or indirectly through the nervous system diarranged the mechanism controlling the carbohydrate metabolism. This toxemia was accredited to some form of long standing autointoxication from the intestinal tract against which the *B. bulgaricus* had proven so effectual. If, however, damage done the pancreas by a long-standing autointoxication had reached the atrophic stage of the pancreatic cells and islands of Langerhans, neither *B. bulgaricus* nor any other line of treatment would reduce the existing diabetes. Cases of diabetes due to pressure irritation of Claude Bernard's diabetic center located at the apex of the calamus scriptorius in the floor of the fourth ventricle (which surgical interference alone might benefit) must be kept in mind as a possible organic cause in any specific case of glycosuria.

**Syringe Cannula Transfusion.**—Dr. EDWARD LINDEMAN of New York read this paper. He said he would confine himself to some of the principles involved in blood transfusion and would speak of some of its applications. When one considered the many facts about the blood, not generally recognized which were known, and the many facts yet to be learned, one could not help but realize its complexity. It was only by a thorough study of this complex tissue in the normal and pathological conditions that one might obtain a clear conception of the possibilities of blood therapy. Many pathological conditions produced changes in quantity and quality of the blood. Failure on the part of the blood to properly and adequately modify its quality to meet the demands required in the various conditions was responsible for the existence of disease, especially infection. Dr. Lindeman took up for consideration some of the conditions in which the blood transfusion therapy might be considered. In one case cited the diagnosis of rheumatic fever with endocarditis was made in a child who was emaciated, very ill, anemic, with petechiæ on the skin, and blood in the stools. The first transfusion was followed by chills and slight temperature. No chills and no rise of temperature followed the succeeding transfusions. Dr. Lindeman had had seven other cases of sepsis in which there was one death, a case of appendix abscess with spreading peritonitis and gangrene of the face.

**Election of Officers.**—*Chairman*, Dr. George Reese Satterlee of New York; *Secretary*, Dr. Nelson G. Russell of Buffalo.

*Thursday, April 30—Third Day.*

**Recent Contributions to the Diagnosis of Nervous Diseases.**—Dr. CHARLES L. DANA of New York read this paper. He said that the continued and intensive study of nervous symptoms which was going on throughout the world had not been without fruitful results. He referred to some contributions and chose for consideration such subjects as seemed to him interesting, and he did not try to present the matter in any complete and systematic way. He said he could hardly touch upon all the psychoneuroses, but here there was a sharp line of cleavage on the lines of psychoanalysis and the protean activities of the *libido*. The cult of psychoanalysis and of the subconscious opened to some new worlds for psychological exploration, full of cultural possibilities and orgiastic interest and delight. To others it opened up only an amazing shibboleth of libidinous suggestion, unproven assertions and futile if not dangerous therapeutics. Dr. Dana called attention to some diagnostic features connected with the peripheral nervous system.

Dr. L. PIERCE CLARK thought that it was possible that they were too hasty in drawing conclusions regarding psychoneuroses. A group of them who were interested in this particular field believed a great deal in the future of neurology as ordinarily considered from the standpoint of betterment of these patients, and the standpoint of cure was going to drift in this direction. In speaking of what had been attempted by the surgeon in the way of relieving some of these hysterical conditions Dr. Clark told of a woman who returned to him recently and showed results of five abdominal operations, as well as other operations, and he asked if it would not have been better if the neurologist had persuaded her to follow his advice and not have so much surgery done. Their progress in neurology was intense gratification to him as well as to many of his friends who had followed this line of work and knew what was being done.

Dr. J. RAMSAY HUNT said that Dr. Dana did not have the time to enter into a discussion of the cerebellum, and studies had recently shown that in the cerebellum there were centers which controlled or governed movements in different directions—that was, to the right, to the left, upward, and downward. Experiments had shown that cortical localization in the cerebellum was almost always in the adult in the Orlandic area in the cortex, so that he felt it was safe to state that they had more exact knowledge of cortical distributions in the cerebellum to-day, and this was a very interesting field of research at the present time. Dr. Hunt felt that one of the important advances made along neurological lines had been in the direction of a study of the cerebrospinal fluid. Neurological investigators and students had added materially to the advancements made in this field. The *Spirochæta pallida* had been found in the spinal fluid in tabes which the neurologists had regarded as a parasyphilitic disease. For many years had work been accomplished in the treatment of certain diseases by injections into the cerebrospinal fluid. They were now treating tabetics by the injection of salvarsanized serum.

**The Proper Relation of Laboratory Work to Neurological Diagnosis.**—Dr. B. SACHS of New York presented this paper. He said that the neurologist had sought to benefit by the advance made in every branch of medicine. They had followed with the keenest interest the great progress of the last decades in the study of cardiac and renal diseases. They had followed closely the advance in the recognition of diseases of the blood. He had tried to glean something from the domain of physiological chemistry. He had hoped to make metabolism mean something especially fruitful in the interpretation of functional nervous disease. He had, above all, looked to the biological laboratory for help in the diagnosis and treatment of many organic diseases of the central nervous system. Twenty years ago in equipping a neurological service at any hospital stress would be laid upon the electrical outfit and possibly upon the hydriatic apparatus. The neurological division of the present day needed these, but it needed still more a well equipped laboratory for the examination of the blood and of the cerebrospinal fluid, a laboratory for the preparation of salvarsan and sera for the treatment of central nervous disease; it also needed facilities of the laboratory for the inoculation of animals to prove the special character of various infectious diseases of the nervous system, many of which were still problematical. An active neurological service made a great demand upon the resources of the best equipped laboratory in any general hospital, and for some of the problems, such as the blood test in poliomyelitis, they were compelled to fall back upon the very special researches of the workers at the Rockefeller Institute and one or two other kindred institutions.

Dr. GRAEME M. HAMMOND said he was in accord with the sentiments expressed by Dr. Sachs. In regard to the diagnosis of nervous diseases the laboratory was not of great service, and what evidence came from it was mainly corroborative. If a man came to him with symptoms of locomotor ataxia he would never think of sending him to the laboratory. He knew that he had syphilis. Whether the laboratory findings were positive or negative made absolutely no difference. He knew the patient had syphilis or he would not have locomotor ataxia. He was not sure that he could depend upon the reports from the laboratory; a great deal depended upon the personal equation of the person making the test. He depended upon the clinical symptoms and not on the laboratory findings. To illustrate this he had a specimen which he wished examined. He divided it into two parts and sent these two parts to two different laboratories; one report came back negative while the other was positive. He also sent one half of a specimen with the other half to the same laboratory and under different names, and again one report was positive, the other negative, although it was the same specimen and was examined by the same man.

**What Facts of Diagnostic or Prognostic Value Can Be Determined from Test-Meal Examination of Patients with Gastric Symptoms.**—Dr. FRANK SMITHIES of Chicago, Ill., presented this paper in which he re-

ported on the findings of a clinical analysis of 7,041 consecutive cases by a uniform method. The work forming the basis of this report was personally performed at the Mayo Clinic at Augustana Hospital. A close association of clinical, laboratory, and operative observations were possible in all the cases. The ages of the patients ranged from fifteen to seventy-eight years. There were two males to each female. More than 32 per cent. of the patients were from farms or rural communities. The average length of time of the gastric disturbance was 6.4 years; the shortest time two weeks, and the longest period was more than forty years. The emptying power of the stomach had been tested by the physiological test meal of mixed food. Experience had taught them that a twelve hour time interval was of greater diagnostic worth than the four to six hour interval. The secretory factor was determined by the Ewald breakfast of second day bread. The time limit in ordinary cases was 50 minutes after administration. This time limit was shorter when the symptomatology indicated abnormally rapid emptying power of the stomach. The size and position of the stomach were ettimated by means of air inflation, with the patient recumbent. The boundaries of the stomach were determined by the auscultatory method, while the inflation was in progress. The average capacity of the stomach was 27 ounces in females and 33 in males, where dilatation did not exist. Where dilatation was present the average capacity in females was 41 ounces and 52 in males. The greatest gastric capacity we associated with nonmalignant pyloric stenosis. The macroscopic appearance of removed gastric contents, apart from evidences indicating gastric retention, was not infrequently of significance. Traumatic blood was noted in 6.4 per cent. of all cases. Its presence was quite as constant where simple spasm existed at the cardia as where ulceration was present. Its appearance upon lavage had no consistent relation to any form of gastric disease other than cancer. In cancer cases (98 per cent. being of the medullary type) traumatic blood on lavage was observed in more than one-half of 218 consecutive cases. Bile coloring in various shades of green or yellow were observed in 11 per cent. of the cases in the series. The green coloration from bile was noted quite constantly in cases of gastric atony, ptosis with relaxed plyorus, dilatation with or without ptosis, intermittent plyoric spasm, induration about the pylorus, and obstruction below the patella of Vater. Of the cancer cases it was interesting to observe that "coffee" colored extracts were noted in but 19 per cent. When such were observed the cases were inoperable. The color of gastric contents was quite as apt to be tan or brownish in partial stenosis with dilatation or atony from nonmalignant causes as from cancer. The odor was, however, a fairly reliable differentiating point between the two conditions. There were 314 cases of achilia gastria; in 96 per cent. of this group the dead white color of the gastric extract, associated with markedly absent chymification, was a characteristic finding. As to odor in nonretention cases the sharpness of the odor was usually a reliable gauge of the free hydrochloric acid index. In retention cases high or low free hydrochloric acid might be masked by the odor of fermentative or putrefactive processes. In 84 per cent. of the cancer group the odor due to volatile organic acids was almost pathognomonic. In 76 per cent. of the nonmalignant retention cases the peasty aroma was almost similarly characteristic. The average quantity of test meal removed in the entire series was 108 c.c.; the average quantity in the nonretention group was 76 c.c.; in the retention class 350 c.c. So-called hypersecretion was as frequently observed in pyloric spasm from appendix or gallbladder disease as from duodenal or gastric ulcer. Mucus was a sign of doubtful diagnostic worth. Chymification was an index of masticatory thoroughness, of the character of the food ingested, of the combining power of hydrochloric acid, of the presence of normal gastric ferments, and of variations in gastric peristalsis and emptying power. The last factor appeared to carry the greatest weight. Of the entire series 12 per cent. of the cases showed some grade of retarded gastric emptying power macroscopically; in 8 per cent. of the series this was a constant finding. In 87 per cent. of the group where gastric retention was a persistent manifestation, some degree of gastric dilatation was an associated complication. In two out of every three cases where this occurred there was clinical history of delayed vomiting. Some of the most marked instances of gastric dilatation proved to have almost perfect emptying power. Persistent demonstration of gastric retention was an indication for surgical intervention. In this series the causes of persistent gastric retention in the order of their frequency were gastric cancer, duodenal ulcer, gastric ulcer, cholecystitis with adhesions, gastric atony, tumor of the pancreas, tumor of the liver, hypernephroma, tuberculous peritonitis, and retroperitoneal sarcoma. The causes of intermittent gastric retention were pyloric spasm associated with appendicitis, or cholecystitis, gallstones, duodenitis, or gastritis in the presence of free hydrochloric acid and gastroptosis. In gastric cancer emptying power was retarded in more than 70 per cent. irrespective of the location of the growth. In surgical gastric ulcer in rather more than 50 per cent. of the instances some grade of retention was proved. Of the pyloric spasms associated with appendicitis, cholecystitis, gallstones, or duodenitis, in rather more than 3 per cent. of instances retention was demonstrated. The sign of differential worth on this group of cases was that of the variability of the exhibition of retention at different examinations. This sign was of special worth to the surgeon who contemplated gastroenterostomy. Unless definite obstruction existed at or near the pylorus the best operative results were only to be expected where artificial stricture was surgically produced. In the records of 482 cases of pyloric spasm with intermittent gastric retention, in which later the appendix had been removed, or where operations on the gall tract had been performed, in only twenty-one instances was any form of gastric stagnation subsequently demonstrated. The most common causes of increased rate of emptying of the stomach occurred in conjunction with achylia gastrica, vagus hypotonia, temporary or permanent atony without marked gastric dilatation, nonobstructing gastric cancer, colitis, and in numerous states in young adults. Much information that could in nowise be neglected was obtained from a determination of the gastric acidity. For the purpose of determining the degree of acidity he divided his series into three groups: (1) Intrinsic gastric disease; (2) where the lesions were chiefly extragastric, and (3) in epilepsy or neurasthenia of the young adult. The author then discussed the demonstration of occult or altered blood, the incidence and significance of organic and gastric extracts, the significance of the demonstration of specific ferments in gastric extracts, the value of the Wolf-Junghaus test for soluble albumin, the significance of the microscopic examination of gastric contents, and the diagnostic worth of the demonstration of microorganisms in the gastric contents. They had made 6,280 examinations by high power after the unfiltered contents had been stained by the agar technique. From their studies they had developed four microscopic pictures which seemed almost pathognomonic of certain disease conditions, but apart from these they could see nothing very significant. In closing these four pictures were described.

Dr. JACOB KAUFMANN of New York said that Dr. Smithies' masterly paper would help a great deal to change the present tendency of underrating the value of gastric analysis and of overestimating, on the other hand, the importance of radiology. When considered alone $x$-ray findings were liable to cause most painful errors in diagnosis. The findings of the $x$-ray examination, of gastric analysis, and of any other method of examination were of value only when taken in connection with the history of the case and all other clinical symptoms, and furthermore when the findings were rightly interpreted. He fully agreed with Dr. Smithies that it was easier and more reliable to base the diagnosis of intermittent pylorospasm—so important a factor in gastric ulcer—on findings resulting from the use of the stomach tube than on $x$-ray findings. He could not, however, endorse Dr. Smithies' attempt at differentiating the various types of hyperacidity on the basis of statistical figuring, because the individual factor played too great a rôle. His own examinations, numbering almost as many as Dr. Smithies, had taught him that the type of secretion in a given case was distinctly individual. He had records of a large series of cases, which on reexamination after intervals of years showed identically in every detail the same secretory condition as on the first examination. The positive finding of blood in the gastric contents should be recorded only when the blood was distinctly visible or recognizable as old blood; so-called "occult blood" should not be taken into account because the introduction of the tube might have caused the bleeding. In the case suspicious of cancer it had been his rule to first examine the feces for occult blood after a few days of appropriate dieting and then examine the

stomach contents. In gastric cancer one could not expect positive findings before the growth had developed. That applied equally to the older and to the more modern tests. The results of the tryptophen test were not reliable; they were often positive without and negative with cancer. When present lactic acid and bacterial fermentation were the only characteristic signs of gastric cancer. The test for lactic acid, however, must be strongly positive and unmistakable. When a moderately strong test was recorded linked with the findings of free hydrochloric acid it meant nothing. Too much stress had been laid on the Boas-Oppler bacillus; of much greater importance was the fact that gastric bacteria was enormously increased, and one usually found numerous types of long and short bacilli and cocci. He had never seen a case in which such pronounced bacterial fermentation was not associated with gastric cancer.

Dr. Fenton B. Turck said that this splendid presentation by Dr. Smithies showed that the motor power of the stomach was of paramount importance, and that atony from various causes played a most conspicuous rôle. Atony was now understood as a form of fatigue of the muscle wall of the hollow viscera. Gastric muscle fatigue might result from overwork due to stenosis produced by persistently overloading the stomach, often disabled by toxins. The two conditions differed materially from the standpoint of diagnosis and treatment. The one was a pathological condition to be treated by surgical means; the other was to be considered from a physiological standpoint, and to be corrected by physiological methods. No more difficult problem of differential diagnosis presented itself to the clinician than to distinguish between these two conditions. The retention of food in the stomach beyond the normal time had been too often regarded as due to some obstruction, usually pyloric. If one was justified in saying that a case was one of pyloric stenosis because of the presence in the gastric contents of food taken the day before then the speaker had seen hundreds of cases of pyloric obstruction permanently cured without surgical interference. The diagnosis of gastric insufficiency involved another factor as well; that was, whether the atony was really of gastric origin and not to be referred to the intestinal muscularis. An accurate knowledge of clinical conditions could not be obtained without careful consideration of the physiology of the gastric movements. The gastric muscle seemed to have an inherent power of rhythmical contraction independent of the central nervous system. The relation of the local and central nervous system to peristalsis was not understood, but other factors must come into play, and one of the most important of these was tension; this quickly stimulated gastric peristalsis. Gastric muscle fell in line with the laws of contraction and fatigue in general, and the experimental work on animals by overworking the stomach and producing dilatation corresponded in etiology and pathology with the clinical observations in atony and fatigue of the gastric muscles in the human being. This could be seen in many cases of rickets; it often followed typhoid fever, and was frequently found in tuberculosis. Even in the healthy individual overwork of the stomach would result in fatigue and dilatation and this would be permanent if the muscle could not recover its power to contract. The differential diagnosis between motor insufficiency due to obstruction and that due to fatigue of the gastric muscle was difficult. The two conditions presented similar history and symptoms, but physical examination would show some characteristic differences. In stenosis the muscle wall hypertrophied to compensate for the increased resistance of the pyloric outlet and would require greater tension than normal to distend it. On the other hand, in gastric myasthenia the muscle became less and less resistant to tension or it showed a greater degree of distension under the same pressure. This difference could readily be tested by artificial inflation of the stomach through a double tube. The energy with which the air was ejected from the stomach would give some idea of the tonicity of the muscle. This could be felt with the hand or cheek, or the ejected air could be passed through a bottle containing soapy water and the amount of force would be indicated by the soapy bubbles formed. It required practice to make this estimation with the hand. If nebulized oil was forced into the stomach, the rapidity with which it passed out would give some estimate of the elasticity of the muscle. It could also be diagnosed by exclusion, by giving the test meal as follows: After washing the patient's stomach at the usual eating time a test meal was given of rice, chopped meat, and toast mixed with a little bran. The time that it took for the meal to pass out of the stomach was carefully noted. The next day the stomach was exercised by inflating it with air through a double tube. This inflation was repeated several times until peristalsis was excited. Then another test meal like the first was given at the same hour of the day. The length of time that this meal remained in the stomach was compared with that of the first. If it was much shorter, then one could be certain that no stenosis was present and that the exercise of the stomach muscle with air had stimulated it to quicker work. Pneumatic gymnastics of the stomach would help to make diagnosis more certain and they were very much dependent upon such methods as their knowledge of the etiology and pathology remained so incomplete. The same method was of great value in examining the colon, and similar methods used in treatment had shown most beneficial results. The trend of modern research had been especially characterized by a growing recognition of the importance of the physiological methods of diagnosis and the need of such methods was conclusively demonstrated by the scholarly report of these 7,000 cases.

**The Determination of Surgical Conditions of the Stomach.**—Dr. Walter A. Bastedo and Dr. Leon T. Le Wald presented this communication, which was illustrated by lantern slides.

(*To be concluded.*)

## Philadelphia Neurological Society.

At a stated meeting held April 24 Dr. James Hendrie Lloyd reported "A Case with Bulbar Symptoms Associated with Bilateral Sixth-nerve Paralysis." The patient was a white man, about twenty-five years old, with a history possibly suggestive of pulmonary tuberculosis, who presented marked internal strabismus, difficulty in swallowing and in speech, with immobility of the tongue and paralysis of the right vocal band and of the velum palati, loss of smell and taste, without affection of sensibility or changes in the optic nerves or a Wassermann reaction. *X*-ray examination disclosed destructive changes in the posterior clinoid processes of the sphenoid bone. It was thought the condition might be one of multiple nuclear degeneration, or a poliomyelitis inferior and superior. Other possibilities suggested were a solitary tubercle of the pons and medulla oblongata and a tumor of the pituitary body.

Dr. Alfred Gordon presented "A Case of Amyotrophic Lateral Sclerosis, with Bulbar Onset." The patient was a woman, 27 years old, who gave a history of having had a right-sided hemiplegia with entire recovery at the age of 15 years old, and who without loss of consciousness or antecedent or attendant acute illness developed difficulty in speaking and in swallowing, soon associated with wasting and weakness in the left upper extremity, subsequently followed by weakness and wasting also in both lower extremities, with exaggeration of the reflexes, but without sensory changes and an absence of Wassermann reaction. The tongue was paralyzed and wasted, and the face was immobile, but with a persistent smile. While originlly the case was considered one of amyotrophic lateral sclerosis beginning with bulbar symptoms the subsequent course of development suggested a vascular lesion involving the upper cord and adjacent pons and medulla.

Wm. G. Spiller presented on behalf of Dr. J. W. McConnell a child with "Paralysis of the Lower Branch of the Right Fifth Nerve and of Both Sixth Nerves." The condition had been observed immediately after birth, it was not progressive, and it was supposed to be due to an aplasia of the nuclear centers involved. There was marked internal strabismus and loss of power in the muscles on the right side of the face.

Dr. D. J. McCarthy presented a communication entitled "Progressive Lenticular Degeneration," reporting four illustrative cases. The disorder is characterized by difficulty in speech and in swallowing, with a variable tremor and increased emotionalism, in conjunction with cirrhotic changes in the liver.

Dr. Wm. G. Spiller presented a communication entitled "Symmetrical Pain in the Heels from Exostosis of the Os Calcis." He reported the case of a man who complained of pain in the heels on walking and standing, without evidences of neuritis, but with a history of gout. *X*-ray examination showed an exostosis of

each os calcis, and for relief surgical procedures were recommended.

Dr. TH. WEISENBURG presented a communication entitled "The Character of Organic Convulsions, with the Description of a New Symptom." He pointed the greater reliability of studies of convulsive movements made with the aid of the cinematograph, as compared with ordinary clinical observation. He was able to determine in a number of cases of Jacksonian epilepsy that the movements are first tonic and subsequently clonic; also that the movements in the upper extremities are always flexor in character, while in the lower extremities they are extensor. He relates these differences to the withdrawal of the influence of the cortex from the cells in the anterior horns of the spinal cord, the cells more remote from the cortex, namely those for the lower extremities being affected differently than those nearer to the cortex, namely those for the upper extremities.

## Books Received.

*The* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

BEITRÄGE ZUR KLINIK DER INFEKTIONSKRANKHEITEN UND ZUR IMMUNITÄTSFORSCHUNG. Herausgegeben von Prof. Dr. L. BRAUER. Paper; price 6 Mks. Curt Kabitzsch, Würzburg.

THIRTY-SIXTH ANNUAL REPORT OF THE BOARD OF HEALTH OF THE STATE OF NEW JERSEY 1912, and Report of the Bureau of Vital Statistics. Cloth; 774 pages. Dispatch Printing Company, Union Hill, N. J.

COMMUNICABLE DISEASES. An Analysis of the Laws and Regulations for the Control Thereof in Force in the United States. By J. W. KERR and A. A. MOLL, A.B. Paper; 699 pages. The Government Printing Office, Washington.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles. By Leading Members of the Medical Profession Throughout the World. Cloth; price $2.00; illustrated; 300 pages. J. B. Lippincott Company, Philadelphia and London.

DE LA NÉPHROPEXIE (Procédé d'Albarran-Marion). Par le Dr. JULES LUZOIR. Price 8 francs. G. Steinheil, Paris, 1913.

## Miscellany.

**The Doctor's Bill.**—Sir John Collie points out that the intervals at which medical accounts should be rendered is always a perplexing problem to a young medical man. It would be well if the latter recognizes early in his career that the public has a very short memory. Evening and night visits, which are so wearing, are often forgotten by a patient long before the account goes in. Small wonder, then, that a man who was very grateful for much kindly assistance in the early weeks of January, should almost have forgotten the occasion, and perhaps raise his eyebrows when the doctor's little bill is presented on July 1. The custom, which prevails in the higher branches of both the legal and medical profession, of looking upon the fee as an honorarium and giving no credit is admirable, but in the physician's sphere of work, this in the vast majority of cases, except in the cases of the very poor, is a practical impossibility. Quarterly accounts have the advantage of automatically weeding out those who never intend to pay at all. The physician should depend upon it, if he is really doing good work, he need have no fear about the effect of asking for his fees. Some medical men willingly allow a large number of patients to run up small accounts, which they know cannot be paid, and indeed they never really expect it. This is not done from philanthropy, but from the mistaken idea that it enhances the value of one's practice. It is bad business. It certainly will increase the number of patients, it will increase the working expenses, it undoubtedly makes large inroads on one's leisure; but the gain, if any gain there be, is wholly disproportionate to the wearing labor expended. Frequently, when a patient is in receipt of a small but regular salary, the suggestion that payment be made by periodical instalments would be gladly accepted. Suppose that when a man in this position saves to pay his doctor's bill, an occasion arises which demands money, the probability is very great that the money laid aside to meet the doctor's bill will be appropriated. This is not right, of course, but with the money in hand very few individuals can resist the temptation; if the money has been paid over, the temptation can not arise, and the doctor is better off.—*British Medical Journal.*

**The Relation of Physician and Patient.**—R. C. Buist points out that the relation to the patient is the primary reason for the doctor's being, and the cardinal principle of the latter's duties is to furnish the best that the medical profession can supply for his needs. Not only must the best within the physician's own knowledge be brought forth, but the limits of this knowledge must be honestly recognized, and inside them must be found a knowledge of a way to the best that is available. This is true in whatever circumstances the patient comes into the doctor's hands. Be it parochial, insurance, hospital, or private patient, he is entitled to the best that the profession can do for him.—*British Medical Journal.*

**Illiteracy and Mortality.**—Statistics show a more or less close parallelism between these two, at any rate, in Italy. In Calabria, in which 78 per cent. of the population is illiterate, the mortality is 30 per thousand; in Sicily, with an illiteracy of 71 per cent., the mortality is 21; in Piedmont an illiteracy of 21 per cent. corresponds to a mortality of 20. —*Rivista Ospedaliera.*

### A CLINICAL STUDY OF TRAUMATIC NERVE PARALYSIS.

By ALEXANDER S. LEVERTY, M.D.,

NEW YORK.

INSTRUCTOR IN NEUROLOGY, PHYSICIAN TO THE NEUROLOGICAL CLINIC, CORNELL UNIVERSITY MEDICAL COLLEGE; ASSISTANT PHYSICIAN, ST. LUKE'S HOSPITAL, O.P.D.

[Introductory Note.—Clinical studies of injuries of nerves have been made from time to time. Although the subject is an old one, it seems justifiable to go over the subject matter again, because the new industrial conditions bring new factors in the etiology of the traumatic nerve conditions. In particular, the passage of workmen's compensation laws will make the study of the traumatic neurosis more vital and call for more specific and detailed knowledge regarding the conditions.—C. L. Dana.]

The following study is a report of 331 cases of traumatic nerve paralysis of the upper and lower extremities, occurring in adults, together with a report of 30 traumatic birth palsies, 10 facial nerve palsies, and 2 post-thoracic nerve palsies, that applied for treatment at the Cornell University Medical College, New York City, Department of Neurology.

The study includes the subjects of nativity, sex age, occupations, causes, occupation as a causative factor, distribution and nerves involved, with a detailed consideration of the individual nerves, length of time the paralysis existed, treatment, conclusions, and illustrated cases.

Nativity: Of 331 cases, 192 were foreign born, 139 were born in United States.

Sex: 289 were males, 42 were females.

Age: There was a gradual increase until the fourth decade, and then a gradual decrease until the seventh decade. Of 331 cases, 119 occurred between the ages of thirty and forty.

Occupation: There were 79 different occupations recorded for the males and 14 for the females. Of 331 cases, 54 were laborers, 27 drivers of vehicles, and 18 were houseworkers. In the remaining occupations the number of cases varied from 1 to 6.

Causes: Of 331 cases, 154, or 46½ per cent., were caused by pressure during sleep induced by alcohol; 21, or 6 per cent., were caused by pressure during sleep not induced by alcohol; 22, or 6 per cent., were caused by pressure induced by crutches, bandages, carrying heavy bundles, and handling various tools; 134, or 40 per cent., were caused by violence, contusions, lacerated, incised, and punctured wounds, crushing, fractures, and dislocations. In 73 cases, of 331 particular occupations had a distinctive bearing as a causative factor.

The duration of the paralysis varied from three months to one and a half years.

Distribution: Nerves Involved—Of 331 cases, 315 occurred in the upper extremities, 16 occurred in the lower extremities.

*Distribution of 315 Cases in the Upper Extremities.*

| | Number | Males | Females |
|---|---|---|---|
| Total arm palsies | 41 | 33 | 8 |
| Musculo-spiral | 179 | 162 | 17 |
| Ulnar | 52 | 43 | 9 |
| Circumflex | 29 | 22 | 7 |
| Median | 8 | 8 | 0 |
| Median and ulnar | 6 | 6 | 0 |
| Totals | 315 | 274 | 41 |

*Distribution in the Lower Extremities.*

Anterior tibial palsies (16 cases): Male, 15; female, 1.

*Total arm palsies* made up 12 per cent. of the cases. Thirty-three per cent. occurred between the ages of forty to seventy years. The percentage of palsies due to violence were about equal in the male and female cases—90 per cent. males and 87 per cent. females. In 42 per cent. of the male cases particular occupation had a distinctive bearing as a causative factor. There was only one female case out of eight in which occupation might be said to be influential, viz., servant falling down stairs. The duration of the paralysis in the majority of cases was up to one year.

*Musculo-Spiral Palsy* occurred in 54 per cent. of the cases. In 179 cases, 114, or 63 per cent., occurred between the ages of twenty to forty years. Of 162 cases, there were 31, or 19 per cent., laborers, and 20, or 12 per cent., drivers. Of 17 female cases, there were 9 houseworkers. Of the 162 male cases, 138, or 85 per cent., were due to pressure; the remaining 15 per cent. were due to violence. Of the 138 pressure cases, 122, or 89 per cent., were caused by pressure during sleep induced by alcohol. In the occupations of laborers and drivers of vehicles 75 per cent. were caused by pressure during sleep induced by alcohol. There was a distinct relation between particular occupations in 13 per cent. of the male cases. In the female cases there was no distinct relation. Of 179 cases, 145, or 80 per cent., presented themselves for treatment during the first month. Duration appears to be from three to six months.

*Ulnar Nerve Palsy.*—The ulnar nerve was paralyzed in 15 per cent. of the cases. Twenty-seven per cent. of the male cases were caused by pressure during sleep induced by alcohol and 25 per cent. were due to pressure caused by handling various tools. Occupation was influential in 30 per cent. of the male cases. Occupation shows no relation in the female cases. Thirty-seven per cent. of the cases were due to violence. The duration of the paralysis varied from three months to one year.

*Circumflex Palsy.*—The circumflex nerve was involved in 8 per cent. of the cases. In 63 per cent.

of the male cases the paralysis was caused by violence. In 3 out of 7 female cases violence was a factor. The duration of the paralysis was from four to seven months.

*Median Nerve Palsy.*—Median nerve paralysis occurs in 2½ per cent. of the cases. All these cases were males. Fifty per cent. were due to pressure during sleep induced by alcohol. Fifty per cent. were due to pressure. Less than 1 per cent. show occupation as a causative factor.

*Median and Ulnar Palsy.*—Combined median and ulnar nerve palsies made up 1½ per cent. of the cases. No female cases were recorded. Fifty per cent. were due to incised wounds and the remaining 50 per cent. were due to pressure and violence. There was a residual paralysis in the cases due to incised wounds. Occupation was influential in 5 out of 6 cases.

*Anterior Tibial Palsy.*—Anterior tibial paralysis made up 5 per cent. of the cases. In 60 per cent. of the cases pressure during sleep induced by alcohol was the cause. In 2 out of 16 cases occupation was influential.

*Traumatic Facial Paralysis.*—Of 10 cases of traumatic facial paralysis, 8 occurred in males and 2 in females. Three cases occurred at the age of thirty-five years and 2 of the cases at forty-one; the remaining 3 cases occurred between twenty to thirty years of age. Occupation showed: Drivers, 2; ironworkers, 2; laborers, 2; painter, 1, and waiter, 1. Four, or 50 per cent., of the male cases were caused by fracture of the base of the skull. Three, or 37 per cent., followed mastoid operations. One was caused by being squeezed between buckets. Injuries were connected with falls from scaffolding, building and wagon. In 5 of the 8 cases particular occupation had a distinctive bearing. In 5 of the cases the right side was involved and in 3 cases the left side. In 5 cases all branches of the nerve were involved, and in 3 cases the superior branch alone. The ophthalmic branch of the facial was involved in one case to a varying degree, causing lagophthalmus. Duration varied from sixteen days to two years. Seven of the eight cases showed a complete reaction of degeneration in the branches of the nerve involved.

Of the two female cases, 1 occurred at nineteen years and 1 at twenty-nine years of age. One was a press girl and one was a servant. The paralysis followed mastoid operations. Occupation had no bearing as a causative factor. One was on the right side and one was on the left. All branches of the nerve were involved and the eye could not be closed in either case and showed a complete reaction of degeneration. Duration, one year in 1 case and three years in 1 case.

*Peripheral Birth Paralysis, of the Upper Arm Type.*—Of 30 cases of of peripheral birth paralysis, of the "upper arm type," 16 occurred in males and 14 in females. The age of the males was from one month to five years. The age of the females was from two months to nine years. There were 14 vertex presentations and 2 breech presentations. In 9 of the 16 male cases, the paralysis occurred after the artificial delivery, and in 7 cases when the labor terminated naturally. In 8 of the 14 vertex presentations paralysis occurred after forceps. In 3 cases traction in the axilla produced the paralysis. In the remaining 3 vertex cases the labor was prolonged but terminated naturally; the paralysis was attributed to pressure upon the shoulder during labor. The paralysis in the 2 breech cases was associated with fracture of the clavicle. Of the 14 female cases, 11 were vertex presentations and the paralysis occurred after artificial delivery. One was a breech presentation and was caused by traction in the shoulder. Two were prolonged but terminated naturally. In 14 of the 16 male cases the deltoid, biceps, brachialis anticus, and supinator longus muscles were paralyzed. In most of the cases atrophy of the muscles occurred and showed a complete reaction of degeneration. In some cases anesthesia in the outer surface of the arm was noted. Three cases were operated on, but the paralysis remained the same as before operation. In 8 of the 14 female cases all of the shoulder muscles were involved and atrophied and showed the reaction of degeneration. In 6 cases only part of the muscles were involved; they also were atrophied and showed the reaction of degeneration. None of the female cases was operated upon.

*Posterior Thoracic Nerve Paralysis.*—Two cases occurred in children, one male eight years of age and one female eight and a half. The male case was caused by pressure while resting in bed for a long time. The female case was due to falling down stairs and striking on her back. Male case existed for three weeks, female case for four months. In both cases electrical examination demonstrated a reaction of degeneration in the serratus magnus muscle.

*Treatment.*—The general treatment included hygiene, baths, tonic and special exercises.

The local treatment, electricity, massage, and mechanical devices. Surgery was demanded in cases caused by dislocation, cut nerves, and callus.

Pressure cases caused during sleep induced by alcohol, in which there was a partial or complete reaction of degeneration, were treated with the positive pole to the muscles and by massage. The constitutional treatment consisted in elimination of the toxic materials, giving of tonics and strychnine. Baths were used, especially the hot and cold, followed by the douche. The cases recovered in from three to six months. In pressure cases caused during sleep not induced by alcohol, in which there was a very slight or no reaction of degeneration, the best results were obtained by electricity, the continuous current and the negative pole to the muscles, used every other day for five or ten minutes, together with massage. In these cases the duration was variable, extending from a few days to one month before cure. Pressure cases due to crutch and tight bandaging were more rebellious to treatment. In one male case of double total arm palsy due to tight bandaging, in which there was a complete reaction of degeneration, sensation returned at the end of three months. At the end of eighteen months there was a partial return of motor power. Another patient with double total arm palsy, due to pressure from crutches and in which there was a partial reaction of degeneration recovered sensation and motor power with some residual weakness in eleven months. A patient with double circumflex palsy due to dislocation, got well in eight months after the reduction of the dislocation.

In a case of musculospiral paralysis due to implication of the nerve in a callus, operative treatment met with partial success.

A case of combined median and ulnar palsy due to incised wounds was treated by suturing. Before suturing the hands were deeply cyanotic; cold stiff, slightly flexed, with atrophy of the interossei and loss of sensation in the distribution of the nerves.

After operation sensation in the hands and fingers returned in about one month. At the same time there was an improvement in the general nutrition of the hands. At the end of six months motion was slightly improved. The improvement of flexion of the first phalanges was more marked than extension of the second and third phalanges.

A case of total arm palsy due to a bullet in which there was no surgical treatment, showed no improvement in the motor power and little in sensation at the end of one year's treatment.

The great majority of pressure cases were cured. The non-alcoholic and those showing the lesser degree of the reaction of degeneration recovered the most rapidly.

*Conclusions.*—Of 331 cases, the males numbered 88 per cent., females 12 per cent. Traumatic paralysis occurs in infancy to old age. Ninety per cent. of the cases occurred between twenty and thirty-five years, the most active part of adult life.

Occupation varied widely. The most predominant occupations were laborers, drivers of vehicles, and houseworkers. Sixteen per cent. were laborers, 8 per cent. were drivers of vehicles, and 5 per cent. were houseworkers.

The most direct, exciting cause was pressure during sleep induced by alcohol; the next in frequency was violence. It does not appear that the accidents were connected with dangerous work, awkwardness, or carelessness. Ninety-five per cent. occurred in the upper extremities and 5 per cent. in the lower.

There was a distinct relation between particular occupation and the trauma in 23 per cent. of the cases.

Eighty per cent. of the cases presented themselves for treatment during the first three months of the paralysis. Fracture at the base of the skull, involving the facial nerve in its course, produced facial palsy in 40 per cent. of the cases.

The female cases were not caused by violence. None of the cases showed a complete recovery.

In the peripheral birth palsies males and females were injured about equally. The great proportion of all cases of peripheral birth palsies of the "upper arm type," as seen in a neurological clinic, are vertex presentation, occurring after artificial delivery. Operation does not improve the condition. When the reaction of degeneration is present improvement is slow and the paralysis may be permanent.

Case I.—Total arm palsy from gunshot wound of brachial plexus. A policeman, 38 years old, was shot with a 38 caliber bullet, at a distance of seven feet, on March 16, 1906, at 10 P. M.

The point of entrance was two inches below the middle of the right clavicle, and the exit, middle of the scapula, toward inner side, two inches below the spine. At the time of injury had a sensation as if a red hot iron was running over his arm and felt as if he had "no arm." He was operated on at 12 P. M. (two hours after the injury). The first portion of the axillary artery was ligated, no suturing of nerves.

On April 11, 1906, less than one month after injury he came to the clinic for treatment. Patient was able to abduct arm partially at angle of 45° adduction; also external and internal rotation of shoulder; no flexion or extension of the forearm, no supination or pronation of the forearm, no extension at wrist, but had good ulnar flexion at wrist. Had good flexion of little, ring, and middle fingers; less power in middle. Interossei muscles of hand supplied by the ulnar nerve were functionally sound. Tendon jerks in right arm absent. There was a slight general wasting of right arm, but no localized atrophy.

Sensation.—Tactile anesthesia in median and musculospiral distribution of hand, also in the cutaneous branch of the musculocutaneous, including diminution of pain and temperature sense, but pain was acute in fingers and hand; loss of deep sense in the radial fingers.

April 23, thirty-eight days after the injury, motion still impaired and patient complained of dull, aching pains in whole of right arm, except ulnar distribution, burning and scalding sensations in median distribution, also paresthesis, occasional sharp shooting pains in dorsum of thumb; little pain in the bullet tract, neck, or shoulder.

June 15, 1906, three months after injury, no pain for three weeks, except when storm is coming. Paralysis was improved, could move all muscles of shoulder, but no flexion of elbow or wrist.

November 23, 1906, eight months after injury, unable to use shoulder muscles. There was general wasting of arm, no flexion or extension of elbow, no extension of wrist or fingers. The movements of the muscles supplied by the ulnar, present, and no atrophy of muscles supplied by the ulnar. The motion of the muscles supplied by the median were lost and atrophy of muscles; no pain, no paresthesia, except occasionally in musculospiral distribution of the hand. Anesthesia to touch, pain, and temperature sense in median distribution. Tactile sense had returned in the musculocutaneous distribution, no trophic changes in the nails. Radial pulse was feeble.

Electrical examination: No faradic response in muscles of arm except ulnar distribution and deltoid. The deltoid was sluggish. At Erbs point, contraction only in deltoid. Galvanic, slow, vermicular contraction in all muscles of arm except deltoid and ulnar distribution. No response to indirect methods through musculospiral or median nerves. Good response in ulnar.

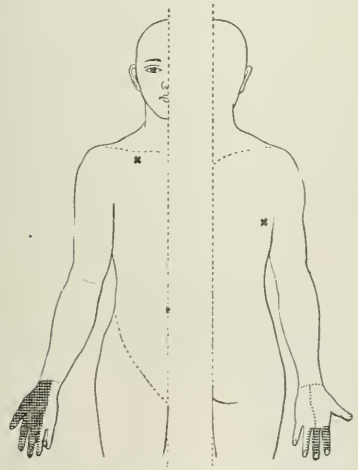

Fig. 1.—Case I. Total arm palsy from gunshot wound of the brachial plexus. Cross shows entrance and exit of the bullet. The area of vertical and horizontal lines shows complete cutaneous anesthesia, protopathic and epicritic. The area of horizontal lines indicates loss of epicritic sensibility only.

Case II.—Circumflex palsy, due to dislocation of the right shoulder, showing area of anesthesia sixteen months after injury. The patient was a butcher, 70 years old. In December, 1899, he fell and struck on his right shoulder, dislocating it. The dislocation was reduced two hours after the accident. After injury he had pain in shoulder; numbness and stiffness of the fingers of the left hand. In the course of two months this wore off.

April 18, 1901, sixteen months after injury, there was atrophy of the right deltoid, and infraspinatus muscles, crepitation in joint, inability to raise the arm laterally from the side, forward and backward movements limited, opposition of the thumb and fingers not possible. Anesthesia to tactile, pain, and temperature sense in region corresponding to the circumflex nerve.

Electrical examination: Complete reaction of degeneration in the deltoid and infraspinatus muscles.

Case III.—Injury to the musculospiral nerve from fracture of humerus illustrating the paralysis of the

hand, the degree of flexion of the fingers, and sensory disturbances. Seven weeks after injury. A laborer, 30 years old, was throwing a heavy stone weighing 14 pounds on July 9, 1905. The arm "cracked" at the juncture of the middle and lower third. The fracture

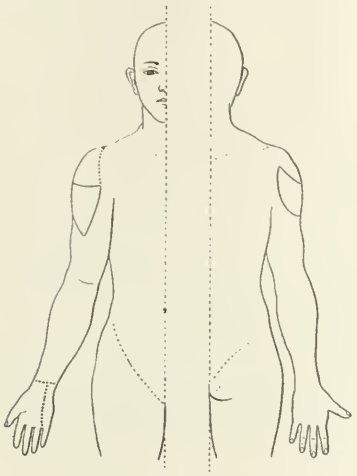

Fig. 2.—Case II. Circumflex palsy. The area of the right upper limb within the black line was anesthetic 16 months after injury.

was set the night of the injury. At the time of the accident the extensor muscles of the wrist and fingers were paralyzed and patient complained of numbness in the musculospiral distribution.

Three weeks after the injury, it was found that the nerve was so involved in the subsequent formation of callus as to occasion its paralysis. At this time an operation was done to free the nerve.

Examination made August 30, 1905, seven weeks after injury. Supination was found imperfect. Extension of the hands and fingers entirely lost. The

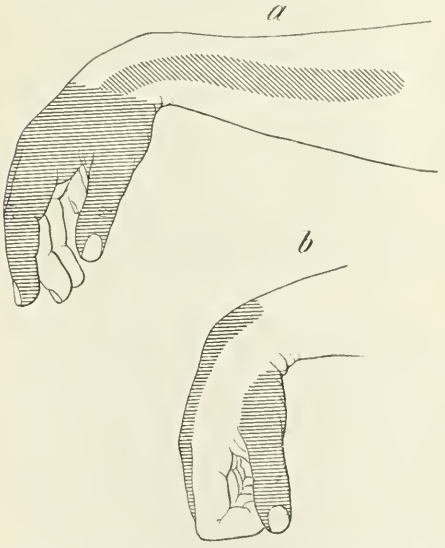

Fig. 3.—Case III. A shows the wrist-drop, pronation of the forearm, the degree of extension of the fingers, and the area of anesthesia, indicated in horizontal lines. Seven weeks after the injury. B shows area of anesthesia and degree of flexion into the palm of the hand. Seven weeks after the injury.

forearm was pronated, and the hands and fingers were passively flaccid. Cut shows area of anesthesia.

Electrical examination: There was a complete reaction of degeneration in the muscles, supplied by the musculospiral nerve.

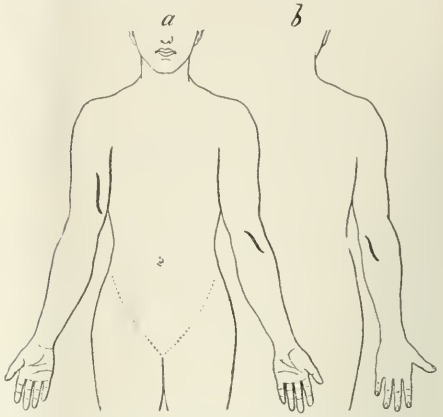

Fig. 4.—Case IV. The points of entrance of the knife. *a* shows the entrance on the anterior surfaces of both arms. *b* shows the exit of the knife wound on the posterior surface of the left arm.

Case IV.—A case illustrating the paralytic, protopathic, and epicritic disturbances after complete section of the median and ulnar nerves of both arms. Six months after the injury. A houseworker, 36 years old, was stabbed in both arms with a carving knife on September 29, 1910. Immediately after the injury the fingers of both hands dropped and there was a loss of sensation in the median and ulnar distributions. The wounds were treated antiseptically in the hospital and were sutured without an anesthetic. There was no history of an attempt to suture the nerves. The wound in the right arm healed in a few days, but the wound in the left arm became infected and incision was done.

At first there was an absence of extension of the fingers, but after a short time slight power of extension returned. Six months after injury, the movements of the thumb and fingers were much impaired; the thenar and hypothenar eminences were flabby and flat. The interossei muscles were atrophied. There was inability to extend the second and third phalanges. Abduction and adduction of the fingers were lost. The muscles in the ulnar distribution of the forearm were atrophied. The left hand was weaker than the right, both hands were cold and cyanotic and showed trophic changes in the thumbs and tips of the fingers. The nails were marked with ridges; the radial pulse in both wrists was small; patient complained of prickly sensations in both hands.

Electrical examination: To faradism there was no response in ulnar and median distribution; to galvanism, AnCC>CaCC. In the muscles supplied by median and ulnar nerves the response was a slow, sluggish, veriform movement, and in some muscles none at all.

The illustrations show the points of injury, the deformity of the hands, the protopathic loss, and the epicritic loss.

Protopathic cutaneous sensibility responds to painful cutaneous stimuli (pricking), also to extremes of cold and heat, 45° C. and over and 10° C. and under.

Epicritic cutaneous sensibility appreciates light touches, of cutaneous localization, recognition of finer differences of temperature, warm and cold.

Case V.—Wound of the median and ulnar nerves. Secondary nerve anastomosis; before operation total anesthesia; after operation only epicritic anesthesia. A tinsmith, 18 years of age, on June 14, 1905, fell off a barrel, cutting his left forearm, about the middle, with a piece of tin. At the time of the injury his wrist dropped, fingers became flexed, with complete anesthesia in the median and ulnar areas. The following morning after the injury the wound was sewed up without suturing the nerves, but three days after the wound became infected, necessitating incision. The wound healed in twelve weeks.

The patient complained of no pain in the hand or fingers, but all sensation was lost over front and back of the hand, except a patch on the dorsum between the thumb and index fingers. Sensation remained absent until secondary suturing, fourteen months later. The

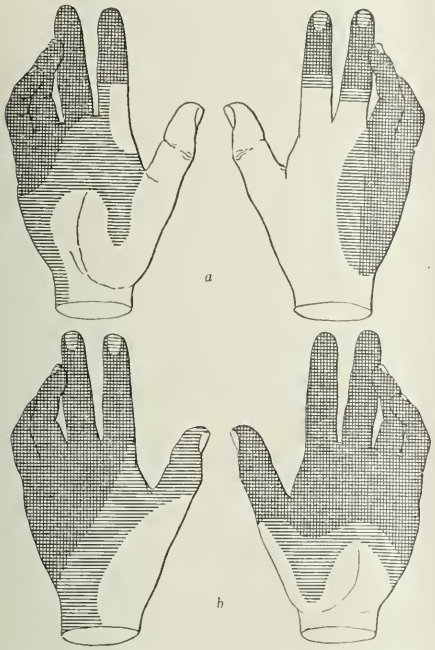

Fig. 5.—Case IV. The area of vertical and horizontal lines show complete cutaneous anesthesia, protopathic and epicritic. The area of horizontal lines indicates loss of epicritic sensibility only. Six months after the injury. *a*, Right hand; *b*, left hand.

median and ulnar nerves were found to be completely severed. One-half hour after operation, it is asserted, that sensation returned in the hand. This lasted two days and disappeared; then there was a gradual return of sensation, but not complete. The diminution of sensation was more marked in the median area than in the ulnar. The patient complained of frequent

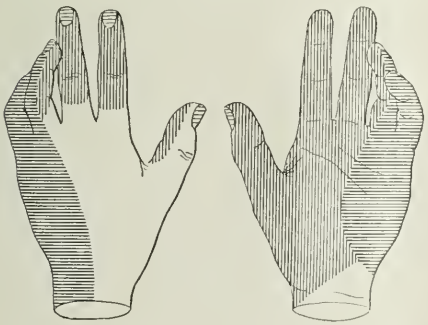

Fig. 6.—Case V. Showing paralysis of the median and ulnar nerves. The horizontal and vertical lines represent the areas in which protopathic cutaneous sensibility returned. After 15 months, following secondary nerve anatomosis there was an absence of epicritic sensibility in that area.

pains in the hand and all the fingers. Motion gradually returned in the hand and fingers.

Electrical examination showed a complete reaction of degeneration in the muscles of the hand. Slight trophic changes in the nails occurred. The radial pulse was small.

Case VI.—Severance of the median nerve, illustrating area of protopathic and epicritic loss. The patient was a ship's steward, thirty-seven years of age, who on October 8, 1912, was cut on the right wrist with a piece of broken glass, severing the median nerve.

Fig. 7.—Case VI. Severance of the median nerve. One month after injury. The area of vertical and horizontal lines show complete cutaneous anesthesia, protopathic and epicritic. The area of horizontal lines indicates loss of epicritic sensibility only.

Twenty-four hours after the injury he was treated in the hospital, but the nerve was not sutured. At the time of the accident he had a loss of sensation in the thumb, index, and middle fingers. One month later the motor power in the long flexors and extensors were present, also all movements of the thumb, though weak. The illustration shows the region of protopathic and epicritic loss, one month after injury.

Case VII.—Ulnar palsy following fracture of the radius and ulnar, showing sensory disturbances in the ulnar distribution. A laborer, 22 years of age, fell and broke his right arm. Five months later there was a badly formed fracture at the junction of the middle and lower third of the radius. A large callous projected into the interosseous space. There were indications also of callous formations in the anterior surface of the ulnar at the junction of the middle and lower third. The union was in a bad position, the arm having been in splints two months. Immediately after the accident there were sensory disturbances as well as motor. These had improved with time and not grown worse.

Examination showed the hand directed toward radial side. There was flattening of the palm and hypothenar eminence also of the first interosseous space. Trophic disturbances were apparent in all four fingers. Tbe

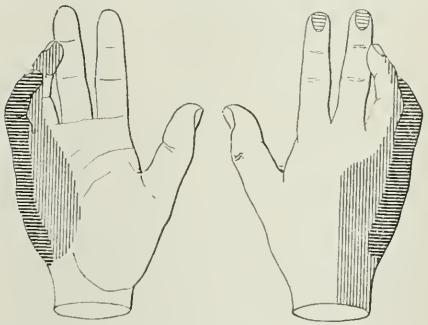

Fig. 8.—Case VII. Ulnar paralysis following fracture of the radius and ulnar of the right arm. Showing the sensory disturbances which existed five months after injury. The horizontal lines indicate the epicritic and protopathic loss in the little finger. The light perpendicular lines indicate the area of returned protopathic cutaneous sensibility. Epicritic cutaneous sensibility was absent in this area.

nails were smaller, presented ridges and were imperfectly developed compared with the right side. Skin was somewhat glossy. The hairs of the skin were present in the ulnar side of the arm and hand. The sensory disturbances are indicated in the illustration.

Electrical Examination: Indirect faradic and gal-

vanic to ulnar lessened; only response, flexor carpis ulnaris and flexor of little finger. On a strong current flexion also of the middle and ring fingers. No adductor pollics response. Direct faradic, no response. Galvanic, slow contraction in thenar eminence, increased on reversal of poles.

167 St. Nicholas Avenue.

## THE MANAGEMENT OF LARYNGEAL TUBERCULOSIS IN SANATORIA AND PRIVATE PRACTICE.*

By WOLFF FREUDENTHAL, M.D.,

NEW YORK.

As a result of a large number of post-mortem examinations, Naegeli asserted that in 97 per cent. of all adults some kind of a tuberculosis lesion is found. He concludes: "Every grown person has tuberculosis." (*Virchow's Archiv*, Vol. 160, 1900.) This tends to show that an occasional infection is not dangerous to the average person. To those exposed, the danger lies in constitutional weakness, in close or prolonged contact with tuberculous patients in the family life or business relation. The disposition is considered as the principal etiological factor, in comparison with which the bacilli play only the rôle of a match, which though inoffensive in itself, if thrown carelessly aside may cause ruin and destruction, provided several factors combine to cause its ignition. Many fires occur daily, and still more cases of tuberculosis. But it is not timely to go into details of the etiology of pulmonary tuberculosis. Everybody knows that it is prevalent to a dreadful degree, and that in spite of the active, often rational, often nonsensical, crusade against it, it has decreased to only a slight extent.

The most severe and serious complication of the disease is the laryngeal involvement. No other condition subjects the patient to such a severe test of endurance as does a deeply ulcerated tuberculous larynx. Few patients in any condition demand relief more earnestly, or spur the physician to greater effort, or demand more attention, or are a source of more anxiety than these cases. Should we not try everything to relieve these most wretched of all patients of their suffering?

It is a great pity that many of our fellow practitioners still believe that tuberculosis of the larynx is an incurable disease. But a short time ago a colleague in charge of a large hospital for tuberculosis cases expressed this view: "The patient is lost as soon as the larynx becomes involved." This would be most hopeless if statistics alone had not proven the fallacy of such a belief. Permit me to quote only one and a very reliable investigator, viz., W. Jobson Horne of London, who for many years had conducted both clinical and pathological research (*Journal of Lar.*, etc., Dec., 1905). His results "showed that 97 per cent. of cases of phthisis experienced symptoms referable to the larynx at one time or another in the course of the disease, and the investigation further went on to show that the routine examination of the larynx in persons suffering from symptoms suggestive of early pulmonary disease would often enable a diagnosis of phthisis to be made at a time when the stethoscope yields no evidence, and that is at a time when the physician can be of the greatest service to his patient." Even if we do not accept these statistics as positive proof, still all men of experience will agree that the larynx is affected in an extraordinarily large percentage of cases, and if this be so it must be equally true that many of them are cured, and, indeed, that is what happens quite frequently with or without our making a diagnosis and with or without treatment. It is true that a certain proportion of the milder cases do get well merely by being placed in proper hygienic surroundings. But how about the others? Can any of these be saved, or is it useless to bother with them? In order to present an outline of my results and plan of treatment, let us consider, first, the management of all cases afflicted with tuberculosis of the larynx in a well-equipped sanatorium. It should be an established rule to examine every case that enters a sanatorium as to the condition of the upper air tract, whether the patient complains of this or not. If this is done as a matter of routine a number of pathological conditions will be found, the correction of which will have a decidedly beneficial effect, not only locally, but as regards the pulmonary affections as well. Permit me to refer to several articles published by me a number of years ago, which have an important bearing on our theme. It was found that many of these patients suffered from an atrophic catarrh of the nose, or from a milder form of this, *i.e.* a rhinitis sicca. Most of these persons have wide nasal passages, and yet they feel that they can not get any air through them. The reason for this is that the mucous membrane of the nose is dried out, or covered with scabs and crusts. The air spaces are large enough but the air itself cannot be "assimilated." I might compare this condition to that of a patient suffering from cholera. He is craving for water, but no sooner drinks it than it leaves the system again without being absorbed. So it is with the air inhaled in the above affection. In the University Clinic at Kiel, Germany, my experiments were repeated by Dr. M. Behr and were corroborated in every instance. (*Brauer's Beiträge zur Klinik der Tuberkulose*, 1904, p. 37.)

Great stress should be laid upon these findings since we gain two points by giving them attention. Firstly, in many patients the characteristic hacking cough described in all textbooks as a premonitory or incipient stage of tuberculosis, has its source in the pharynx, being caused by the dry secretions of atrophic rhinitis getting down into this region from the nose; or you may find simply a postnasal catarrh. If one treat this nasopharyngeal catarrh according to the customary methods, one will be sure to eliminate the cough originating in the above manner. In this way we have accomplished a great deal already, for here is a chance of arresting the disease in the beginning. "Principiis obsta" is an old rule which should be followed. On the other hand, one will benefit the patient by restoring the nasal mucosa to a normal condition, so that the inhaled air can be warmed and moistened and thus rendered fit for breathing purposes.

The following example may be cited. A physician from a neighboring city called on me and told me that the week before he had had a pulmonary hemorrhage, night sweats, and rise in temperature, and there had been tubercle bacilli in the sputum; in short, he gave a plain history of tuberculosis. The doctor called on me to find out whether his hoarseness was due to laryngeal tuberculosis, and, if so, he knew he was lost. On examination, a bleeding vessel was seen in about the center of the left vocal cord—a very rare occurrence indeed. This was cauterized with a strong solution of chloride of zinc.

*Read by invitation at the annual meeting of the Tompkins County Medical Society at Ithaca, N. Y., March 10, 1914.

Besides, his nose and pharynx were sprayed with a mild alkaline solution, on account of his naso-pharyngeal catarrh, and as a result the cough stopped almost instantaneously (he had been coughing for the last ten years, or more) and he suffered no longer from night sweats or temperature. I do not claim to have cured his pulmonary condition with these simple applications, which every beginner in laryngology can make, but the constant irritation from the pharynx and nose was stopped and so a rational and very simple treatment of his general condition was inaugurated.

Another obstacle frequently encountered is a deviation of the nasal septum or spurs. If they are of such a nature as to materially interfere with respiration they should be removed. This can be done easily with very little loss of blood and in almost any stage of tuberculosis. Adenoids should also be curetted, but look out for the tonsils, *i.e.* do not operate on them if the disease has been positively established. I have seen several fatalities occur in patients who had been sent away by me to recuperate. They were operated on against my advice and died of *pulmonary* hemorrhage in from three to eight days after tonsillectomy had been done. If a simple *laryngitis* is present, treatment of this will be indicated if it causes a cough. If not, leave it alone. But if tuberculosis of the larynx has actually set in, what then?

The management of such cases is often one of the most difficult tasks that confront the laryngologist. But it is worth all the work and all the pains we take, for the progress in the therapy of this condition has been marvelous. It is natural that these patients should have sanatorium treatment. Here again I want to make a plea for these poor sufferers. We admit so-called early cases, which are no menace to the community nor to their family, as long as their sputum is negative. We build expensive places for those who can be housed just as well in a much less elaborate style, but we frequently reject those who need it most, *i.e.* the tuberculous subjects with laryngeal complications. That hospital is the best, said a prominent German scientist, which admits the worst cases. According to this view, with which I heartily coincide, there are mighty few satisfactory sanatoria for tuberculosis here and abroad. This is all wrong, as every institution of this kind should be forced to admit patients with laryngeal tuberculosis. The general treatment received there of itself often exerts a curative effect in incipient cases. The rest-cure, especially of the voice, the good air and suitable nourishment, are sometimes so stimulating that slight lesions, as superficial erosions, slight infiltrations, etc., are healed.

In other instances, in which ulcers appear, with papillary outgrowths, and localized and diffuse infiltrations, a more active therapy is indicated. No matter in what state the lungs may be, two requirements must be met, viz., to stop the cough and remove the dysphagia. There are various means at our disposal, and it will depend largely upon the experience and judgment of the physician as to which will be chosen. Some have proposed major operations, *i.e.* the entire removal of the affected parts right into the healthy tissue, as has been done surgically in other parts of the body; in other words, partial or total laryngectomy. Theoretically, this is the correct mode of procedure. Practically, however, it has not proven a success. By far the majority of patients operated on in this way succumb quickly to pneumonia and other complications, and only few recover from it. Even simple tracheotomy, which has been recommended as a prophylactic measure, is of no value. It is not more than six months ago that I was forced to do a hurried tracheotomy for dyspnea in a young woman. The wound never healed, but kept discharging a mass of pus, and apparently a new infection of the system had set in. She died recently. Such fatalities perhaps occur oftener than we know. Other patients survive, but have to wear a tracheotomy tube for years without benefit. Nowadays tracheotomy should be performed only on account of dyspnea which cannot be otherwise relieved.

We are therefore limited to minor surgical work *within* the larynx. It is well known that the disease manifests itself frequently on the posterior wall (its anterior portion) and on the anterior wall, *i.e.* the epiglottis. For a long time deep ulcerations and infiltrations may persist on the lateral wall of the interior of the larynx without causing dysphagia or any other serious trouble; but difficulties arise as soon as the region of the arytenoids or the epiglottis becomes involved. Then dysphagia sets in and the fear of the dreaded pain in swallowing reduces the amount of food taken to a minimum. Therefore, what can be done? This condition must be overcome by every means at your disposal, or your patient is lost.

Let us start with the epiglottis. This organ may be severely affected, and in that case is apt to nullify all therapeutic efforts in the larynx and lungs. If ulcers have formed on its lingual side they are easily treated by means to be discussed shortly. At times they yield quickly to treatment. On the other hand, we may find the epiglottis greatly infiltrated, either principally on one side or equally on both sides (the well-known omega and turban-shaped forms). In such cases, if dysphagia is pronounced, all our efforts towards alleviating it will fail. (1) On account of the inability to reach the ulcers lower down in the larynx, the epiglottis occluding the introitus laryngis, and (2) because ulcers have formed on the lower, *i.e.* laryngeal surface of the flattened epiglottis, which cannot be reached by any application. Under these circumstances the best we can do is to amputate the epiglottis either with some cutting forceps, as for example A. Alexander's of Berlin, or, better still, with the cold snare, as advocated by P. Gerber (*Zeitschrift für Lar., Rhin.*, etc., p. 739, 1909). This operation is extremely simple and afterwards enables you to treat the lesions further down. Occasionally improvement is noticed immediately when the epiglottis is the only part affected. If, however, ulcers are present further down, they should be especially treated.

Ulcerations: The first thing to strive for, as has been said above, is to remove the pain in deglutition and incidentally the laryngeal cough. To accomplish this we have to produce local analgesia of long duration, *i.e.* painlessness of the parts lasting for days. We have given up using cocaine daily, or even several times a day, for such purposes. This drug produces anesthesia and aside from its cumulative, toxic effect, has other shortcomings. Prolonged analgesia can be produced by orthoform or anesthesin. They can be applied as a powder or in the emulsion recommended by the writer some years ago. The important points to be remembered in applying the emulsion or the powder are that the parts to be treated must be clean. If they are not, any bland spray will remove all the débris. Secondly, these drugs must be applied in such a manner that

they remain on the ulcer. If too much is applied at one time the patient will cough it all up. I take pleasure in repeating the formula of the emulsion here:

℞ Orthoform, 6 grams.
Menthol, 0.5 to 5 grams.
Hexamethylenamine, 0.50 gram.
Sweet almond oil, 15 grams.
Powdered acacia, 10 grams.
Water, ad 60 grams.
M. f. emulsio.

Such medication alone, if used correctly, will often produce cicatrization of an ulcer. This is accomplished by simply putting the parts at rest through analgesia. To make this clear I may be allowed to mention here the investigations of Prof. G. Spiess on the value of anesthesia (analgesia) in inflammatory processes. The old classical symptoms of an inflammation were: rubor, calor, tumor, and dolor. According to the observations of Spiess, however, it is evident that the "primary dolor" is the factor in causing inflammation. The irritation of the sensitive nerves leads reflexly to hyperemia, *i.e.* rubor. That naturally causes calor and leads to a tumefaction (tumor). Spiess produces anesthesia of the larynx by submucous injections of novocaine (2 per cent. to 5 per cent.) and has thus verified his experiments (*Archiv für Laryngologie*, Vol. 21, No. 1). I have not used these injections, but have reached the same end with applications of orthoform or anesthesin and feel convinced that Spiess is right in his deductions.

But these analgesic remedies, like everything else, will cure only a certain percentage. The reasons for these failures are: first, in some instances we cannot reach the seat of the ulcers; second, they are sometimes so located that no fluid or powder will adhere (posterior laryngeal wall), etc., and thirdly, some ulcers will not heal under analgesic treatment alone. In that event we resort to caustics. Of these I would mention chloride of zinc, in solutions ranging from 3 to 10 and 15 per cent. nitrate of silver, argyrol, etc. These caustics have to be followed within about half an hour by the insufflation of orthoform in powder or in the form of the emulsion. The most effective caustic is the galvanocautery (point), used first by Grünwald of Munich. (*Münchener med. Woch.*, No. 25, 1903) and (*Wiener medizin. Woch.*, No. 28, 1905). I have made use of the galvanocautery in patients with deep solitary ulcerations and in such cases good results will occasionally be obtained. For multiple ulcers this method cannot be recommended. The reaction after the galvanocautery is sometimes unpleasant and unavoidable. Like Kofler of Vienna I have noticed perichondritis of the arytenoids in a case in which the cautery was applied too near the processus vocalis. There are other reactions which, however, are omitted here.

Instead of the galvanocautery I have also employed fulguration. In the *Laryngoscope*, July, 1912, I published my experience with this method which gave some encouraging results. Since that time suspension laryngoscopy has been introduced which has opened new channels for treatment. Consequently I have given up the application of the high frequency current as well as of galvanocautery, at least for the present, and now operate mostly under suspension laryngoscopy. This new method of Killian's, described by me on different occasions, has opened a new field for our therapeutic endeavors. It is quite impossible in this paper to give a description of the method; suffice it to say, that with it the larynx is opened widely to direct inspection and that there is an excellent opportunity to reach its different parts, especially its posterior wall, which is so easily affected. We are enabled to curette thoroughly all ulcerations which, after all, is the most satisfactory surgical method. I have done this frequently and have had some excellent immediate results. I say immediate, because these ulcers recur and have to be curetted over and over again. The procedure is not painful, the loss of blood minimal, and the dangers connected with the method practically nil.

After doing curettage under suspension it would be best to apply a strong caustic, as the galvanocautery or pure lactic acid. There is, however, the danger of edema of the larynx, for which we have to be constantly on the lookout. For that reason it is often wise to proceed slowly, *i.e.* to curette only some of the most troublesome parts at the first sitting. When, for some reason, the whole, or part of the epiglottis has been removed and ulcers then become visible they should be curetted in the same sitting under suspension laryngoscopy.

Excisions of infiltrated portions or of granulations: Some years ago Grünwald, Spiess, and other laryngologists expressed the view that half-hearted surgery was to be condemned here. They preferred to remove as much as possible of the affected parts. With suspension laryngoscopy they now have the best chance to accomplish this. But is it wise to do so? There was a time when I did a good deal of such work. Undoubtedly some persons were benefited, but a large majority were not, and therefore the method was given up for a time and the patients were apparently as well off as before. The only exception to this rule were infiltrations causing dyspnea, and in such instances something had to be done to relieve this. With the appearance of suspension laryngoscopy things have changed again. The first time I operated by this method was for interarytenoid papillary outgrowths. Several laryngologists of New York City, including myself, had tried in vain to remove the entire mass by the indirect way. I then attempted suspension laryngoscopy and I was amazed at the ease with which the work could be done. Other observations soon followed and one point was noticed immediately. The infiltrations and tumefactions in the larynx are always larger than they appear to us, and it was frequently a matter of surprise what big pieces could be removed before normal tissues were reached. Soon afterward we encountered cases that have become more frequent nowadays. These show advanced tuberculous lesions of the larynx often very difficult to diagnose, but without positive signs in the lungs. These are most interesting and instructive cases and they bring nearer to us the possibility of a primary infection of the larynx. One example may be cited:

Case I.—G. H., a sailor, aged 40, was referred to me in September, 1912, on account of hoarseness, which had come on gradually during the last ten weeks. No pain, no cough, but a heavy feeling in his chest. The larynx showed an irregular infiltration of the left vocal cord and a thickening of the entire right one, which was immovable. Quite a large ulceration was seen on the posterior wall. In spite of the fact that the lungs showed no positive evidence of any tuberculous affection I considered the case to be one of tuberculosis. On October 18 several pieces were removed from the vocal cord and the ulcerated surface was curetted under suspension laryngoscopy. The immediate result was satisfactory. The ulcer healed and the patient could breathe easier. Within a week he left for a country place. At the beginning of Decem-

ber, 1912, he returned, as he did not feel comfortable. On that day the sputum for the first time showed the presence of a few tubercle bacilli. There were some new ulcerations, which were treated with orthoform emulsion. The pain disappeared, but not the ulcers. These were curetted again under suspension on December 20, and once more the patient felt so much better that he left for the mountains. In February, 1913, he returned to the city with some dyspnea. Sputum positive, but chest findings almost the same as in the beginning. The larynx, however, had changed surprisingly. There were irregular masses springing up from both vocal cords; the arytenoids were markedly swollen, so that very little of the posterior wall was visible, and little space was left for breathing. Patient did not care to undergo another operation, and was kept under observation, the dyspnea growing steadily worse. March 17—The dyspnea was so marked that I came very near doing a tracheotomy at my office, but finally succeeded in getting him to a hospital. There I removed five large pieces of tissue from the larynx under suspension laryngoscopy, local anesthesia being employed. The bleeding during and after the operation was minimal, in spite of the fact that there had been a very extensive removal of tissue. The further history of the case proved that we were right in our deductions. After the operation the patient was put to bed and ice applied externally and given by the mouth. All the instruments required for tracheotomy were placed next to his bed in case of immediate necessity. His breathing was better than before the operation, but about six hours later it again became quite bad, due, undoubtedly, to edema of the larynx, which, however, subsided gradually. March 27—Fulguration was applied to hasten the process of healing, with the result that the edema again appeared next day, together with dyspnea. This subsided after application of cocaine and adrenalin, but soon recurred. Examination showed a dislocation of the left arytenoid, which was flattened and lower than the right one. The dyspnea became so marked that on March 31 I removed part of the overhanging tissue from the right vocal cord. After that the breathing remained free, and about two weeks later the patient again left the city. In this case the thorough surgical procedure was surely life-saving and this could only be accomplished with the aid of suspension laryngoscopy.

I have operated on a large number of patients with similar infiltrations, although cases as pronounced as the one just cited are rare, and I have invariably found that the infiltrations recur sooner or later. But while it was formerly noticeable that the general condition of the patient suffered after excision (fever, etc.), with suspension laryngoscopy it is quite the reverse. The patients generally improve after the reaction is over and also feel better subjectively. However, I cannot yet give a final opinion on that question, as I want to see many more cases before doing so. One point is certain: that the excision of an interarytenoid thickening is often of the greatest benefit in the early stages of the disease, if followed at the same sitting by a thorough curetting of an ulcer below it, which generally cannot be seen by indirect laryngoscopy. All former attempts at the removal of those evenly spread interarytenoid infiltrations and papillary outgrowths appear to us now simple playwork.

If infiltrations as well as ulcers recur, we have to excise and curette them under suspension as often as may become necessary and as long as the patient derives any benefit. We do this in spite of the very pessimistic remarks of one of the best known laryngologists, viz., Professor Hajek of Vienna, who said (*Centralblatt f. Lar.*, p. 20, 1914) that he would make the best prognosis in the case of those patients who live under the most favorable hygienic conditions and are not being treated locally at all. My experience, which extends over twenty years' work in the Montefiore Home, a sanatorium for the tuberculous, differs. Good hygienic surroundings, a nourishing diet, etc., are certainly most desirable and ought to be encouraged. Even when you advise your patient to move from the cellar of a tenement house to the top floor you have improved his hygienic and climatic conditions, sometimes just as much as by sending him to a climatic resort. But these changes will never prevent the appearance of ulcers, etc. On the other hand, I have seen patients living in the worst and most unhygienic tenement districts of New York City who came to the dispensary with marked dysphagia and improved after careful treatment even in spite of their surroundings. One example of many may suffice to prove the former statement:

Case II.—Mr. C. B. was referred to me by a laryngologist of a neighboring city. Patient had deep ulcerations on both sides, interarytenoid thickening, and below that in the trachea an ulceration; advanced tuberculosis of lungs. Under suspension he was curetted thoroughly and left for the mountains ten days later in a greatly improved condition. Four weeks later he had to return to the city, as he had difficulty in swallowing, which was not relieved at all by frequent applications by the local laryngologist. Again he had to be curetted under suspension laryngoscopy, whereupon his condition quickly improved. After a further treatment of two weeks I sent him to one of the best known sanatoria, which has a recognized laryngologist on its staff. Patient stayed there four weeks, had all the benefits of the sanatorium, but his laryngeal condition grew worse. He was given an atomizer containing a 2 per cent. solution of cocaine, but his dysphagia became so pronounced that he dreaded meal time. Finally he was advised to return to this city, which he reached in an almost moribund state. With the simplest means possible, *i. e.* those described above, analgesia was produced and within a few days he could swallow nourishment. Now, *i. e.* twelve days later, he has gained the 2 pounds which he had lost at the sanatorium.

This case is not unique; on the contrary, in most sanatoria they send the patient back to the city as soon as there is a sign of laryngeal involvement. This is not a desirable condition; for what use are the sanatoria if they cannot, or do not care to treat those most dependent upon them? If a patient in a sanatorium shows but slight infiltrations of the bands or the aryepiglottic fold, or slight injection of the cords without any symptoms excepting perhaps a little hoarseness, he does not need to be treated locally. But with the appearance of more serious symptoms, especially dysphagia, it is my practice to be as active as possible and not to limit myself to one remedy alone. For this reason the other means used by me will now be given. Very helpful are the different rays used therapeutically for the past years, viz. (1) the actinic rays; (2) the high frequency current, and (3) the rays emanating from radium.

1. The actinic rays. One of the first orders given to a patient is to keep in the sun as much as possible, *i.e.* in the winter. In the summer the early morning hours are especially recommended, *i.e.* up to 9 or 10 A. M., when the sun is not so very hot. As a substitute for the sunlight the electric arc light can be used and its chemical or actinic rays applied externally to the affected parts. As an adjuvant to other remedies it is sometimes of great benefit for its analgesic effects.

2. The same can be said of the high frequency current. Of late it has been my custom to apply the current intralaryngeally. It seems to have some curative effect in producing cicatrization. Applied for a longer period externally, it relieves dysphagia to a certain degree.

3. Radium. The local use of radium has been

followed by marvelous results, but they were *very exceptional.* Patients who have been exposed for half an hour felt free from pain for several months. In these cases there had been no cough and the lungs were but slightly affected. Even when all other means had failed, relief from pain for a day or for a few days frequently occurred. Yet, for obvious reasons we must avoid making promises in regard to this much abused and occasionally wonderful element. I have worked for ten years with radium and would refer to my publications.*

*Injections of Alcohol.*—There are cases in which not one of any of the therapeutic measures mentioned will give relief. For such sufferers, Rudolf Hoffmann of Munich was the first to use injections of alcohol into the superior laryngeal nerve. His aim was to produce analgesia of long duration.

The place where the superior pharyngeal nerve penetrates the membrana thyrohyoidea can be felt with the finger from the outside. If the patient be placed on his back and the larynx pushed toward the affected side the most painful spot can be determined with the finger. Here the needle puncture is made in a direct vertical line to the body, a little more toward the outer side. The needle is inserted to a depth of about 1½ cm., meanwhile feeling for the place where the patient complains of the greatest pain, and here the alcohol is injected. Hoffmann recommends 85 per cent. alcohol, and of a temperature of 45° C., equal to about 112° F. The same proportion has been used by me. After the subsidence of the initial pain, which is sometimes quite severe, another injection is immediately made. Hoffmann advises a strong and somewhat blunt needle, which is preferable, as it avoids the blood vessels and is less liable to break. It is well to tell the patient neither to swallow nor to talk until the procedure has been completed. If one succeeds in striking the external branch of the superior laryngeal nerve, one will obtain immediate amelioration of pain in many instances, the patient being able to swallow solid food and to drink water.

The treatment and supervision of laryngeal tuberculosis in private practice is often difficult and sometimes impossible. Yet in milder cases a good deal can be accomplished. The first thing is to make the patient's home as sanitary as possible, a task often difficult to fulfill. The second consideration is to relieve dysphagia and cough by any of the advocated means, which is at the disposal of the practitioner and if successful, he ought to be able to cure certainly 50 per cent. of patients afflicted with tuberculosis of the larynx in any stage.

If dysphagia cannot then be overcome the lack of proper nutrition will soon be evident and the patient will succumb to the disease. But before this critical event, all the means at one's disposal should be tried, one after the other. Optimism is nowhere so much indicated as in the therapy of tuberculosis, for it greatly assists the physician as well as the patient.

## OBSERVATIONS, BASED ON FORTY-FIVE YEARS OF ELECTROTHERAPEUTIC WORK.

By A. D. ROCKWELL, M.D.,

NEW YORK.

As fifty years of medical practice are now to my credit, forty-five of which have been devoted more or less to the study of electrotherapeutics, it has been suggested that I give some sort of résumé or conclusion relating thereto. Because of my partial retirement from the more active duties of professional work, I find myself the more ready to do this, and trust the opinions expressed will be received in the spirit in which they are given, both by those who believe little in, and care less for, the well-accredited values of this wondrous physical agent, as well as by those whose enthusiasm is so apt to carry them somewhat beyond the border of judicial estimates. In the Medical Record of November 15, 1866, will be found my first article relating to electricity in medicine, and entitled "Cases of Rheumatism and Neuralgia Cured by Electricity." If I had the title to write again, I would put it somewhat in this way: "Rheumatism and Neuralgia Treated by Electricity," or "Recovery Following the Use of Electricity." For while to cure, really means to care for, which, for the most part, is only what we physicians do, yet as commonly interpreted by the laity, it means something marvelously more.

Following this first effort, and running through the various issues of the Medical Record for 1867, were five articles on the "Medical Uses of Electricity," written jointly with Dr. George M. Beard. These articles were, if I recollect aright, reproduced in the London *Lancet* and in some of the German medical journals.

The only reason why they were thus honored was, in my opinion, not because of the so-called cases of cures recorded, but because of the enunciation and attempted demonstration of the rather new idea, that electrization was more than a mere irritant, useful to prick up paralyzed muscles, but possessing nutritional values of far-reaching importance. It is not my purpose, however, to review further these investigations, now a matter of medical history.

In looking over the therapeutic part, it is easy to see now how enthusiasm over apparent and immediate results, interfered with accurate deductions in individual conditions of disease. We followed too much the lines of least resistance, and failed to realize what every one must finally realize, that he cannot, except after the most careful training, be trusted either to observe or to report his observations with accuracy.

Even with the imperfect means for instrumentation possessed in those early days, we did, however, witness results both novel and interesting, and I remember when I first awoke to the fact that we had, even in the ordinary induction-coil a means of positively though inadequately influencing circulatory changes and nutritional activities, I was amazed to think that in all my medical training not one word of this was ever heard. Quackery was therefore rampant in the use of this agent.

Money was coined by quacks of every degree, and as in ophthalmology, quackery had a free field, until the profession, under the leadership of the lamented Agnew, took it in hand and banished the advertising eye doctor, so electricity in medicine under the guidance of reputable physicians, has become an unprofitable field for the pure charlatan. The respect,

or lack of respect, in which this agent and the medical man who dealt in it was held, is illustrated by the remark of a distinguished member of the State Medical Society. When I presented a paper for its consideration, he exclaimed, "Is this man regular?" But for the support of some minds more hospitable, it is doubtful whether it would have been accepted. In the seventies the field of electrotherapeutics became much enlarged by the freer utilization of what is commonly termed the galvanic current. Previously, the voltaic pile was the main dependence, rendering experimentation very unsatisfactory.

The only remark that I care to make about this neglected manifestation of electricity is, that it is a great pity that it should be so little used by those who claim mastership in this department. No man can rightly claim thoroughness in electrotherapeutics who has not mastered the technique of the use of the galvanic current.

Later occurred the recrudescence of static or franklinic electricity, first abroad, and later in this country, mainly through the efforts of Dr. Wm. J. Morton. It is a brilliant and impressive manifestation of electric force, and if we could give credence to the dictum of Moebius, that at least four-fifths of the cures effected by electricity are due to psychic influences, it might be believed of this modality more than any other. For myself, I can only say that after a continuous use of static electrification since its introduction, I am far from rating it like some others, as the most efficient form of electrical treatment. Far be it from me, however, to attempt to decry a faithful servant which has carried us far.

Though it possesses neither chemical nor cataphoric action, nor electrolytic effects of moment, yet it acts physically with wonderful vigor, and is either sedative or stimulant according to the method of its application. To say that its action is also psychic, is to speak only in its favor; and if as a purveyor of suggestion, electricity is of value, I am sure that none of its manifestations are fitted to give more interesting results in this direction than static electricity. But to my mind, we have in the development of the high frequency current, reached the high water mark thus far, in the application of electricity to disease. In considering this most interesting and truly wonderful manifestation of electric force, it is well to bear in mind that every form of electricity depends upon the resistance to its passage for the good or ill it does. If it meets with no appreciable resistance as in passing through a metal conductor, its effects are nil, but through the air it develops ozone, and through the living tissue, heat. All currents do this, but such modalities as the faradaic, galvanic, and static, cannot be efficiently utilized for this purpose, because of their powerful chemical, and neuromuscular effects. All these currents would kill, long before enough current strength was developed to give even a small fraction of the heat imparted to living tissue by a perfectly painless and even unappreciable diathermic application of the high frequency current.

In the death chamber at Ossining, with an alternating current of low frequencies, having a potential of 1,900 volts, sufficient to force three or four amperes through the body, a heat so intense is instantly developed under the electrodes as to be almost unbearable to the touch, and death is instantaneous.

With an ampere, or milliampere, strength almost equal to this, and a potential far in excess, the high frequency current on the contrary, develops very positive degrees of heat throughout the whole body, with only agreeable effects. It is seen, therefore, that the action of high frequency currents on organic compounds, living or dead, is most remarkable, and quite different from anything heretofore known in connection with electrical currents. Faradaic or static electricity passed through water, has little appreciable effect.

The galvanic current on the other hand, causes immediate chemical decomposition, while the high frequency develops extreme heat but with no electrolytic effect. A raw potato subjected to a powerful galvanic current, is burned only on the surface, and the electrolytic effects are seen mainly at the points of contact, while the effect of the faradaic current is nil, and the static, mechanical. On the other hand, the passage of one thousand milliamperes, more or less, of the high frequency current, develops not only a high degree of heat sufficient to cook the potato, but to cook it from within outward.

An egg with its shell on, is in the same way cooked from within outward, while if we pass the current through the white of an egg in a U-shaped tube, we see, in a few minutes, a coagulation of the central portion only.

Herein then, in addition to its pronounced calorific properties, consists the absolutely unique physical and physiological effects of high frequency currents on living as well as on dead tissue, viz., its action from within outward. On the surface of the body under properly adapted electrodes, we get profuse perspiration but little redness compared with the galvanic current, while calorific and circulatory changes are most marked within.

Therapeutically, the best results are not obtained through the autoconduction couch, useful as this method is, but in the use of large, flexible metal electrodes. The greatest care and nicety of adaptation is necessary in the placing of these electrodes. Let an air gap occur anywhere between the plate and the body, the resultant spark, even though minute, may cause a disagreeable excoriation.

It has been questioned whether by the diathermic method, there may not be some liability of overheating the interior of the body. This would seem to be quite impossible, for long before such a condition could be reached, the exterior heat would become altogether unbearable.

A possible exception to this rule is when the path of the current is through the cardiovascular centers, in the treatment of which it is well to observe caution. So much can be said therapeutically, about the high frequency current, that I shall content myself with saying very little, and this little along the broad, general principle of its action. Chronic diseases afford the widest field for its activities. These currents of high frequency, high potential and amperage which a few years ago would have been unbelievable, have developed new physical and physiological phenomena and greatly enlarged the sphere of electricity in medicine.

Now, as always, the fundamental idea of the therapeutics of electricity, is its nutritional influence.

As an energizing principle, it exceeds all other physical agents, because of its more powerful and far-reaching effects on the circulation, the secretory and excretory processes of the body, and on absorption. It adds a definite amount of calories of heat to the body, in a way altogether new and unthought of until recently. For the lowering of high blood pressure, and the relief of its many distressing symptoms, the diathermic application of the high

frequency current is invaluable. It is of course only in cases where the arterial changes are not too far advanced, that there is hope of permanent relief, but even then the effects are often ameliorative. I shall not, however, attempt to enumerate individual pathological conditions in which it is of service. A knowledge of its physical and physiological activities which I have tried to make clear should be a good guide for its therapeutic use.

It cannot be claimed that electricity in medicine has kept pace with electricity in commerce. If this were so, medicine might become really a science, rather than an art. It has, however, followed in its footsteps, if even at a distance, and every new development for its commercial use, is likely in the future as in the past, to redound to its value as a therapeutic agent.

Why is not electricity more extensively used in our hospitals and public institutions? Perhaps, the truth was partly given expression in a remark made to me some years ago, by a distinguished surgeon, who had requested me to accompany him to a hospital with which he was connected, and administer this agent. The apparatus was there, but he did not believe in "hospital electricity." The inference was plain. The internes to whom was left this method of treatment, had no more exact training in the matter, than have those who generally administer electricity in our large private sanatoriums, or the nurses who are often called upon. But that it may be made useful I have exact knowledge. For a dozen years or more back in the seventies and eighties, the writer was the electrotherapeutist of the Women's Hospital in the State of New York.

The position was no sinecure, and in looking over the records of the great number of cases treated in those years, I am reimpressed with the fact that a very useful work was done there, even with the incomplete apparatus then available.

Flushing.

## CESAREAN SECTION.

### THREE METHODS OF PERFORMING THE OPERATION WITH ILLUSTRATIVE CASES.*

By S. J. DRUSKIN, B.S., M.D.,

NEW YORK.

INSTRUCTOR IN GYNECOLOGY AND ATTENDING GYNECOLOGIST, FORDHAM UNIVERSITY MEDICAL SCHOOL; ATTENDING OBSTETRICIAN, SYDENHAM HOSPITAL; ASSOCIATE SURGEON, JEWISH MATERNITY HOSPITAL

The field for purely obstetric operations is becoming more and more limited. This is the result of increased experience in the management of cases of dystocia, of a fuller knowledge of their outcome, and of a better appreciation of the dangers incident to obstetric interference. The field for surgical operations, on the other hand, has correspondingly widened, and a number of new surgical procedures have been devised. It is not the intention of this paper to describe the various surgical procedures, but rather to briefly discuss the three leading methods of performing cesarean section applicable to certain cases of dystocia.

Case I.—Classical cesarean section with sterilization. Mrs. R. K., age 25, Para, III.; no history of rickets. First child delivered by cesarean section at Bellevue Hospital December 27, 1910. Patient did not do well and was confined to bed for four weeks. The second child was also delivered by cesarean section at the Sloane Maternity Hospital, July 24, 1912. Patient had a very stormy recovery, was bedridden with chills and fever for eight weeks, and left the hospital at the end of three months. It took six months for the abdominal wound to heal. In both cases, she was operated before labor had set in. She menstruated first at 14, regularly every two weeks, duration 1½ days, very scant and without pains. Last menses, April 10, 1913, as usual. Date of expected confinement January 17, 1914. Examination showed a generally contracted pelvis.

January 16, 1914, patient was at full term. Had already had two cesareans; the last one in particular running an unfavorable postoperative course. I suspected an imperfectly healed uterine scar, and therefore did not permit patient to go into labor, and decided on a classical cesarean section with sterilization against further pregnancy.

*Operation.*—At the outset, pituitrin and ergot, 1 c.c. of each were given intramuscularly. A median incision was made, beginning at the umbilicus and extending upwards 14 centimeters. Extensive firm adhesions between the abdominal wall and uterus were encountered. Above, near the fundus, the omentum adhered to both the abdominal wall and uterus. Owing to the firm attachment of the uterus to the abdominal wall, I carried the incision downwards an additional 14 centimeters. Found adhesions between the sides of the uterus and the intestines. Separated all adhesions, and freed the uterus. Examined uterus for previous cesarean scars, but they were not discernible. Uterine wall appeared to be firm. A median incision of the uterus 12 centimeters long was made, child extracted, and placenta removed manually. Uterus contracted firmly into a ball and there was very little bleeding; closed uterine wound with interrupted catgut sutures, taking in the entire thickness of the uterine wall, except the mucosa. Covered these with interrupted Lambert sutures. As the suturing progressed, the work was rendered more difficult by the gradual thickening of the uterine wall, reaching a thickness of 5 centimeters. A portion of the right tube and a wedge-shaped part of the right cornua, were excised. There was some bleeding from the cornua; the wound was sutured and covered with peritoneum. The left tube was extirpated in toto, including its insertion into the uterus, with little or no bleeding. Covered the raw surfaces with peritoneum, and closed abdominal wound in two layers. The postpartum period was uneventful. The abdominal wound healed by primary union except for a small section near the umbilicus where it encountered the old scar. Patient was out of bed on thirteenth day, and left the hospital on the nineteenth day.

An examination made on April 11, 1914, showed two broad ugly scars on either side of the median line, and a fresh lineal scar, twice as long as either of the others. The fundus uteri was about a finger's breadth below the end of the scar. The cervix was above the symphysis and the uterus seemed to be attached to the abdominal wall. Patient felt well.

The deductions to be drawn from this case are: (1) The classical cesarean section is fraught with great risk. This patient was operated upon on two occasions, under the most favorable conditions, and in the service of two of the most eminent obstetricians in New York, and yet passed through recoveries more or less stormy. (2) Because of this danger, patients who have had two or more cesareans should be protected against further pregnancy by sterilization. This case also demonstrates to a marked degree the effectiveness of pituitary extract on the uterus. This extract, especially if given in combination with ergot, will cause contractions of the uterus even before labor has begun.

Generally speaking, the elective classical cesarean is indicated (1) in cases of absolutely contracted pelves, (2) in cases where a cesarean section has already been performed, and (3) in multiparas with slight contractions of the pelves, where under the guidance of expert obstetricians the patients have failed to deliver living children by the natural route.

Case II.—Extraperitoneal cesarean section. Mrs. J.

*Read before the Eastern Medical Society, April 17, 1914.

G., aged 21, Para I, was admitted to the Sydenham Hospital, January 11, 1914, at 6.30 A. M. The patient, a short slender woman, stated that she had been having labor pains every 10 minutes for the preceding 6½ hours and that the membranes had ruptured just prior to her admission. No history was given of rickets or other diseases bearing on the case.

*Examination.*—Pelvis generally contracted. Measurements: interspinous 19.5; intercristal 26; intertrochanteric 31; conjugate diagonal 10 minus; conjugate vera 8¼; double promontory, moderately projecting. The internal os was obliterated; the external os admitted one finger; head of child above the brim; back to the right; small parts to the left. Liquor amnii dribbling away. Labor pains continued, but descent into the pelvis did not take place. January 13, at 11.45 A. M., patient received pituitrin five minims, intramuscularly. Pains became strong; half hour later came a gush of liquor amnium. The last examination made at 2 P. M. showed the ext. os four fingers dilated; membranes ruptured; head well fixed with large diameter in the pelvic inlet. At 4 P. M. thinning of the lower uterine segment having occurred and the fetal heart sounds being good, extraperitoneal cesarean section was decided on. Patient had been in labor 63 hours. Preliminary filling of the bladder having been unsuccessful, was dispensed with.

*Operation.*—A median incision was made two centimeters above the symphysis and extending upward 12 centimeters. Incision of the fascia; separation of the recti muscles; separation of the prevascular connective tissue; separation of the bladder from the lower uterine segment on the left side; incision through the ligamentum umbilicalis sinistra; separation of the peritoneal fold from bladder as far as the urachus, sharp and blunt; separation of the peritoneal fold from the lower uterine, segment on the left; retraction of the bladder to the right. A plexus of large veins was exposed without injury or bleeding. Median incision of the lower uterine segment, 10 to 12 centimeters long. The right ear presents; finger put into mouth and face rotated anteriorly; forceps applied bilaterally; head extracted by flexon with ease; body follows. Child cries. Placenta removed manually; uterus well contracted; bleeding minimal. Cervical incision closed by running catgut suture, taking in the entire thickness of the cervix and was covered by a second layer of interrupted sutures. The bladder was replaced and fixed above to the peritoneal fold and at the left to the pelvic connective tissue. Drain was inserted; abdominal wound closed in three layers. At the time the uterus was incised, patient received Pituitrin 1 c.c. and Ergot 1 c.c. intramuscularly.

*Postoperative History.*—The condition of the patient, the next day, was very good. Although it was necessary to catheterize her several times during labor, she now was able to urinate spontaneously in spite of the extensive separation of the bladder. The patient complained of hunger and of not getting enough nourishment. The drain was shortened daily and removed entirely on the fifth day. The patient was out of bed on the seventh day. Except for a bronchitis contracted on the fifth day, patient was well. Examination made February 17 did not show any general or local disturbance.

Before referring his patient to the surgeon for cesarean section the general practitioner might bear in mind the following facts: (1) Delivery occurs spontaneously in over 80 per cent. of all cases of contracted pelves, and that even in marked degrees of contraction (C. V. = 7 — 7½) delivery is spontaneous in 50 per cent. of the cases. (2) That in such cases of contracted pelves where delivery is spontaneous, the maternal mortality is one or less in a thousand. (3) That the maternal mortality of those delivered by cesarean section is always comparatively high. Even the most favorable records show a mortality of 1 per cent and over. It would seem then, from the above facts that if every case of contracted pelvis were cesareanized, at least eight cases out of every ten would be subjected to a serious operation unnecessarily, and that even in marked degrees of contraction (C. V. = 7 — 7½) every second case would be operated on needlessly.

What then, should be the management of a case of contracted pelvis? It must be laid down as a rule that every case of contracted pelvis should be referred to a hospital for confinement; firstly, in order that the physician in attendance may not be subjected to interference on the part of the family and forced to go counter to his better judgment, and secondly, that he may be in position to meet the demands of the case properly should intervention be deemed necessary. The management of the caes in the hospital should be conservative. The physician in charge should be clear as to the things he must not do. Then only will he be unlikely to err as to the things he should do. The "don'ts" may be enumerated as follows:

(*a*) Do not make repeated vaginal examinations during labor; first, because the necessary information can be obtained and the progress of the case followed by a careful external examination supplemented if necessary by rectal examination, and, second, because even the most careful vaginal examination lowers the asepsis and renders the patient less fit for cesarean section in case the operation is decided on.

(*b*) Do not perform a high forceps operation in contracted pelvis; first, because the use of the forceps in such cases violates a fundamental principle of physics, namely, a reduction in one diameter of a solid spherical body involves a corresponding increase in a diameter perpendicular to it and vice versa. The head enters the pelvic inlet with the biparietal or bitemporal diameters corresponding with the anteroposterior diameter of the pelvis, the frontooccipital lying in the transverse or oblique diameter of the pelvis.

The obstruction to the head occurs at the anteroposterior diameter, but the forceps can only be applied to the frontooccipital diameter. This application of the forceps will cause an increase in the biparietal diameter, the very diameter which has to be reduced to make the passage of the head possible. In fact the greater the contraction of the pelvis and consequent resistance to the pull, the greater will be the tendency to increase the biparietal diameter owing to the firm grip of the forceps on the frontooccipital diameter. Second, do not perform a high forceps because the results are very bad, the majority of the children dying during extraction, the mother usually being crippled for life if she is fortunate enough to survive.

(*c*) Do not perform a prophylactic version, first, because it is a disputed question whether the aftercoming head will pass through the inlet more readily than the forecoming head, and, second, because the mortality of the children is high and the results to the mother, especially if a primipara, are serious on account of sepsis and injury to the pelvic floor.

(*d*) Do not perform induction of labor, first, because it is suitable only for the minor forms of contractions where spontaneous delivery is fully 80 per cent. and, second, because the maternal mortality through sepsis is higher than in properly managed cases of cesarean section, and, third, the mortality of the children during the first two weeks is unusually high.

(*e*) Do not perform hebosteotomy or pubiotomy on a primipara on account of the injury to the soft parts. In a multipara, where these have been well stretched, it is only permissible when the disproportion between the head and the pelvis is slight, and where the asepsis is doubtful.

(*f*) Do not perform craniotomy on the living child except where symptoms of infection are already manifest.

Having given the natural forces a trial, having strengthened the labor pains by the administration of pituitary extract, having perhaps aided descent of the head into the pelvis by rupturing the bag of waters, and having increased the anteroposterior diameter of the inlet by the Walcher position, and having after all these procedures and maneuvers failed to deliver the child by the natural route, we still have at our command an operation that is relatively safe and efficient, namely, the extraperitoneal cesarean section.

Case III.—Vaginal cesarean section or anterior hysterotomy. Mrs. R. G., age 30, Para III., was admitted to the hospital December 20, 1913, on account of uterine bleeding. The patient had been suffering from biliary colic for ten years, last attack four weeks before admission. Had two children, both pregnancies and labor normal; no miscarriages, no abortions. First menses at 12 years, regularly every 28 days, very profuse, lasting 4 days. Patient did not remember date of last normal menstruation, having stained or bled slightly at each expected menstrual period, but she considered herself pregnant about four and half months. Two weeks prior to above date, the patient bled profusely. One week later there was an escape of liquor amnium, and patient bled up to the time of admission.

*Treatment.*—The patient was put to bed and sedatives were administered. December 23: Patient bled and morphine was given hypodermically. December 28: She bled profusely and was packed. December 29, 3 A. M.: Packing was expelled, bleeding recurred and she was repacked.

*Examination.*—December 29, 10 A. M.: Pulse was 92, temperature 100.6°. Fundus was one to two fingers' breadth below the umbilicus. No fetal heart sounds elicited. Bled from vagina. External cervical os admitted two fingers; internal os, one finger; cervical canal long and rigid. Membranes ruptured, body of fetus presenting. Lower edge of placenta was palpated at the left margin of the internal os.

*Diagnosis.*—Five and a half months pregnancy; protracted miscarriage; placenta prævia lateralis.

*Operation.*—The cervix dilated manually to admit two fingers. Further dilatation having been unsuccessful, vaginal cesarean section was proceeded with. The cervix was well exposed. The portio vaginalis was grasped with tenaculli forceps on both sides. It was drawn down well into the vaginal orifice. A transverse incision was made through the mucous layer over the anterior wall of the portio, two centimeters above the external os. The bladder was separated up to and beyond the internal os. A median incision was made through the entire anterior wall of the cervix beyond the internal os. The fetus and placenta were removed manually. The uterus was irrigated with a one per cent. iodine solution. The patient was given pituitary extract 1 c.c. intramuscularly. The cervical wound was closed with plain interrupted sutures taking in the entire cervical wall except the vaginal mucosa. Especial pains were taken to suture the upper angle of the wound with precision. All bleeding was checked by ligature or suture. The vaginal mucosa was closed transversely except for a small opening to admit a drain. An iodiform drain was inserted into the vaginal wound and another into the uterine cavity. The vagina was packed.

*Postoperative History.*—December 30: Packing and drains were removed. January 3: Patient was out of bed. January 7: Wound healed by primary union. Patient was discharged.

A vaginal cesarean section may be defined as a delivery through the natural route by incision of the uterus. I would limit its application to periods of pregnancy beyond the twenty-eighth week, when the fetus is already viable. For periods under twenty-eight weeks the designation anterior hysterotomy I deem more appropriate. The case reported therefore was one of anterior hysterotomy. The operation was decided on, firstly, because it was a prolonged case of threatened miscarriage, secondly, it was complicated by placenta previa, thirdly, patient was not only bleeding, but also running slight temperature, and manual dilatation proved unsuccessful.

Heretofore the curette has been used almost exclusively as a therapeutic instrument. The best practice of today, however, has discarded it for this purpose, except in the earliest periods of pregnancy. It is now used principally as a diagnostic instrument. In more advanced stages of pregnancy the practice of the most eminent surgeons in cases of induced or threatened abortion is to empty the uterus manually, inserting one or two fingers into the uterine cavity. Where manual or instrumental dilatation is difficult and insufficient, cutting of the cervix is resorted to.

Of the various methods in vogue for the treatment of placenta previa, the surgical procedures, in contradistinction to the purely obstetrical methods, have given the best results. Where there is a viable fetus and dilatation of the cervix has not set in or has just begun, the abdominal cesarean section is the operation of choice. However, where dilatation has progressed, and the patient has been handled, the vaginal cesarean is more advisable. Caution must be observed to extend the incision sufficiently up into the uterus to obviate the possibility of tearing during extraction. The vaginal cesarean is also employed in other conditions where rapid emptying of the uterus is deemed advisable, such as eclampsia, premature separation of placenta, and sometimes where the heart, lungs, or kidneys are diseased.

*Conclusions.*—(1) In the lesser degrees of contracted pelves, conservative treatment gives the best results, for both mother and child. (2) When interference is called for, the cutting operations should be chosen in preference to the purely obstetric operations. (3) The classical cesarean section should be reserved for elective cases of contracted pelves and for clean cases of placenta previa. (4) The extraperitoneal cesarean should be the operation of choice in cases that have been handled by outsiders, and in cases that have been a long time in labor with ruptured membranes. (5) Pubiotomy should have a limited application. (6) The vaginal cesarean section may be advantageously substituted in the majority of cases for the stretching and tearing operations, whenever rapid emptying ofthe uterus may be desirable, and in placenta previa where dilatation has progressed but is incomplete.

107 West One Hundred and Eighteenth Street.

## TOBACCO AMBLYOPIA.

By GEORGE W. VANDEGRIFT, M.A., M.D.,

NEW YORK.

INSTRUCTOR IN OPHTHALMOLOGY, CORNELL UNIVERSITY MEDICAL COLLEGE; ASSIST. SURGEON, N. Y. EYE AND EAR INFIRMARY; ETC.

While the subject of the toxic influence of tobacco on the optic nerves is described fairly thoroughly in the text books of ophthalmology, it is seldom mentioned in the general medical literature of the day. The disease is more prevalent probably than ophthalmologists suspect, for in its slight manifestations it is present in many men whose occupations do not necessitate its discovery. When the only symptom is a very small red-green blind area over the fixation points of the eyes the disease is very apt to be overlooked, except in engineers and others

in whom quick and accurate perception of colored signals is a prerequisite to their continued employment. This early stage of macular red-green color blindness may persist for several months before diminution of vision begins, at which time the great majority of the cases are discovered or brought to the physician's attention. Indeed, most observers claim that diminution of vision is the first manifestation of the disease, developing before the scotoma. This claim is based on the fact that almost all cases have some diminution of vision when seen, the incipient cases with normal vision and the red-green scotoma being almost unknown.

The disease is usually found in men about or after the age of thirty-five, and more frequently in pipe and cigar smokers and chewers than in cigarette smokers. The latter class more easily escapes probably first because there is no absorption through the mucous membrane of the lips, the paper wrapper serving as protection, and second, because of the rapid and almost complete combustion of the tobacco. The amount of tobacco necessary to cause the disease varies greatly, as some men are affected by very moderate amounts, while others exhibit the disease only after prolonged immoderate consumption. As tobacco amblyopia is more prevalent among men of small incomes, such as laborers and artisans, it may be that the cheaper varieties of tobacco are more prone to cause the disease. As smokers are generally to a greater or less extent consumers of alcoholic drinks, the latter intoxicant by many is considered an accessory before the fact. The etiological influence of each of these drugs is difficult to separate, for while we have undoubted cases of alcoholic retrobulbar neuritis, and undoubted cases, though few in number, of tobacco retrobulbar neuritis, the great majority of cases use the two drugs to a more or less equal extent. But we at the present time will restrict our discussion to those cases due to tobacco alone.

To determine the toxic substances in tobacco that cause the inflammation it is necessary to take into account not only ingestion into the system by means of the smoke but also absorption through the mucous membrane of the mouth and lips from direct contact with the cigar and chewing tobacco, and also absorption through the skin of those who work in tobacco factories and do not use it in any form of indulgence. Most experiments on tobacco have been made to determine the substances that produce toxic effects on the general system, particularly through the agency of smoke, neglecting the fact that absorption often takes place from direct contact of the tobacco through mucous membrane and skin. These substances that produce harmful general effects and result from the combustion of the tobacco have been fairly accurately determined, but whether they produce retrobulbar neuritis also we do not know; we can only surmise that they do.

Tobacco smoke has been analyzed and found to contain many substances in themselves toxic, such as carbon monoxide, and dioxide, marsh gas, hydrogen sulphide, hydrogen cyanide, furfurol, phenols, pyridine, empyreumatic oils and a trace of nicotine. Most of these substances, such as hydrogen cyanide, furfurol, and empyreumatic oils, produce general weakness, nausea, and headaches, but the quantity present in smoke is so very small that they cannot produce serious effects except by accumulative action. A short time after a cigar is smoked carbon monoxide is found in the blood, a poison of well-known properties. The most toxic substance in the smoke is pyridine, which is found in the largest quantity. Nicotine, upon which the odium of guilt ever has been laid, always can be found to some extent. In the burning ashes at the cigar end it is quickly and completely destroyed, leaving no poisonous intermediate substances. Just behind the glowing end is a region of high heat, where the nicotine is volatilized as it would be in a retort over a bunsen burner and here the poisonous substances before mentioned are manufactured, particularly pyridine. A little behind this region the nicotine is not destroyed, but carried as such in the smoke. Through chewing and through absorption from the moistened end of the cigar in the mouth, and through the skin of the hands of workers in tobacco the nicotine is absorbed probably in pure state. It appears likely, therefore, that nicotine and its decomposition products, particularly pyridine, cause the systemic symptoms of tobacco poisoning and the retrobulbar neuritis of tobacco amblyopia.

The length of time required for the production of tobacco amblyopia is difficult to ascertain for many reasons, chief of which is that smoking as a rule begins at an early age, and the incipiency of the disease is apt to pass unnoticed. Nettleship has reported a case that developed in three years, and the case I will report later in this paper developed the disease in less than two years, the habit of smoking having been acquired more than twenty-five years before.

Tobacco amblyopia is a chronic retrobulbar neuritis similar in pathology and symptomatology to the retrobulbar neuritis that may develop from the use of stramonium, chloral, opium, chloroform, arsenic, lead, iodoform, cannabis indica, and from the toxin of diabetes. Tobacco may produce sudden acute blindness, which is extremely rare and needs no further mention here.

The lesion of chronic retrobulbar neuritis has been found by several observers to be in the macular bundle of nerve fibers in the optic nerves chiasm and tracts. The primary inflammation is a parenchymatous neuritis that later is followed by an increase of neuroglia and interstitial connective tissue. It has been suggested that the lesion begins in the retina at the macula and travels thence along the macular bundle of nerve fibers. Clinically this is born out by the fact that in a few reported cases the first symptom discovered was a red-green scotoma that persisted for some time before diminution of vision commenced. Not all the fibers of the macular bundle are affected, for while the scotoma for red and green may be complete, that for form is very rarely absolute.

The symptoms of tobacco amblyopia are general and local. General subjective symptoms may be absent entirely or consist of irritability, insomnia, general weakness, and impairment of digestion. The first local symptom noticed as a rule by the patient is impairment of vision. He seems to be looking through a fog, and sees relatively better by subdued light when the pupils are dilated, a fact long ago recognized and used to name the disease, "amblyopia nyctalopia." Rarely does the patient notice the macular defect for red and green unless his occupation is such as demands careful differentiation of colors. The objective symptoms are so clearly defined as to make the disease, chronic retrobulbar neuritis, a distinct entity. Externally the eyes present no pathological appearances. The nerve head may show also no untoward appear-

ance, though it may present a paleness in the outer and lower quadrant, especially late in the course of the disease. Rarely we see cases in which the nerve head shows a mild neuritis. In alcoholic amblyopia congestion of the disc is a common though not constant occurrence.

Peripheral vision for form and colors is always normal except in very old cases where atrophy has intervened or where syphilis has been a concomitant cause. Central vision is diminished according to the time the disease has lasted. It may vary from little or no diminution in incipient cases to the perception of form only in old cases. Usually as we see the cases the vision varies from 20/50 to 20/200.

The pathognomonic symptom of retrobulbar neuritis, whether caused by tobacco or other toxic agent, is a distinctive defect, or a scotoma in the center of the visual fields. This scotoma is for red and green, and beginning over the fixation point, spreads towards the normal blind spot in an oval manner. At times perception for red and green is abolished on the temporal side. Within this scotoma perception of red and green is absent, though form is recognized with more or less reduction, depending on the diminution of vision. Usually there is a scotoma in each eye of similar aspect, but at times we find one more advanced than the other; and in the incipiency of the disease we may find only one scotoma, color perception in the macula of the other eye being present but sluggish. Of course, in making the test for color scotoma we must be careful to determine the absence of congenital red-green color blindness, a condition which is characterized by color blindness over the whole field, while in retrobulbar neuritis the blindness is limited to the scotoma around the fixation point.

It may not be amiss at this point to report a case of retrobulbar neuritis due to tobacco that exemplifies many of the points brought forward in this paper:

An engineer, forty-five years of age, consulted me for an examination of his eyes because he had failed in his examination in signal work on the railroad. Every two years for the past twenty-five years, during which he was in his present situation of engine driver, he had passed successfully the examination to test his acuity of vision and color perception. At his last examination, held one week before I saw him, he had been rejected for failing to read quickly and accurately the colors as flashed by a William's signal lantern. On my examination I found the following: Vision of both eyes normal. All structures of the eyes normal in appearance, including the nerve heads. In the field of vision of the right eye was a scotoma for red and green, discoverable by means of small pieces of red and green paper about 0.5 mm. square held 30 cm. before the eye. Larger pieces of paper, 2 mm. square, were recognized after two or three seconds display. The scotoma for the colors was absolute over the fixation point only, perception being dull towards the blind spot. The peripheral color perception was normal. If the papers were moved slowly before the eye from side to side the colors were perceived very slowly, and this was probably the reason for his rejection at the examination, for he had no difficulty in recognizing large colored objects stationary or mobile. In the field of vision of the left eye a difference was noticed. At the fixation point was a scotoma for green, but red was recognized after an appreciable interval of time and concentration. All other parts of the fields were normal.

The patient was nervous, sleepless and worried over the prospect of being permanently discharged from his work unless cured within a short time, having been promised a re-examination in a month's time. He was in perfect general health, no lesions of any organs being discoverable. Wassermann reaction was negative. He had never taken alcohol in any form, a statement proven by his wife and the evidence of many friends. He had smoked about six cigars and six pipes of tobacco a day for the last thirty years.

Here a diagnosis of retrobulbar neuritis of tobacco origin was positive. Tobacco was stopped and the patient received hyperdermically 1/40 gr. of strychnine sulphate daily. At the end of one week the scotoma presented the following: Right Eye—Scotoma for red absolute; green perceived sluggishly. Left Eye—Red and green both perceived, though slowly. At the end of two weeks: Right Eye—Red perceived slowly at fixation point; green normal. Left Eye—Red and green normal. At the end of three weeks red and green were perceived normally in both eyes. For all of these tests pieces of green paper 0.5 mm. square were used. Acuity of vision at all times normal.

This case presents several points of interest besides the positive diagnosis. It showed that the scotoma began before any loss of vision developed. It showed that the disease probably developed subsequent to the examination held two years before. It showed that pallor of the lower outer quadrant of the nerve head is probably a late manifestation; and also it showed that very likely perception of green is the first to be lost and the first to return, a manifestation frequently observed.

The prognosis of tobacco amblyopia is excellent even in cases of long standing. It may be necessary to persist in treatment for many weeks before improvement commences, and many months may pass before a complete cure is attained, though six to eight is sufficient time in which to cure the average case. Not only is a cure almost always possible, but a relapse is almost unknown, even though the patient returns to the use of tobacco in large quantities.

Strychnine is considered the best remedy for the disease outside of the abstinence from tobacco. The drug must be begun with the average doses, but as quickly as possible pushed to the physiological limit. It is also necessary to combat the patient's irritability, worry, and general debility that may be present.

## THE PROVOCATIVE WASSERMANN REACTION.

By MARSHALL CARLETON PEASE, JR., M.D.,

NEW YORK.

INSTRUCTOR IN PEDIATRICS AND CLINICAL PATHOLOGY AT THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; CLINICAL PATHOLOGIST TO THE RED CROSS HOSPITAL AND THE RANDALL'S ISLAND HOSPITAL FOR CHILDREN.

The Wassermann reaction is not now believed to be specific in the strict sense of the word, although the "provocative" Wassermann seems to have some claims for specificity. In any case it has been conclusively shown that less than 30 per cent. of primary syphilitics show a positive Wassermann reaction during the first week of the disease; and at the end of the fifth week nearly 20 per cent. of undoubted cases are still negative. In a series of 125 cases tested at Washington ten were negative at the end of two months. In the secondary stage of syphilis from 90 to 95 per cent. of the cases are positive, the variations in the figures depending on the type and severity of the treatment and, to a certain exent, upon the technique used. If the treatment has been inadequate the higher figure will be approximately correct, leaving about 5 per cent. of negative reactions in the secondary stage not accounted for by the Wassermann test. In the tertiary stage of cases having symptoms from 85 to 90 per cent. are positive; while in the latent

stage the number of positives fall off to about 65 per cent. These last cases present no symptoms, and in most instances the test is made to determine whether or not the disease has been cured.

It will be noted from these statistics, which have been gathered from many sources, that it is possible to have a negative Wassermann reaction at any stage of syphilis, even though symptoms are present and it is possible to demonstrate the presence of living spirochatæ in the open lesion. A second test is demanded in all stages of syphilis after a weak positive. This second test should be made after a more or less brief interval. Under certain conditions there are a few diseases which tend to give a weak positive, but it is the common opinion that a full positive reaction in a non-syphilitic case is at the least suggestive of imperfect technique and demands a second application of the test. A single negative reaction is of no value in excluding syphilis, and it is only when such a reaction has been obtained on repeated examinations, extending over a period of at least a year that it can be considered as good evidence of the absence of the disease. Even under such circumstances it is well to have the result corroborated by the luetin test and the provocative Wassermann test.

It is perhaps unfortunate that luetin is not within the reach of every physician, for it is a test of no little delicacy in the later stages of syphilis, and is simple in its application. The provocative Wassermann, however, apparently gives even better results than the luetin test in the late stages of syphilis, and besides has a wider usefulness in that it is applicable to primary, secondary, and tertiary conditions that give a negative reaction to the ordinary Wassermann test.

The test is carried out with 0.4 grams of salvarsan or 0.6 grams of neosalvarsan. The blood should be taken immediately before the injection and on several following days. It has been found that the test is most apt to become positive on the two following days, but occasionally does not appear for seven or more days. A fairly safe rule for obtaining specimens is to take the blood during the forty-eight hours immediately following the injection and again after seven and fourteen days.

It has long been known that in a syphilitic a negative Wassermann could be converted into a positive one by an injection of salvarsan. Gennerich and Milian in 1910 first suggested that advantage be taken of this fact for diagnostic purposes, but it is only recently that the possibilities of a provocative Wassermann have interested more than a select few of the profession. An analogous effect to the provocative Wassermann is seen in the so-called Herxheimer reaction—or the accentuation of the clinical symptoms of the disease immediately following treatment with salvarsan. The "provocative" Wassermann can be obtained in every stage of the infection; in the early chancre stage before the ordinary Wassermann reaction is positive, a provocative Wassermann may be very strong. A negative in the secondary stage may be changed into a positive provocative test. It is, however, in the tertiary and latent stages of syphilis that the reaction is of most value. The probable explanation of the test is that when the spirochetæ are killed their toxic action is temporarily increased with a corresponding increase of the bodies concerned in the Wassermann reaction. It is fair at the present time to assume that a positive Wassermann indicates the presence of living spirochætæ, and therefore a positive provocative test is proof that the patient is not cured and needs further treatment.

The importance of the test is clearly indicated in the following series of cases:

| Case | Diagnosis | Wassermann | Luetin Test | Provocative Wassermann |
|---|---|---|---|---|
| 1 | Initial lesion 3 weeks ago | Negative | Not made | Positive |
| 2 | Initial lesion 4 weeks ago | Negative | Not made | Positive |
| 3 | Initial lesion 6 weeks ago | Negative | Not made | Positive |
| 4 | Initial lesion 6 weeks ago | Weak positive | Not made | Positive |
| 5 | Initial lesion 8 weeks ago | Weak positive | Not made | Positive |
| 6 | Initial lesion 12 weeks ago | Negative | Doubtful | Positive |
| 7 | Initial lesion 12 weeks ago | Weak positive | Doubtful | Positive |
| 8 | Initial lesion 16 weeks ago | Weak positive | Weak positive | Positive |

| Case | Diagnosis | Treatment, Years | Wassermann | Luetin Test | Provocative Wassermann |
|---|---|---|---|---|---|
| 9 | Ext. rectus palsy, Argyll-Robertson pupil | 3 | Negative series, after a positive | Positive | Positive |
| 10 | Cong. syphilis | 3 (?) | Negative | Positive | Positive |
| 11 | Congsyphilis | 3-4 (?) | Negative | Not made | Positive |
| 12 | Specific throat | 2 | Negative | Not made | Positive |
| 13 | No symptoms. History of infection many years ago | 3 | Negative | Negative | Negative |
| 14 | No symptoms. History of infection many years ago | 1 | Negative | Negative | Negative |
| 15 | No symptoms. History of infection many years ago | 1 | Negative | Negative | Negative |
| 16 | No symptoms. History of syphilis | Little | Weak positive | Positive | Positive |
| 17 | No symptoms. History of syphilis | Indefinite | Negative | Positive | Positive |
| 18 | No symptoms. History of syphilis | Indefinite | Negative | Positive | Positive |
| 19 | Optic nerve atrophy. History of syphilis | 2 (?) | Very weak, positive | Not made | Positive |
| 20 | Epithelioma of tongue. History of syphilis | Unknown | Negative | Negative | Negative |
| 21 | Specific laryngitis | 1 | Negative | Doubtful | Positive |
| 22 | Paralysis of ext. rectus | 1-2 | Negative | Not made | Positive |
| 23 | Iritis, specific | Unknown | Weak positive | Positive | Positive |
| 24 | Congenital | Unknown | Weak positive | Positive | Positive |
| 25 | Spinal cord lesion (specific?) | None | Weak positive | Positive | Positive |
| 26 | Spinal cord lesion. No history of syphilis | None | Negative | Negative | Negative |
| 27 | Beginning tabes | Unknown | Negative | Positive | Positive |
| 28 | Tabes | Unknown | Negative | Doubtful | Positive |
| 29 | Congenital. Tertiary ulcers | Unknown | Negative | Not made | Positive |

These cases have been gathered from many sources. The majority of them were incidental to routine examinations of private patients sent for a Wassermann test, in which the evidences of a syphilitic taint were so well known as to warrant energetic treatment in spite of a negative Wassermann reaction, or because there was a positive luetin test. A very few of them have deliberately received an injection of neosalvarsan or salvarsan in order to determine the question of a cure. In one of the (negative) cases treatment

was instituted without any expectation of beneficial results as a desperate measure. The lack of intention in this series is a fault which is of no little importance in interpreting the provocative Wassermann test. A considerable number of known syphilitic cases in which the symptoms and treatment have been followed by the clinician from the beginning should be subjected to the test. It is also granted that this series is inadequate as regards numbers and that the group is in a manner a selected one. It would have been of more value if it had been a consecutive series of thirty or more cases known to have had syphilis.

It has seemed worth while, however, to bring these particular cases together as proof that the test has a real place in the diagnosis of certain obscure cases of syphilis and as emphasizing the now accepted fact that treatment may change a negative Wassermann into a positive one. The test appears to be fully as reliable as the luetin test, so far as any conclusions can be drawn from these cases in which both tests were made. The indications for a provocative Wassermann test are (1) a doubtful positive reaction and (2) a negative test in the presence of a history or symptoms which point to a syphilitic infection. As has already been stated a positive Wassermann indicates the presence of living spirochetes and therefore a negative provocative Wassermann reaction is the best evidence available at the present time of the actual cure of syphilis.

109 West Eighty-seventh Street.

## THE PREVENTION OF PSYCHIC TRAUMA.

By HENRY S. MUNRO, M.D.,

OMAHA, NEB.

A LAD, eleven years of age, went with his parents from a Southern State to a city in the middle West. Upon his first day at school the boys gave him a "rolling," by turning him over and over, many times, on the grass, as was their custom to do with each new boy at that school. They dealt with him rather roughly. When his father came home that evening the boy related the incident and seemed to feel somewhat humiliated by the experience. His father only laughed, and replied: "I'm sure that they are a great bunch of boys, and that you will enjoy their association when you come to know them well; now, you go and help roll another boy to-morrow."

On his second day in school, as well as on the third, the experience was repeated, and the father was unable to persuade the child that such experiences, if rightly interpreted, would be of inestimable value to him. The boy's appetite was disturbed, and he seemed restless and unable to sleep soundly. The morning of the fourth day, he frankly stated to his father that he did not desire to return to school, for, said he: "I do not like such treatment, and there is not another 'new boy' for them to roll."

"All right," replied the father, "you will not have to let them roll you any more; come with me and let's see what we can do to bring about a cure of such thoughtless conduct on the part of those boys, who should be taught to behave better."

The father and the lad proceeded to a hardware store and purchased an effectual fighting tool, in the form of a good pocket knife. Taking the boy aside, the father addressed him as follows: "Now, my boy, when the bunch proceed to deal with you again, you sail into them with this knife, and jab it into their eyes, or stomachs, or faces, or hearts, and *cut for all that you are worth*. But listen: Do not cut them until you have given them fair warning not to roll you on the grass again. Now, if you allow them to roll you any more, I will take a part in your punishment in a manner that you will not soon forget."

"Papa, you do not have to talk to me that way. You just give me that knife and tell me to use it. If they can get to me again, they can roll me a hundred times if they want to do so," was his reply.

The father again cautioned him that it would be unmanly for him to cut any of the boys until he had given them fair warning. He then proceeded to the school and had an interview with the principal, relating the entire matter as here recited, though assuring her positively that the boy would use the knife, and use it effectually, if such an experience were again repeated.

The lady school principal in question became indignant, and said: "You had no business giving your boy that knife and telling him to do any such thing. Why did you not come to me, and I would have prevented the boys from rolling him again, without subjecting *them* to such danger?" "Yes, madam, but you would not have restored self-respect to the boy, nor have conserved his rights as an individual. If I am wrong, you have recourse to the law. I have fulfilled my duty when I have equipped him for self-protection, and notified you to look after the welfare of the boys during playtime."

Two policemen were speedily brought to guard the school boys during recess, and strenuous lectures were given in each room of the entire school upon the necessity of observing the rules of the school during play time, with a threat of expulsion if there was any more "rolling."

The lad returned home that evening, highly elated over the reaction which had been induced as the result of his having a knife in his pocket, knowing nothing of my visit, and he afterward found great pleasure in his association with the entire group of boys, and he did splendid work during his further stay at that school.

As to whether or not the father was right or wrong in his way of dealing with the matter, "right" or "wrong" did not enter into his consideration. What he did was simply his individual reaction to the stimuli of the factors of his environment, approved by his own judgment, and this mode of reaction on his part would undoubtedly tend to influence the future reaction to the stimuli of environment by the boy.

The response of the individual, or of a nation, to environmental stimuli, is determined by the phylogenetic and ontogenetic history of the individual or of the group, though reason and judgment should at all times be in control.

Justice, as a psychic attribute, is evolved together with the self and species-preservative instinct, and, where this is a dominating element of human character, the individual can act with absolute freedom at all times, and his decisions are as unerring as the rock of Gibraltar is stable; and his philosophy of life will ultimately meet the approval of the entire herd, because it is in harmony with the laws of nature, true to the law of evolution in general, and adapted to the welfare of the entire medical profession, and that of the larger social body as well.

The primary cause of "disease," as we understand it to-day, is due to a blocking, or arrest, of sub-conscious instinctive psychophysical potentialities that are striving for expression. These arrests or dispersions of energy may be compared to the right and left arms of a man placed together and consuming the entire energy of the central battery, the brain, in the effort of each to shove the other member up or down, as the case may be, instead of working in harmonious cooperation for the preservation of the personal self and the species. This internal conflict, this eternal warring, results in a waste of energy, a leak constantly going on, robbing the central storehouse or dynamo of power that should be normally employed in running the entire physiological machinery. This depletion or waste of psychophysical potential is indicated by abnormal emotional manifestations, and can be diagnosticated by the word association experiments. These cause an abnormal response to environmental stimuli on the part of the patient, or moods of depression with the corresponding disturbance of the function of every organ and cell in the body; an alteration of the glandular secretions, or an abnormal biochemistry of metabolism; and, in its grosser manifestations, producing such conditions as indigestion, constipation, intestinal stasis, and the entire "Arbuthnot Lane series" of symptoms as the sequence, such as cardiovascular, nephritic, hepatic, nervous, circulatory, respiratory, and other manifestations of disease. Herein is the cause back of the perverted physiology which results in pathological anatomy, such as goiter, cancer, rheumatoid arthritis, diseases of the skin, eyes, ears, nose, and throat. This lowered psychophysical potential, as the result of misadaptation to environment, with its corresponding functional disturbances, lessens the immunity of the individual to bacteriological invasion, and is the cause back of the entire "cause" of disease. In other words, disease is a social affair and must be fought socially.

In the light of the foregoing conclusions, are we giving due attention to the cause, prevention, and cure of disease? Is it not time that the medical profession awake from its long sleep and give due heed to those who are crying to us for help?

506 Brandeis Theatre Building.

## DIVULSION OF ARM AND SCAPULA.

By G. K. DICKINSON, M.D.,

JERSEY CITY, N. J.

A SHORT statement of the subjoined case seems of sufficient interest to warrant publication:

On January 14, 1914, S. Z., 23 years old, while oiling machinery had his right arm caught between a thirty-inch pulley and a thirty-inch rubber belt of a coal-conveyor, making forty-one revolutions a minute. The arm was completely divulged, with loss not only of the arm but of the scapula. The muscles were torn off close to the body and the skin evenly torn, but with rather a long cuff. The accident occurred at the bottom of a pit fifteen feet deep with perpendicular sides. The man was alone at the time. After the injury, with the aid of his remaining arm, he walked up the fifteen foot ladder, down an incline for one hundred and sixty feet to the foreman and about five hundred more to the office, where he insisted upon sitting up. An ambulance was called and the patient removed to Christ Hospital, where it was found the blood vessels and nerves had been torn off and had receded, so there had been no hemorrhage whatever from the wound. The pulse in the other arm was slow and good. His blood pressure was 140. He expressed no pain. In the afternoon he was etherized and the traumatic portion explored. Neither the arteries nor nerves were discoverable. One small postscapular blood vessel began to bleed and was ligated. The wound was swabbed out with tincture of iodine, the superabundant skin flap was excised, and the skin was sutured around a rubber tube drain. Recovery was uneventful. The amputated arm was afterward found in a crooked position hanging over on a bar of the machinery.

280 Montgomery Street.

## Medicolegal Notes.

**Reading Medical Authorities to Jury.**—In an action on an accident insurance policy for the death of the insured from pancreatitis, the plaintiff claimed that the disease was caused by a violent wrench which the insured sustained in attempting suddenly to rise when a street car on which he was riding started to rock, while the defendant attempted to show that the pancreatitis arose from indigestion. Expert witnesses were introduced on both sides. One or two of these had previously seen one case of pencreatitis, but none of them had seen enough of the disease to speak as experts upon it, independently of medical authority; and they all relied on and referred to medical authorities for the conclusions which they stated. When the experts for the defendant had testified that pancreatitis could not be caused by the external injury, the trial court allowed them, on cross-examination, to be asked if certain medical authorities, known to be authoritative, did not give instances of pancreatitis having been so caused, and the statements of these authorities were permitted to be read to the witnesses as a part of the question. It was held that this was proper. When one doctor testifies that the medical authorities teach so and so, and another doctor testifies that they teach the contrary, the jury would have little light to guide them in determining between the conflicting statements. But if the medical authorities referred to are presented to the witnesses, and read in the hearing of the jury, they can form a more intelligent idea as to which of the witnesses is supported by the text.—Travelers' Insurance Company v. Davies, Kentucky Court of Appeals, 153 S. W. 956.

**Evidence of Usual and Customary Treatment.**—In an action for negligent and unskilled treatment of an injury by a hospital physician, it was held that the testimony of a nurse of some years' experience, otherwise properly qualified, on whether the treatment given the plaintiff was the usual and customary treatment, should have been admitted.—Klodek v. May Creek Logging Co., Washington Supreme Court, 129 Pac. 99.

**Compensation—No Implied Promise by Mother of Patient Living with Husband.**—A physician, it is held by the New York Court of Appeals, may not recover on an implied contract by a mother to pay for medical services rendered to a daughter living with her husband, the husband consenting to the physician treating her, though the mother importuned the physician to treat the daughter. It is well settled, said the court, that a physician, in the absence of a special contract, may recover upon an implied agreement to pay for his services *quantum meruit*, when they have been rendered at the request of the patient, or of a person who, in the eye of the law, is regarded as being under a legal obligation to provide such professional services for the patient; such as the husband, or the parent of a minor child. In the present case, notwithstanding the anxiety, the importunity, and the prayers of the defendant, the legal obligation of the husband was not shifted to, or assumed by, the defendant, and there was no express promise by her to pay. It would, it was added, be a simple matter, in cases where the physician is called upon to attend a person, at the instance of some one not standing in a responsible relation to the patient, to inform himself as to whom he shall look to for compensation.—McGuire v. Hughes, 207 N. Y. 516, 101 N. E. 460.

**Agreement as to Division of Fees.**—A family physician, for whose services his employer is personally liable, cannot, it is held, without the knowledge of all the facts by the employer, enter into a contract with a surgeon, whom the physician has called in to perform operations, by which the surgeon is to divide his fees with the physician. Such a contract is void as against public policy.—McNair v. Parr, Michigan Supreme Court, 143 N. W. 42.

New York, May 30, 1914.

## "PAINLESS CHILDBIRTH" AND PAINFUL MAGAZINE EXPLOITATION.

AN article that is likely to arouse the interest of certain of the laity appears in one of the popular magazines for June under the caption "Painless Childbirth." It is written by two women who made a special study of the method at Freiburg in Baden, where Krönig and Gauss have made trial of scopolamine-morphine narcosis in midwifery. This method has been closely watched by the medical profession for a number of years; it has been tried throughout Europe and considerable difference of opinion has arisen as to the value of this attempt to rob the lying-in room of some of its terrors. A comprehensive review of narcosis in childbirth is presented by H. Fuchs of Danzig in the *Universal Medical Record* for December, 1913. He compares the relative merits of chloroform and of ether, preferring the latter in hospital cases; of nitrous oxide and oxygen; of cocainization of the genital area of the nose, as devised by Fliess; of hypnosis; of suggestion-narcosis; of the use of drugs such as chloral hydrate, and finally of scopolamine-morphine narcosis.

The essential of this method consists in the production of a clouding of consciousness, a "twilight sleep" (Dämmerschlaf) as it is called. "When the pains come, the women usually cry out just as loud as any other lying-in woman, answer the question whether they have pains in the affirmative, but during the intervals between the pains fall into a deep sleep. If awakened from this sleep and questioned about the pains they have suffered there is a complete loss of memory, that is, if the semi-sleep is complete. Psychologically the facts of the case are that the pains are perceived at the moment, but then make no impression; they leave behind in the higher cerebral centers no memory picture. It results that, if the semi-sleep is properly produced the whole of the processes of labor are banished from remembrance." During twilight sleep there is a loss of psychic control and the assistance of the patient cannot be obtained by the accoucheur. To the question whether scopolamine-morphine anesthesia is harmless to the organism as a whole, Fuchs answers in the affirmative, but he believes that this combination of drugs adversely influences the course of labor, increasing the pain intervals, and shortening and weakening the pains themselves. Prolongation of labor is a regular consequence of the twilight-sleep. Furthermore scopolamine-morphine anesthesia is not innocuous to the child. According to Fuchs, the excitability of the respiratory center is lowered with the result that one-fourth of the children are born in a state of oligopnea or apnea.

If one now turns to the account of the method of Krönig and Gauss as given in the magazine article one notices the exaggerations and circumlocutions that are almost inseparable from this type of literature. The statement is made that twilight sleep "is not in any way injurious to the mother," and "in no way injurious to the child." It is stated that in the Freiburg clinic forceps "are almost never used," and on page 44 this is contradicted by the statement that "the frequency of forceps cases has settled down to an average of from 6 to 7 per cent." If it were not misleading to the unthinking reader most amusing indeed would be the testimony that is cited of some of the patients who journeyed to Freiburg to experience the benefits of twilight sleep. Thus we are told of the Scotch noblewoman who in spite of the precedent that the heir of the family should be born "in his own heather and beneath his own castle walls," nevertheless journeyed to the clinic, in possession of two German sentences: The first was "Where is Professor Krönig?" and the second was, "I will have a painless child." "The 'painless child' from recent photographs, is the most beautiful child that the heart of a Raeburn might ache to paint. Her baby having been so very satisfactory, she is one of the mothers who returned for a second." Another glowing testimonial of the Freiburg method appears in the recital of a case in which a woman gave birth to a boy at 5 o'clock in the morning, at 8 was sitting up enjoying her coffee and rolls, at noon ate a typical German midday meal of soup, meat, vegetables, and compote, and in a week was returning calls of congratulation.

One of the serious drawbacks of the popularization of medical topics in magazines is the fact that usually the whole truth is not presented. A glowing account of one phase of the subject is usually given and the reader receives a distorted idea of a subject which wise men are still weighing in the balance. This is particularly true of the question of "painless childbirth." Even if one disregard the valid sentimental objection to the open discussion of such a topic, there can be nothing but condemnation of the unreal and one-sided portrayal in a popular magazine of a strictly medical subject such as that of analgesia in obstetrics.

## CANCER OF THE TONGUE IN EARLY LIFE.

JUST at present considerable thought is being given to the subject of oral sepsis hence this seems an opportune time to call attention to another and very important one of the conditions that may arise from neglect of the teeth, namely, cancer of the tongue. Gorse and Dupuich (*Revue de Chir.*, March, 1913)

made a study of this subject, their attention having been drawn to the condition by a case occurring in a soldier 22 years of age, who came under their care in October, 1911. His mother had died from cancer of the uterus; no other cases of cancer in the family. In February, 1911, a small ulceration had appeared on his tongue opposite a carious tooth. Due to the constant irritation of rubbing against the teeth, the ulceration gradually increased in extent. Finally the carious tooth was removed but the ulceration continued to increase and the employment of antisyphilitic treatment had no effect upon its progress. When seen by the authors he had an ulceration of the right side of the tongue opposite the last three molars. The ulcer was irregular in shape, shallow with thickened edges, the floor of the ulcer having a grayish appearance with some yellowish spots. The ulcer rested upon a somewhat smaller base which extended into the depths of the tongue. There was little tendency to bleeding. Near the angle of the jaw there was one slightly indurated, enlarged, movable lymphatic gland. His general condition was good. No evidences of tuberculosis in the lungs or elsewhere. Under local anesthesia the right side of the tongue and a portion of the floor of the mouth were removed on November 29, 1911. There were no postoperative complications. Recurrence took place rapidly, however, and he died during the following May. Microscopical examination showed that the tumor was a typical epithelioma.

Cancer of the tongue is rare before the age of thirty years, though cases *may* occur at any age. In the vast majority of instances cancer of the tongue occurs between the ages of 40 and 60. Of the statistics quoted by the authors the following are of particular interest. Among 80 cases of cancer of the tongue reported by Butlin, there were only two under 30 years of age. Barker in 290 cases reported by various authors found eight between 20 and 30. Piquantin, in his thesis, collected the statistics of 155 cases of cancer of the tongue in the female. The age was noted in 137 cases and among these there were three patients between 10 and 20 years of age, fifteen between 20 and 30. Loison, in 342 observations of cancer of the tongue of both sexes, found only nine between the ages of 15 and 30 years. In their entire search of the literature, Gorse and Dupuich were able to find but thirty well-authenticated cases in which the patients were not over 30 years of age. The majority of these cases occurred in females, while in later years males are much more frequently affected. According to the statistics of Butlin and Spencer and those of Barker, the ratio of females to males afflicted with cancer of the tongue is about 15 to 100; while the statistics of numerous authors, covering nearly 2000 cases, show a proportion of 17 females per 100 cases.

The authors say, regarding the etiology of these cases, "the true cause of cancer in the young cannot be stated, as we still remain ignorant of the real nature of the cancerous affections. As the cause second in importance one must recognize the irritations—chemical, infectious, and, especially, mechanical. The mechanical irritations come particularly from sharp-edged or carious teeth (as seen in eight cases out of the thirty), or from an ill-fitting plate (two cases)." These two causes together thus account for one-third of these cases. They found no reference in this series to the development of cancer of the tongue under the influence of a chemical irritant (tobacco, alcohol, etc.). Syphilis seems to play only a minor rôle in the etiology of cancer of the tongue in the young. Two patients only could be suspected of having a specific history. The absence of previous syphilitic manifestations is noted in nine cases and these patients did not derive any benefit from treatment with mercury or the iodides.

Regarding the pathological anatomy the authors say, "Cancer of the tongue in young subjects presents itself almost always under the form of an ulceration more or less deep or sinuous, resting upon an indurated base, with small yellowish or white points, pressure of which squeezes out vermicelli-like masses. The ulcer has a grayish floor and indurated, rigid borders, perpendicular or overhanging. Sometimes the ulceration is covered with fine or luxuriant papillary formations. Finally, but more rarely, there may be a nodule which remains such or which ulcerates, or there may be a scirrhous mass. The ulceration is generally single but may be multiple, and one may find as many as three distinct centers of malignant ulceration. They usually bleed at the least touch. The site of the cancerous involvement is more frequently the border than the body of the tongue." The authors found the site of the lesion mentioned in 24 of the 30 cases: 18 on the border, 4 on the tip, 1 on the back, and 1 on the inferior surface. They call attention to this localization upon the borders and tip of the tongue as a proof of the causative action of contact with pointed or carious teeth. Recurrence after operation takes place *in situ*, in the lymphatic glands, in the neighboring salivary glands, or at the level of the soft palate.

In considering the symptomatology and diagnosis the authors emphasize two points: "the affection is very manifestly painful, *very* painful even, and irradiations and otalgia are frequent. * * * On the other hand, the patient retains for a very long time the appearance of good health, a fresh complexion without cachexia, an excellent general condition." Cancerous ulceration must be distinguished from that of syphilis and tuberculosis, as well as simple ulceration due to the teeth. Sometimes it is only by means of histological and bacteriological examinations that one is able to elucidate the problem.

Cancer of the tongue in young subjects has an especially grave prognosis. Of these 30 cases there was one ten-year and one two-year cure. The rest died within two to ten months or could not be traced. As a large proportion of these cases had as their apparent exciting cause rough, sharp-edged, or carious teeth, it seems certain that proper attention to the teeth will do much to lessen the liability to cancer of the tongue—a malady which may affect even those in the second decade of life, and which has an appalling mortality.

## STUDY OF THE INTERNAL SECRETIONS.

An almost illimitable field of scientific research is afforded by the internal secretions. Although, in this field students are still groping to a great extent in the dark, the obscurity becomes every now and then illumined by a light which serves to show the infinite possibilities which would accrue from a more thorough elucidation of the whole subject. In short, sufficient progress has been made already to demonstrate clearly that a complete knowledge of the functions and correlations of the internal secretions would place in the hands of the medical practitioner the most formidable weapon to fight disease which has as yet been vouchsafed to him. But much water must flow under the bridge before this Utopia is realized, and in the meantime steady and persistent work in the direction of unraveling the tangled skein must be the order of the day.

In *American Medicine* for April, 1914, is a series of articles dealing with the internal secretions written by those who have made a special study of the matter. The issue constitutes a valuable contribution to the literature of the internal secretions, and also indicates the existing situation with regard to them. On the one hand, it draws attention to the great advances made, and on the other hand, distinctly denotes the many gaps which will have to be bridged ere it can be affirmed that the task is ended and that tangible results have been evolved.

The literature of the internal secretions during the past few years has been vast, almost overpowering, and while it is well that every phase of the question should be dissected and ventilated at the same time, the advice given by the late Dr. Roswell Park may be taken to heart. He pointed out that what we, perhaps, most need is an accurate combination of clinical observation and post-mortem pathological study. Better would it be now, in the opinion of the Buffalo surgeon, if students of the subject would cease from all literary effort save collecting and collating facts, would familiarize themselves with the already enormous bibliography and literature of the subject, all this for a period of a few years, and then assign to some committee or commission, or possibly to some unusually equipped individual, the duty of digesting and of presenting anew the total material thus accumulated. It is worthy of note that American students of the internal secretions are well to the front. Cushing, Ott, Simpson, MacCallum, Klotz, Beebe, Sajous, to mention some of the more prominent, have contributed largely to the sum of our knowledge thereof, and may be confidently expected to lay bare yet further the secrets of this comparatively unknown domain of research. So far as a definite knowledge of the internal secretions is concerned, the future is full of hope.

## HYALINE DEGENERATION OF THE ISLANDS OF LANGERHANS.

The knowledge of the diseases of the pancreas has been greatly extended within recent years, chiefly in two directions. First, in the close anatomical and physiological relationships between the pancreas and the liver there has been discerned an adequate cause for the frequent involvement of the pancreas in affections of the biliary passages. Second, pathological changes in the pancreas have been described as one of the most common causes of diabetes mellitus. These changes consist in a sclerosis or in a hyaline degeneration of the islands of Langerhans. But the latter change is not necessarily confined to cases of diabetes, for it has been observed in cases in which there had been no diabetic manifestations during life.

A series of six cases of this nature are reported by R. L. Cecil in the *American Journal of the Medical Sciences*, May, 1914. The patients had died, respectively, from epithelioma of the inferior maxilla, cirrhosis of the liver, acute pericarditis, typhoid fever, a possible endotheliama of the left orbit, and cardiorenal disease. In every case there was noted an interstitial pancreatitis of the type usually seen in diabetes, with thickening of the arterioles. Both sclerotic and hyaline changes were detected in the islands of Langerhans, but many of these islands were perfectly normal. In two of the cases there was a well-marked cirrhosis of the liver. As regards the kidneys, in every instance there was a definite fibrosis and a hyaline degeneration of some of the glomeruli.

Of eminent significance is the fact that in all of the cases studied by Cecil there was present a more or less pronounced arteriosclerosis. It is probable that this was responsible for the coincident degenerative changes in the pancreas and in the kidney. And just as lesions in the latter organ may be present without giving any clinical evidence of renal disease, so also a considerable degree of pancreatic involvement may exist without giving rise to glycosuria. The factor of safety in the physiology of the pancreas is well illustrated by the fact that hyaline degeneration of the islands of Langerhans may occur up to a certain point without producing that disturbance of carbohydrate metabolism whose outward expression is glycosuria. The fact is emphasized that the fundamental lesion is a sclerosis of the smaller vessels supplying the islands of Langerhans.

## The Insert Bone Graft in Fractures of the Patella

The insert bone graft, as developed and popularized by Albee in the treatment of Pott's disease and in ununited fractures of the long bones (*Am. Jour. Surg.*, Jan. 1914), is apparently destined to have a still wider field of application. This seems the direct corollary to be drawn from the consideration of the two cases of fracture of the patella reported by Rogers (*Annals of Surgery*, April, 1914) as having been successfully treated by the autogenous bone graft. The technique in these cases did not include the grooving of the fragments for the reception of the graft, which was taken from the crest of the tibia, hence the periosteum which had been turned back to allow apposition of graft and raw surface could not be made to cover over the graft, but was "drawn up to, or over, the transplant with a couple of catgut sutures." The remaining means of holding the fragments and trans-

plant in place was "a figure-eight suture of chromicized catgut or kangaroo tendon, which grasps the ligamentum patellæ and quadriceps tendon immediately below and above the broken bone and crosses in front of the transplant." An examination of the radiograms shows that in both cases there was a buckling of the fragments, so that the articular surfaces of the fragments were not restored to the same plane, although, fortunately, a perfect functional result was obtained in each instance. Grooving of the fragments deeply enough for the reception of the transplant, so that the patellar periosteum may be firmly sutured over it near the fracture line of each fragment, should result in the restoration of the proper alignment of the articular surfaces, with the increased probability of perfect anatomical and cosmetic, as well as functional result.

## News of the Week.

**Women Doctors Graduate.**—The annual commencement exercises of the New York Medical College and Hospital for Women were held at the Waldorf on May 20, when seven graduates received their diplomas.

**City Death Rate.**—For the first twenty weeks of 1914 the death rate in New York City was 15.35 per 1,000 of population, as compared with 15.56 for the corresponding period of last year. During the week ending May 17, there occurred in the city 1,533 deaths, an increase of two over the number for the same week of 1913. There was an increase of 47 in the deaths from typhoid and scarlet fever, while pulmonary tuberculosis showed a decrease of 26 deaths.

**Lebanon Hospital.**—At the annual meeting of the Lebanon Hospital, Bronx, New York, it was reported that during the previous year 49,057 patients had been treated at the hospital, of whom 419 had died; that the ambulances had responded to 2,888 calls; and that the cost of running the hospital and the training school was $165,267.98.

**Montefiore Home.**—The new buildings of the Montefiore Home on Gun Hill Road, Bronx, New York, were opened for public inspection on May 17, and it was estimated that at least 3,000 people took advantage of the opportunity to visit the plant. The Home now has 239 men and 177 women patients, a total of only 34 less than its capacity, and the Country Sanitarium at Bedford Hills has 107 men and 73 women inmates, which is as many as it can accommodate. At the business meeting preceding the public reception the proposal to change the name of the institution resulted in the adoption of the titles: "Montefiore Home, Hospital, and Country Sanitarium for Chronic Diseases."

**"Mikveh" Baths.**—A conference, called by the Commissioner of Health of New York, was held recently to consider the subject of "Mikvehs," the cleansing baths whose regular use is required by the Jewish faith. These baths in New York have been made the subject of a bacteriological investigation by Dr. Mannheimer of Columbia University and independently also by the Department of Health, and their investigations have shown that the Mikveh baths, as at present conducted, are a serious menace to the health of the people using them and have indicated the need of steps to render them sanitary. While no definite program has been formulated, the Department announces that it is believed that insistence on regulations similar to those adopted for the floating baths would prove feasible. These provide for a preliminary cleansing shower bath and for the cleanliness of the water. The problem has been presented to the Board of Authoritative Rabbis of the Jewish community of New York, with the request that they submit suggestions for regulations to the Health Department.

**Dr. Henry Pickering Walcott** of Boston, whose term of service as a member of the Massachusetts State Board of Health expired on May 19, received a remarkable tribute from his professional brethren on his retirement. This was an address signed by 2,200 members of the medical profession in Massachusetts, commemorating Dr. Walcott's thirty-three years of service as health officer and chairman of the State Board of Health, and expressing their appreciation of his work.

**Dr. Smith Ely Jelliffe** of this city has been elected corresponding member of the Paris Neurological Society.

**Dr. Jacques Loeb** of the Rockefeller Institute of this city has been elected corresponding member of the French Academy of Science in the Section on Anatomy and Zoology, to succeed the late Lord Avebury.

**Dr. Mark J. Schoenberg** has received the Lucien Howe prize of the Medical Society of the State of New York for his research work on ocular anaphylaxis.

**Sir Francis Henry Laking, M.D.,** physician in ordinary and surgeon apothecary to the King of England and the Prince of Wales, died at his home in London on May 21 at the age of sixty-seven years. Sir Francis was consulting physician to the Victoria Hospital for Children and apothecary to his Majesty's household. He was educated at Heidelberg and St. George's Hospital, London, and was created a knight in 1893 and a baronet in 1902. He was also a commander of the Legion of Honor, and had received a number of other decorations.

**Dr. Stephen Townsend** of London died at his home on May 20. He became a member of the Royal College of Surgeons in 1883 and a fellow in 1887, and for several years was lecturer and examiner on first aid to the injured to the London County Council. He was also well known in the literary world and was the husband of Mrs. Frances Hodgson Burnett, well known as an American writer.

**Gifts to Charities.**—By the will of the late Mrs. Henry T. Cutter of New York, the Presbyterian Hospital, New York, the Seney Hospital, Brooklyn, and the Mount Vernon Hospital receive bequests of $20,000 each, while the Hospital for Deformities and Joint Diseases, New York, receives a bequest of $25,000.

St. Rose's Home for Incurable Cancer, New York, receives a bequest of $1,000 under the will of the late Margaret F. Kennedy of this city.

**The Harrington Lectures** of the Medical Department of the University of Buffalo will be given by Professor Ludwig Pick of Berlin on the evening of June 2 and in the afternoons of June 3 and 4. The title given is "Some Recent Advances in Pathological Anatomy." The lectures will be illustrated by lantern slides and many Lumière plates.

**New York Neurological Society.**—Dr. Paul Federn of Vienna will speak on the "Psychological Roots of Masochism," and Dr. W. J. Maloney on the "Relationship of Syphilis to Tabes" at the next regular meeting, to be held June 2, 1914. The meeting is open to all members of the medical profession.

**Medical Society Elections.**—Florida State Medical Association: Annual meeting at Orlando on May 14. Officers elected: *President,* Dr. F. Clifton Moor, Tallahassee; *Vice-Presidents,* Dr. Calvin D. Christ, Orlando; Dr. Thomas Truelsen, Tampa; Dr. John A. Simmons, Arcadia; *Secretary-Treasurer,* Dr. Graham E. Henson, Jacksonville; *Librarian,* Dr. James B. Pasco, Jacksonville. *Delegate to the A. M. A.,* Dr. John MacDiarmid of De Land. The next annual meeting will be held in De Land.

Oklahoma State Medical Association: Annual meeting at Guthrie on May 12 to 14. Officers elected: *President,* Dr. John William Riley, Oklahoma City; *Secretary-Treasurer,* Dr. Claude A. Thompson, Muskogee. Bartlesville was selected as the place for the next convention.

Southwestern Kentucky Medical Association: Forty-fourth annual meeting at Paducah on May 13 and 14. Officers elected: *President,* Dr. Benjamin P. Earle, Dawson Springs; *Vice-Presidents,* Dr. John L. Dismukes, Mayfield; and Dr. W. F. Peeples, Spring Hill; *Secretary,* Dr. James T. Reddick, Paducah; *Treasurer,* Dr. Henry G. Reynolds, Paducah.

Bristol South District (Mass.) Medical Society: Annual meeting at Fall River on May 14. Officers elected: *President,* Dr. Ralph W. Jackson, Fall River: *Vice-President,* Dr. Charles Austin Bonney, Jr., New Bedford; *Secretary-Treasurer,* Dr. Alanson J. Abbe, Fall River.

Franklin District (Mass.) Medical Society: Annual meeting at Greenfield on May 12. Officers elected: *President,* Dr. John Edwin Urquhart, Ashfield; *Vice-President,* Dr. Harry N. Howe, Greenfield; *Secretary-Treasurer,* Dr. George Pierce Twitchell, Greenfield.

Ohio Homeopathic Medical Society: Annual meeting at Columbus on May 11 and 12. Officers elected: *President,* Dr. Romeo O. Keiser, Columbus; *Vice-Presidents,* Dr. Ira O. Denman, Toledo; Dr. Gertrude K. Meck, Cleveland; *Secretary,* Dr. J. G. Keiser, Columbus; *Treasurer,* Dr. Thomas T. Church, Salem.

Texas Roentgen Ray Association.—This association was formed recently at a meeting of the Texas State Medical Association in Houston. The organization consists of those physicians who are interested in the *x*-rays and in electrotherapeutics, and meetings will be held each year in connection with the conventions of the State Association. The following officers have been elected: *President,* Dr. George D. Bond, Fort Worth; *Vice-President,* Dr. William Oscar Sauermann, Houston; *Secretary-Treasurer,* Dr. J. W. Torbett, Marlin.

**Obituary Notes.**—Dr. F. E. Daniel of Austin, Texas, editor of the *Texas Medical Journal,* popularly known as the "Red Back," died at his home on May 14 after an illness of long duration. He was born in Greenville County, Va., July 18, 1859, and was educated in Vicksburg, Miss. He served as surgeon in the Confederate Army from 1862 to the end of the war, and then began practice in Austin where he established his journal in 1885.

Dr. Winfield Scott Wells of Providence, R. I., a graduate of Rush Medical College, Chicago, in 1890, and a member of the Rhode Island and Providence District Medical Societies, died suddenly at his home, on May 2, aged 54 years.

Dr. Fred W. Meddaugh of Williamsport, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1909, and a member of the Medical Society of the State of Pennsylvania and the Lycoming County Medical Society, died on May 5, as the result of an automobile accident, at the age of 27 years.

Dr. John A. Brobst of Allentown, Pa., a graduate of the College of Physicians and Surgeons, Baltimore, in 1885, died at his home on May 4, aged 62 years.

Dr. Elmer B. Eddy of Providence, R. I., a graduate of the College of Physicians and Surgeons, New York, in 1873, died suddenly at his home, on May 6, aged 64 years.

Dr. Henry Cabell Tabb of Richmond, Va., a graduate of the Medical College of Virginia, Richmond, in 1869, and a member of the Medical Society of Virginia and the Richmond Academy of Medicine and Surgery, died at his home, on May 7, after a long illness, aged 75 years.

Dr. Levi Secord of Brantford, Ont., a graduate of the St. Lawrence School of Medicine, Quebec, in 1876, and Mayor of Brantford in 1893 and 1894, died at the Brantford General Hospital, on May 8, aged 60 years.

Dr. Nicholson C. Washington of St. Louis, Mo., a graduate of Washington University, Medical Department, St. Louis, in 1867, died at his home, after a long illness, on May 7, aged 70 years.

Dr. Joseph E. A. Lanouette of Manchester, Pa., a graduate of the University of Bishop College, Faculty of Medicine, Montreal, in 1872, formerly a surgeon in the Canadian militia, and known for his work in the smallpox epidemic in 1885, and a member of the New Hampshire and Hillsboro County Medical Societies, died at his home, on May 16, aged 64 years.

Dr. Thomas Mackaness Ludlow Chrystie of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1867, a veteran of the Civil War, formerly surgeon to the New York Orthopedic Dispensary and Hospital, and a trustee of the institution, and a member of the New York State and County Medical Societies, died at his home in Rye on May 19, aged 73 years.

Dr. Daniel Morris Woolley of Brooklyn, N. Y., a graduate of the New York University Medical College in 1885, died in a senatorium on May 18 from cancer of the liver, aged 64 years.

Dr. Lewis Hodges Clapp of Brooklyn, N. Y., graduate of the New York Homeopathic Medical College and Hospital in 1904, died on May 17, following an operation for appendicitis at Lakewood, N. J., aged 33 years.

Dr. James Gillespie Hunt of Utica, N. Y., a graduate of the Jefferson Medical College, Philadelphia, in 1871, formerly State Commissioner of Health, surgeon to the Faxton Hospital, and a member of the New York State and Oneida County Medical Societies, died at his home on May 19, aged 69 years.

Dr. Jeptha C. Clark of Andover, N. J., a graduate of the New York Homeopathic Medical College and Hospital in 1885, formerly coroner of Sussex County, and a member of the Andover Board of Education, died at his home from paralysis on May 16, aged 54 years.

Dr. Howard B. Gates of Los Angeles, Cal., a graduate of the New York Homeopathic Medical College and Hospital in 1895, and a member of the American Medical Association, the Medical Society of the State of California, and the Los Angeles County Medical Society, died on May 8 at Rome, Italy, where he had gone in search of health, aged 47 years.

Dr. James D. Whitney of San Jose. Cal., a grad-

uate of the Cooper Medical College, San Francisco, in 1863, died at his home on May 8.

Dr. WILLIAM B. RICHMOND of Terre Haute, Ind., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1899, died suddenly, in church, on May 10, aged 38 years.

Dr. NILES T. QUALES of Chicago, Ill., a graduate of the Rush Medical College, Chicago, in 1866, and a member of the American Medical Association and the Illinois State and Chicago Medical Societies, died at his home from pneumonia, on May 23, aged 83 years. Dr. Quales was a Scandinavian by birth and a few years ago was decorated by the King of Norway with the Cross of St. Olaf.

Dr. SAMUEL B. WRIGHT of Stanford, Ill., a graduate of the Medical Department of the University of Nashville, Tenn., in 1875, died at his home on May 14, aged 64 years.

Dr. GEORGE DRESSER of Chicopee, Mass., a graduate of the Harvard University Medical School in 1862, and a member of the Massachusetts and Hampden District Medical Societies, died at his home after a long illness on May 16, aged 76 years.

Dr. ROBERT B. NELSON of Memphis, Tenn., a graduate of the Medical Department of Vanderbilt University, Nashville, Tenn., in 1903, and a member of the Tennessee State and Shelby County Medical Associations, died at his home from the effects of injuries received in a railroad accident, on May 12, aged 33 years.

Dr. DAVID ALEXANDER RYAN of Chicago, Ill., a graduate of the Dearborn Medical College, Chicago, in 1906, died at his home on May 15.

## Correspondence.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

KING EDWARD'S HOSPITAL FUND—CEREBROSPINAL DISEASE AND TREATMENT—JOINT COMMITTEE OF CLERGY AND DOCTORS—OBITUARY.

LONDON, May 8, 1914.

AT the annual meeting of King Edward's Hospital Fund on the 1st inst., the Council had a successful year to report. The Hon. Treasurer, Lord Rothschild, mentioned that as a result of the installments of the late Sir Julius Wernher's already received, the investments of the Fund were brought up to £2,000,000. Another legacy to which he thought he ought to refer was the Harman bequest of ground rents, worth £1,382 a year. The surveyor's report, recently received, estimated the value of this at £25,000.

The Hon. Secretary, Sir Savile Crossley, presented the draft report of the Council for the year 1913, showing the total receipts, £187,704 odd, of this the amount distributed among the hospitals was £151,000, while the £6,500 remaining went to sanatoria and convalescent homes taking London patients.

Statistics show that the cost of working hospitals increased in the last year by as much as £22,000, and this can hardly be altogether due to more costly methods of treatment since it does not nullify the previous tendency to economy. To assist separate hospitals to ascertain how their own expenditure is affected by special or avoidable causes tables have been given in the report of the Fund comparing averages at various institutions.

The uniform system of accounts recommended, having given rise to some discussion, a joint committee of the King's Fund, the Secondary Fund, and the Saturday Fund held consultation with some hospital secretaries, and the three funds eventually issued a memorandum containing suggestions and regulations designed to promote uniformity in the statistics of the various hospitals. Coming with such influence it may be hoped that the scheme will meet with general acceptance.

The diagnosis and treatment of cerebrospinal syphilis, including tabes and general paralysis, was the text of a most important communication to the Medical Society of London on the 27th ult. by Dr. Purves Stewart. He treated the subject with great skill from the outset, in which he insisted on the existence of a preclinical stage which it was desirable to recognize. This he said can be accomplished by examination of the blood and the cerebrospinal fluid.

It will be remarked by most practitioners that nearly if not all their patients do not come to them in this preclinical stage, so that however acute they may be in detecting early symptoms they will almost always be too late. The examination of the fluids will remain, therefore, in the hands of specialists, as will for the most part the treatment proposed—which is the latest attempt to get at the spirochetes in these same fluids. For though mercury and salvarsan are fatal to these organisms they require to attack them directly in the tissues infected. Some substances can pass from the blood stream into the cerebrospinal fluid, *e.g.* alcohol; others cannot, and among these mercurial and arsenical salts. It is, therefore, in order to reach the organism or its toxin that the remedies have been injected in different cases by three routes —intravenously, intraspinally and intracranially. Dr. Stewart said that the most thorough method of attack in general paralysis would be by all three routes concurrently, and that it may be in the future this combination may be adopted. He did not claim that we have as yet a cure for this or tabes, but in suitable cases may obtain arrest, though only time can show if that will be permanent. Salvarsanized blood serum has been used here and in Edinburgh, also in New York. In Paris quite recently Ravcust has introduced neosalvarsan—a 6 per cent. solution in distilled water —into the spinal theca by a very fine syringe and lumbar puncture needle, after withdrawing some fluid for examination. Dr. Stewart has adopted this route during the last six months. Of the intracranial routes there are several, and he recommends the selection of the one least likely to damage the brain structures, and says cortical applications for this reason are preferable to intraventricular. It is to be considered whether the risks of repeated cranial operations can be justified unless they can be proved to be more efficient than intraspinal injections.

Dr. Stewart found enesol useful against the lightning pains, and it could be given by simple hypodermic injection. He had employed sodium nucleinate by large intramuscular injections, as studied by Donath, for the purpose of inducing artificial pyrexia, increased temperature, being known to be beneficial in general paralysis. Urotropin was also useful in general paralysis; taken by the mouth it is partly eliminated in the cerebrospinal fluid as formic aldehyde. He then related cases treated by the combined intravenous and intrathecal method with salvarsanized serum or neosalvarsan.

In the discussions of this paper Mr. C. A. Ballance stated that in ordinary cases of syphilis he thought the best treatment was intramuscular injections of mercury combined with intravenous salvarsan. A rise of temperature could be produced by injecting Coley's fluid. The arachnoid being very definitely separated it would seem proper to inject into the subarachnoid space rather than into the subdural. He thought it no more dangerous to inject into the intracranial subarachnoid space than into the spinal. He made an opening into the skull immediately in front of the bregma and passed a fine canala three inches long through the anterior part of the corpus callosum into the anterior cornu of the lateral ventricle. He used 30 to 60 c.c. of salvarsan solution, preceded and followed by a little saline, in five cases but he could not speak of the benefit, though no complications occurred. Dr. Batten had tried sodium nucleinate in two cases without benefit. He had also tried salvarsanized serum in one case without effect. He considered the intrathecal method dangerous. Dr. Armstrong-Jones had given up mercury in late general paralysis. Pneumonia was frequent in these cases, but they did not appear to improve from the high temperature as some other forms of lunacy did. Almost complete recovery could be seen in patients who seemed to have definite parenchymatous degeneration, and that without any treatment at all. He had found little benefit from neosalvarsan, and he considered lumbar puncture dangerous. Piercing the frontal bone seemed difficult too, though sixty cases had been recorded. In 330 cases of general paralysis the average duration from admission to death had been sixteen months. Dr. Gordon Lane said sodium nucleinate led to increase of the red corpuscles and a leucocytosis, mostly of the large lymphocytes.

The President, Sir David Ferrier, complimented Dr. Stewart on the critical way in which he had stated his conclusions, but felt some disappointment with the results. It could not be said that any case had been cured by intrathecal treatment. In the only case he had seen neosalvarsan tried the result was disastrous, and symptoms being intensified.

A joint committee of clergy and doctors formed as a result of conferences between members of the two professions which met in 1910 and 1911 to inquire into spiritual faith and mental healing, has issued a report this week. They strongly deprecate the treatment of disease by unqualified persons, while laying stress on the importance attached to spiritual influences as contributory to recovery.

The death occurred on May 1 of Lt.-Col. J. A. Shaw, late of the R. A. M. C. He served in the Soudan expedition in 1882, and was mentioned in despatches, receiving a bronze star with the clasp. He was again in the Soudan in 1887, and received similar distinctions. He graduated in 1862-63 at the Queens University, and took F.R.C.S.I.

Dr. Richard Hughes, who died at Hitchin, M.B.Lond, 1880, is said to have practised for a time at Vienna, Berlin, and Manchester.

---

**Tonsillitis and Appendicitis.**—L. Verdelet reports two cases which show the intimate relationship between affections of the pharynx and intestinal troubles and particularly the important rôle which tonsillar infection may play in the genesis of appendicitis.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux.*

## OUR VIENNA LETTER.

(From Our Regular Correspondent.)

A CASE OF BENZINOMANIA—PALLIDIN REACTION—IRRADIATION OF THE THYMUS IN CASES OF GRAVES' DISEASE—FAMILIAL ICTERUS—SUGGESTIVE THERAPY IN CHILDREN—APHTHAE TROPICAE (SPRUE)—HYPERNEPHROMA OF THE AUDITORY CANAL.

VIENNA, March 1, 1914.

A CASE of benzinomania was presented by Schmelz before the Vienna Medical Society. The patient was a child who had acquired the habit of pouring benzine on a handkerchief and inhaling it. Interdiction and punishment were of no use. The child stated that she has pleasant dreams during the benzine intoxication. Resorting to hypnosis, the speaker suggested to the child a disgust for benzine and an inclination to vomit while inhaling it and thenceforth the girl did not inhale it any more. In the literature there are described only two cases of benzinomania.

An accessory to the Wassermann reaction of great value is the pallidin reaction devised by Klausner and Fischer. Pallidin is an extract of lungs affected with pneumonia alba. One can obtain the same reaction with an extract of the lymphatic glands of children affected with hereditary syphilis. K. Müller demonstrated the cases of two children in whom the syphilitic reaction was obtained with an extract of lymphatic glands. The extract was inoculated intracutaneously or cutaneously in the upper arm. At the end of 24 hours there appeared a papule with an erythematous halo. After 48 hours the reaction reached its highest point. Sometimes a lymphangitis appeared. The intracutaneous vaccination gives a more marked reaction than the cutaneous one. The reaction is specific for tertiary and hereditary cases.

Starting from the viewpoint that in addition to the thyroid, the thymus also plays a rôle in the etiology of Graves' disease, and that surgeons have had pronounced success in performing thymectomy in cases of this condition when thyroidectomy had failed, Stoerk has subjected the region of the thymus to the action of the Roentgen rays. In the Society of Internal Medicine and Pediatrics he presented 4 cases showing the typical symptoms of this disease: trembling, palpitation of the heart, nervousness, general excitement, loss of weight, exophthalmos etc. The upper part of the sternum was irradiated energetically several times. After every irradiation the number of the leucocytes and lymphocytes in the blood increased and fell again to the normal soon afterward. In one woman the thyroid increased in size. This method of treatment has not yet been perfected. In microscopic preparations of an irradiated thymus of the rabbit, Stoerk showed that the volume of the organ decreases and that the gland undergoes induration. In addition the gland shows a pronounced colloid formation and an increase in the follicles.

Before the same society Prof. Eppinger presented two brothers affected with familial icterus. The mother, a grandmother, and an aunt of the patients, and a child of one of them, were also icteric. This type of jaundice shows some traits similar to the acquired hemolytic icterus, and like the latter, it is to be traced to a disease of the spleen. On one of the patients splenectomy was performed some time ago. The icterus disappeared within nine days and has not returned. The second patient was also to be subjected to this operation.

Professor Hamburger contributed a further example of suggestive therapy in children in a case of chronic intermittent nervous diarrhea in a boy. The patient had from time to time attacks of diarrhea, in which he had from seven to ten liquid stools during the day or night. In spite of these he was in a good state of nutrition. The symptoms were such as to suggest a nervous origin for the diarrhea. The patient received, twice a day, 5 drops of tinctura amara. The diet was not changed. The attacks of diarrhea stopped completely.

Hugo Salomon demonstrated the intestine removed from a patient who had died from aphthæ tropicæ (sprue). A man 30 years of age had suffered from a gradually increasing diarrhea for several years, with the appearance from time to time of an eruption of vesicles on the abdomen. These vesicles disappeared temporarily, but recently they were continually in evidence. The diarrheic stools had an alkaline reaction, sometimes contained blood and always contained mucus. The diarrhea did not respond to any form of treatment. The patient died finally from inanition. At the autopsy a condition of irritation of the small and large intestine was found. There was also a marked edema and attenuation of the intestinal wall, and at the lowest portion of the jejunum about twenty polypi were found. In the vesicles present in the mouth, which vesicles gradually turned into small ulcers, the *Oidium albicans*, thrush fungus, was found. Aphthous stomatitis has no uniform etiology.

The rare localization of a metastasis from a hypernephroma was indicated in a case presented by O. Benesi before the Vienna Medical Society. The patient had a swelling like a follicle in the left auditory canal, which swelling when touched with a probe bled slightly. The patient also had ringing in the ears and was somewhat deaf. Exploratory excision revealed a perithelial tumor, which was supposed to be a metastasis from a malignant hypernephroma. Further examination demonstrated the presence of a tumor of the left kidney.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

A CHOLERA CARRIER FROM AN UNINFECTED COUNTRY—A NEW MALARIAL MOSQUITO—EXTRACT OF RICE POLISHINGS IN THE PROPHYLAXIS OF BERIBERI—GOOD EFFECT OF DISPENSARIES IN THE MORO PROVINCE—SMALLPOX IN SAMAR—NATIVE DOCTORS FOR THE CONSTABULARY—PERSONALS.

MANILA, P. I., March 28, 1914.

It may perhaps be remembered that some time ago a case of beriberi, in a Chinaman, was reported as having arrived on the S.S. *Prinz Sigismund* at Manila from German New Guinea at 8 o'clock in the morning and that death took place later on the same day. Upon autopsy it was found, in addition to beriberi, that he had been a true cholera vibrio carrier. A further investigation of this matter shows that this Chinaman had been a permanent resident of Rabaul, German New Guinea, for a number of years and that he had embarked on the vessel eleven days previously. These facts were communicated to the officials of German New Guinea, who state in reply that in accordance with the best information available no cholera has ever occurred among residents of New Guinea. In view of the foregoing, it is most difficult to account for the manner in which this case may have been infected with cholera vibrios. The vessel came directly to Manila without any stop en route. The only hypothesis which has suggested itself is that perhaps some members of the crew, most of whom are recruited at Canton or Hongkong where cholera exists almost constantly, may be cholera carriers and have infected the beriberi victim on the voyage between New Guinea and Manila.

The Bureau of Science is conducting a number of investigations with regard to the possibility of the *Myzomyia rossii* mosquito being responsible for conveying malarial fever. The preliminary experiments apparently confirm the observations of Banks, made some years ago, that this mosquito is capable of conveying malarial infection.

Among the legislation passed by the Philippine Legislature is an act appropriating a small sum to the Bureau of Science for the purpose of preparing and distributing an extract of rice polishings with the hope that its administration will reduce the incidence of beriberi, particularly among children.

The effect of the dispensaries that are being established throughout the Moro Province by Major E. L. Munson, the health officer for that province, is becoming apparent through better public order which prevails among the Moros in the districts in which the dispensaries are in operation. The work of the government in this direction is being greatly aided by the different church denominations that are also opening up dispensaries. Recently Mrs. Lorillard Spencer of New York opened a dispensary and an industrial school in Jolo. It is being generally recognized that furnishing medical relief to primitive peoples does more to win them to the ways of civilization than stationing regiments of soldiers among them.

Smallpox in epidemic form has made its appearance in the province of Samar and a few cases are reported in Surigao, which is in Mindanao and close to Samar. The cause for the outbreak is due to the failure effectively to vaccinate the children that were born since the last systematic vaccination of the residents of Samar took place. It has been the practice for the Insular Bureau of Health to vaccinate all the residents of a province and then in order to meet the demands for more local autonomy to depend upon the local officials to vaccinate at six months intervals all children that are born in the interim. Experience shows, however, that the local officials either will not or cannot carry out this vaccination successfully, with the result that smallpox makes its appearance and hundreds of lives are sacrificed. Smallpox has invariably been stamped out in every province which was vaccinated by the central Bureau of Health. The bill which was introduced into the last legislature which had for its object the more central control of sanitation of the provinces and which would largely have corrected conditions of this kind, was defeated.

Recently there has been much agitation against appointing more American doctors to fill vacancies in the Constabulary, as a result of which it has been semi-officially announced that only Filipinos will be named hereafter.

Dr. W. E. Woodbury, who has been Superintendent of the Philippine General Hospital during the past few years, has resigned and has returned to the United States. Dr. John E. Snodgrass, formerly Assistant to the Director of Health, has succeeded him.

Assistant Surgeon D. C. Turnipseed of the U. S.

Public Health Service, has completed his term of duty in the Philippine Islands and has been ordered to proceed to San Francisco for assignment. Dr. S. K. Carson of Iloilo, has been named as Acting Assistant Surgeon in the U. S. Public Health Service and will fill the vacancy left by Dr. Turnipseed.

1. On Territorial Autonomy in Cerebral Circulation and Its Role in the Genesis of Symptoms in the Psychoneuroses. J. W. Courtney.
2. Ten Tests by Which the Physician May Determine when a Patient Is Cured of Gonorrhea. C. M. Whitney.
3. Some Hygienic Tests Applied to Orthopedic Conditions. H. W. Marshall and H. L. Langnecker.

**1. Territorial Autonomy in Cerebral Circulation and the Psychoneuroses.**—J. W. Courtney postulates the existence of the power of independent dilatation and contraction on the part of the vessels of the brain. One may logically assume that this organ, in common with other parts of the economy, is provided with an identical autonomic circulatory apparatus, and receives under normal circumstances a supply of blood nicely proportioned in quantity to the functional activity of the moment. When one considers that this activity is a constantly changing one with regard to both area and intensity, one may carry this assumption further and safely postulate the existence of a territorial autonomy in cerebral circulation. Physiologically there is presumptive evidence of this condition on every hand. Pathologically there are two forms of presumptive evidence of the existence of cerebral territorial circulatory autonomy: direct and indirect. The first is clearly manifest when the cranium is opened and certain portions of the cortex are observed in cases in which the brain has been contused by a diffused traumatizing force. Here one not infrequently finds in the absence of all discoverable pressure from within or without, cortical areas that are absolutely pulseless side by side with others which are pulsating normally. Indirect evidence on the point in question is derived from observations in regions other than the brain, whose vessels are supplied by the autonomic system. The author assumes that the disordered brain function underlying hysteria is directly traceable to changes in vascular tension. The mode of onset, the distribution and the general behavior of hysterical symptoms all accord with such a view. In the emotional induced crises one sees very clearly evidence of the varying degrees with which different brain areas respond to the change in vascularity. Beginning with small facial muscles the motor excitement affects progressively more numerous muscles and larger muscles and finally ends in sardonic laughter and violent contortions. Phenomena in the intellectual sphere, such as changes in the personality, are explainable on precisely the same ground.

**3. Hygienic Tests Applied to Orthopedic Conditions.**—H. W. Marshall and H. L. Langnecker state that medical literature of the past shows scanty hygienic data applied to orthopedic cases. Practically none of the older records can be considered complete or adequate in showing quantitative variations which occur from time to time. An attempt has been made by the authors to tabulate in more available form some of the more easily measured normal functions and conditions, arranging them in a way that they can be understood in a glance, and showing variable proportions among different combinations, as well as the absolute degrees each measurement exhibits. The relation of each observed condition to the average figures for the same condition among collected large series also is roughly indicated. Data pertaining to normal individuals have been set down arbitrarily in a table at points marked off upon a straight line. Variations from these averages have been indicated in a convenient way upon perpendicular lines drawn through the straight line of averages, one for each average figure. Each perpendicular has then been divided into a scale to show degree of variations possible for each separate condition. Having selected this method of recording results, patients have been weighed, measured, tested with spirometers, blood pressure apparatus, dynamometers, etc., and from results obtained a curve has been plotted for each individual. Using the table as the pattern for all records, sheets of thin paper have been placed over the table and straight lines drawn upon the blank sheets to coincide exactly with the straight line of averages of the table. Then various numbers obtained from each patient are marked off upon the individual sheets by looking through them to the right places upon the proper perpendiculars of the table. Points thus located then have been joined together into a continuous irregular line. These irregular curves show easily the variable combinations, the deviations of each variable from the average, and the changes that occur from time to time.

**1. Salvarsan and Brain Tumor Symptoms Dependent upon Syphilis.**—J. Collins states that during the past four years he has encountered at the Neurological Institute several patients who had fairly typical histories and physical signs of brain tumor, which have yielded very promptly to salvarsan medication. None of these cases was suspected to be of syphilitic origin. The pathological process in the author's cases was predominantly meningeal. In the first case there must have been, in addition to meningeal involvement, an increase of intracranial pressure, probably due to increase in the intraventricular fluid, constituting in reality a hydrocephalus. In no other way can the papilledema be satisfactorily explained. In the second case the somnolency was due to a similar increase of intraventricular pressure. Brain syphilis displays itself in one of three forms, affecting the blood vessels, or meninges, or producing a new formation sufficiently circumscribed to be considered a tumor. The meningeal variety is by far the most common. It affects predominantly the base of the brain and the convexities. The first two cases were striking examples of the former, the third case was an example of the latter. When the meningitis is of the gummatous variety, which it is usually, the symptoms accompanying it are most complex and desperate, and one has to depend upon the serological examination for the diagnosis. On the other hand, when the meningitis is of the simpler exudative variety, the diagnosis is more readily made clinically. Headache is the chief and most constant symptom. It is alleged to be worse at night, but this

is by no means always so. Scarcely any two patients describe this pain in the same way or localize it in the same place. The next most common symptom is paralysis of one or more of the eye muscles, and the motor oculi is often affected. In the third of the author's cases the pathological process was a convex meningitis.

2. **Constitutional Dysmenorrhea.**—S. W. Bandler notes that preceding the menopause, instances of constitutional dysmenorrhea become frequent. There is the type of case in which the annoyances have been present for a varying number of years from puberty on, or else have developed at a later period, or have come on after marriage, or have been aggravated by various circumstances. Then comes another and important type, the cases into whose histories these annoyances have come as a new process. These patients in their earlier years had slight, if any, premenstrual annoyances. As they approach the period of life when they look forward to the menopause their menstruation continues and even grows stronger, with or without intervals of amenorrhea, and marked cyclic states of irritability appear. These cases are in a large number of instances examples of hyperthyroidism; and some of them are cases of actual or relative hyperthyroidism. Besides one finds instances of the very opposite type, in which a phlegmatic and depressed state results, a condition often due to hypothyroidism. The cause of this dysthyroidism lies in the thyroid glands and ovaries. Either the latter function with marked energy, or overshadow the thyroid activity, or they actually overstimulate or rouse the thyroid gland, or else they work with less than their former power, but the thyroid fails to regress with equal degree, and a state of cyclic hyperthyroidism results. The administration of thyroid gland extract between menstrual periods and before menstrual periods, serves to aid in making the diagnosis. In the hyperthyroid cases the premenstrual annoyances are brought out in the intervals, or are brought on earlier, or are accentuated by the administration of thyroid extract. Among the medicinal methods, preparations of bromides and of valerian, and not infrequently ovariin, help to diminish the annoyance. In the hyperthyroid or hyperovarian type small doses of thyroid are of special value. In some of the hyperthyroid cases small doses of opium and belladonna are absolutely necessary to give the patient relief, not so much from pain and discomfort as from the irritability and often almost maniacal restlessness which typifies these hyperthroid cases. In the hyperthyroid form, or hyperovarian type, thyroid be given.

3. **Apraxia in Relation to Aphasia.**—J. H. W. Rhein points out that the relation that apraxia holds to the subject of aphasia has been hitherto exemplified in connection with certain forms of aphasia only, namely, motor aphasia, agraphia, amimia, and amusia, but the recent work of Liepmann shows that not only motor aphasia but every form of expressive aphasia and apraxia are similar. Before reviewing Liepmann's ideas without which no discussion of the relation of apraxia to aphasia could be complete, the author refers to some of the features of apraxia in order to show clearly the bearing one has on the other. Apraxia is an inability to perform purposeful movements, while at the same time the object and its use are recognized and the limbs can be readily moved; in other words they are not paralyzed. The apraxia is usually unilateral, affects simple movements, and gives rise to amorphous instead of purposeful movements. There is recognized also an ideatory apraxia which affects mainly the manipulation of objects, for example, a cigar is rubbed against the match box in an effort to light the cigar. This is called association apraxia by Bonhoffer. There is then the Glied-kinetic apraxia of Kliest in which movements which arise from practice, such as writing, drawing, and knitting are implicated. This is the cortical apraxia of Heilbronner. Finally, there is amnesic apraxia in which the subject forgets, on command or invitation, how to perform certain purposeful movements. While aphasia may or may not accompany apraxia they are often associated in the same case.

4. **Anarthria and Its Relation to Aphasia.**—T. H. Weisenburg defines anarthria as an inability to articulate words, and by dysarthria a less degree of difficulty in articulation. At least this is the meaning that has always been ascribed to these words until Marie interpreted anarthria differently. In the usual accepted view the anarthric speech is slow, weak, monotonous, indistinct and sometimes hesitating or scanning. This impairment varies in different cases, and is the result either of an involvement of the motor nuclei in the medulla and pons, that is, the motor nuclei of the twelfth, eleventh, tenth, ninth, seventh, and fifth cranial nerves or of their central connection between the above mentioned nuclei and the cortical centers in the lowest portion of the precentral convolution. In other words, it occurs either in true bulbar or pseudobulbar palsy. Marie, and later Moutier, however, define anarthria as a more or less pronounced disturbance in the articulation of words, not dependent upon paralysis of the lips and tongue. Possibly it is a kind of incoordination or ataxia. It often exists pure in the isolated state associated with no other changes, in which case it is the anarthria of Pierre Marie. An individual often young (syphilitic or cardiac) is the victim of a right-sided hemiplegia. When he recovers from his coma or somnolence, he cannot speak. His tongue though not paralyzed does not obey his will. He understands all, but says nothing. There is but one symptom, the suppression of articulate speech. Sometimes monosyllables are preserved, and are used for every attempt of speech. Communication by gesture is perfectly well done.

9. **Shock.**—E. Boise believes that the cause of the low blood pressure in shock is imperfect filling of the heart and arteries, and that this imperfect filling is due, not to a weakened venopressor mechanism, but to a tonic contraction of the heart by reason of which it cannot relax sufficiently to receive blood from the engorged veins. The author bases this conclusion on the following facts: First, on his charts, as made by the myocardiograph during series of experiments; second, on the fact that the author has seen the heart, under continued stimulation, grow small and harder; third, on the evidence of Henderson, who states that rapidly induced acapnia may cause such a severe cardiac hypertonus that death results from cardiac tetanus; fourth, on the contributory evidence of Groedel, Mowitz, Dietelen, and others who state that in the so-called collapse of athletes after severe and prolonged exertion they have, with the orthodiagraph, seen the heart grow smaller and firmly contracted rather than acutely dilated, as has been heretofore believed and taught.

**2. Chaparro Amargosa in the Treatment of Amebic Dysentery.**—P. I. Nixon states that one is indebted to the Mexicans for the name "chaparro amargosa." It means "bitter bush." It has been a domestic remedy among the Mexicans of Southwest Texas and Mexico for many years. It is said that General Zachary Taylor's soldiers learned its secrets during the Mexican War and profited not a little from its use. Botanically it is classified as *Castela nicjolsoni*, Hook, and belongs to the Simarubaceæ, of which family quassia and simaruba are also members. Putegnat states that "it is hardly to be distinguished from the entire-leaved plants of the Simarubaceæ," but places it in "the natural order Ochnaceæ." The first attempt to bring this remedy before the profession was made by Putegnat of Brownsville, Tex., in 1883. He studied the plant botanically and chemically and recommended it as an antiperiodic and incidentally mentioned that it had been used in cases of diarrhea and dysentery. Chaparro amargosa is a small thorny bush, which is indigenous to Southwest Texas and Northern Mexico, growing on thin rocky mesquite or post-oak land and having an especial tendency to be found on small rocky hills. It grows to be a bush two or three feet in height, its size depending on the comparative richness of the soil on which it is found. Its leaves are small and lanceolate, its flowers pink and very small. The matured fruit is a red berry which is about the size of a pea. All parts of the plant from the root to the berry possess the characteristic bitter taste and medicinal properties. It is on the market as a fluid extract, the dose being from one to three fluid drams before meals. The author reports ten cases of undoubted amebic dysentery of from three weeks' to four years' standing. Nine patients were given the infusion of chaparro amargosa and one the detannated fluid extract; all were cured and there apparently was no recurrence so far as could be determined, the period of freedom from symptoms ranging from ten months to two years, with the exception of the last case. In only one case was a living ameba found in the stools after treatment was given. The cases averaged less than two days before the stools became normal. There were no liver abscesses or other complications. The experimental data proved the amebicidal action of chaparro amargosa no less surely than did the clinical results, the drug undoubtedly having an elective affinity for the protoplasm of *Entameba histolytica*.

8. **Value of Kidney Tests.**—W. E. Stevens states that in normal cases the time of appearance of sugar and phenolsulphonephthalein is comparatively the same on both sides. In normal cases the phloridzin, phenolsulphonephthalein, and urea tests show almost identical values for both kidneys, their efficiency as comparative tests thus appearing to be about equal. In pathological cases all three tests show almost equally low values on the diseases as compared with the healthy side, thus demonstrating their almost equal practical value. The simultaneous application of the preceding tests tends toward greater accuracy of results, is not especially time consuming, is not complicated and does not require more than the ordinary skill, which can be attained by an intelligent nurse. Moreover it gives positive assurance as to which kidney is performing the greater amount of work, thus rendering unnecessary a reputation of ureteral catheterization for the purpose of gathering additional evidence regarding renal functions. In pathological cases a coincident diminished functional value on one side in all three tests points unmistakably to a marked defect in the corresponding kidney. This in the presence of a normal functional value on the opposite side, and satisfactory total functional values as ascertained by blood cryoscopy, the bladder phenolsulphonephthalein test, etc., would permit of the removal of the diseased organ. A single renal functional test may lead to erroneous deductions and does not give sufficient assurance to justify a radical operation such as removal of the kidney. Prior to operation, comparative functional tests should be strengthened by tests of total renal function. The urea test consumes the least time and is accompanied by a minimum of discomfort to the patient. Moreover, it is not based on the elimination of a foreign substance. As compared with the phloridzin test the phenolsulphonephthalein test is subject to fewer technical errors and is less time consuming, a factor of no little importance to the patient as well as to the physician. On the other hand, the quantitative estimation of the excreted dye even with the Dubosecq colorimeter is subject to a not negligible amount of error, while following phloridzin injection the estimation of sugar by means of the Lohnstein saccharimeter is mathematically correct.

**2. Massive Collapse of the Lungs Following Abdominal Operations.**—T. R. Elliot states that in the Bradshaw lecture of 1908 W. Pasteur discussed the nature of massive lobar collapse of the lungs, as contrasted with the scattered lobular collapse that occurs passively when the bronchioles are obstructed by secretion and the alveoli are slowly emptied by absorption of their air into the circulating blood. The authors report eleven cases of postoperative collapse which agreed closely with Pasteur's description. One feature he laid little stress on—and this feature the authors regard as critical. All had mucopurulent expectoration and fever, 101° to 103° F., preceding the collapse. There is no reason why fever should develop in a simply nonseptic case with reflex inhibition and "active collapse." This fever, which makes the resemblance to pneumonia all the closer, is caused by a purulent bronchitis perhaps determined by a preceding infection of the air tubes. Together with this, some unknown cause, either thoracic or abdominal, produces a reflex immobility of the diaphragm and as the combined result of these two disorders of respiration the lower lobe of the lung undergoes pas-

sive collapse throughout its mass. This may occur at any time in the first week after the operation. Since the volume of the collapsed lung is much reduced, movements occur to restore the balance of intrapleural pressures and the heart is displaced to the affected side, while the contralateral lung is overdistended. Pain and cyanosis develop when the displacement is rapid and extreme. At first there are immobility, a dullness of percussion note, and a weakness of breath sounds on the collapsed side, whereas the other may be so hyperresonant as to resemble the state of pneumothorax. Later, as the bronchial airway opens up, the breath sounds become tubular with egophony and whispering pectoriloquy. All the signs vanish in two or three days if the right diagnosis is made and active treatment is adopted. Otherwise the collapse may persist, the infection may spread through the lung, and pleurisy or true pneumonic consolidation develops as a complication. The chief criteria are fever, the greenish mucopurulent sputum, and the displacement of the heart. These together give the distinction from pneumonia or pulmonary embolism, the latter disaster being in the worst cases suggested by the acute onset of pain and cyanosis. The aim of treatment is to open up the lung before the infection spreads into its substance. Expectorants are given with potassium iodide, the patient is encouraged to make full inspiratory efforts, especially of an abdominal type, and if possible for five minutes every hour despite pain that may be felt from the abdominal stitches. If the abdomen has been tightly bandaged this impediment to breathing should be slackened. It is conceivable that the worst cases of cyanosis and pain might be relieved by an intrapleural injection of oxygen, in order to restore the balance of volume and push back the displaced heart and the overdistended lung. Fortunately these urgent conditions are rare, and the authors have had no occasion to try this method since the possibility of such a line of treatment occurred to them.

**4. Death from Hyperacute Streptococcal Infection.**—G. Jefferson concludes that the radical removal of tuberculous glands of the neck while a rational procedure, is not unfraught with danger. This is especially the case in the presence of a sinus. Two cases operated upon by the author died from a fulminating streptococcal infection, one twelve hours, the other twenty hours after operation. The exact source of infection was not discovered, but was probably the walls of the sinuses present. Prophylactic treatment should be carried out for a few days before operation—the sinuses should be well swabbed out with iodine or similar antiseptic. The wound should be well washed out with saline before it is closed and drainage should be employed, preferably through a separate stab wound in the skin flap. In children at least probably no treatment will avail when once the bacteriemia is established.

**1. Cause and Cure of Cancer.**—W. S. L. Barlow suggests that in radiations, and particularly in radium radiations, there is an agency which might well serve as a cause of cancer to the exclusion of all others. The author's grounds for making this statement are as follows: (1) Radium is widely distributed throughout nature in such quantities as have been shown capable of inducing accelerated division of cells. (2) Bacteria suspended in a radium-containing fluid collect the radium from that fluid. (3) The alpha rays of radium cause the disappearance of Altmann's granules from normal cells which contain them, while Altmann's granules are absent from the essential cells of malignant growths. (4) The element radium may occur in normal tissues, but if present is found on an average in much smaller quantity than it is found in carcinomatous tissue (whether primary or secondary) or in the tissues of carcinomatous patients. (5) Whereas gallstones unassociated with carcinoma of the gall bladder contain no radium or at most traces but little outside the range of experimental detection, gallstones associated with primary carcinoma of the gall bladder always contain relatively large amounts of radium. (6) Exposure to *x*-radiation over long periods is liable to be followed by carcinoma of the exposed parts. Although a cause of cancer, radium at the same time acts as a cure. The grounds upon which the author bases this belief are the following: (1) In a sufficient dose radium and other radiations are capable of killing every type of cell met with in cancer. (2) The action of radiation upon cells is selective, or conversely, all varieties of cells are not equally vulnerable to radiations. (3) There is some evidence that an active immunity is produced as the result of acting upon malignant cells with radium. The author offers the following practical considerations: The microscopic examination by a competent morbid histologist should be made of every case subjected to radium treatment. The amount of radium in use should be verified periodically by a competent physicist. It should be recognized that the metabolic processes of every patient after exposure to a considerable dose of radium are profoundly modified at least for a time. Treatment with radium should not follow immediately upon operation. If radium treatment of a malignant new growth be decided upon, such treatment should not be preceded by complete removal of the main part of the growth. Whatever may be the case in the future, for the present radium treatment in malignant disease should be confined to those cases for which modern surgery cannot offer a fair prospect by operation.

**4. X-rays and Radium in the Treatment of Cancer.**—F. H. Johnson concludes that in early cases, whether for preoperative or postoperative irradiation, the Roentgen bulb is to be preferred to the radium tube. When surgical removal is impossible, a tube of radium should be buried in the center of the tumor, but the *x*-rays should be used on the growth including the surrounding area, and any organs in which a metastasis is likely to occur. This combined treatment may result in some actual necrosis in the immediate neighborhood of the radium, but as long as this is confined to the interior of the neoplasm, no harm will result. Finally, radium therapy is the method of choice in cancer of the vagina, uterus, and rectum, but even here *x*-rays form a useful adjunct, so far as adjacent parts are concerned. Also, in practice one finds that one has to wait at least three or four weeks to obtain a supply of radium. Nothing less than 50 milligrams is of much value, and the market price of this is $4,000 to $5,000. Consequently, most institutions are com-

pelled to hire their supplies, and pending the arrival of the latter, the *x*-rays should be used vigorously in all cases. Even uterine, rectal, and esophageal cancer can usually be held in check during the unavoidable period of waiting. There are today thousands of cancer patients who believe, and whose friends believe that they are being left to die because sufficient radium is not available to treat them. This belief adds greatly to their mental distress, and the author has endeavored to show that this belief for the most part is erroneous. The Roentgen rays skilfully applied are of service in relieving pain, preventing ulceration, and causing the shrinkage or disappearance of external growths. Active life can be prolonged almost always for months, and sometimes for years. In pelvic cancer the insertion of a radium tube appears to be of greater value, but there is as yet little evidence to show that the results of the new therapy are, on the whole, more lasting than those of the older method.

*May* 4, 1914.

**Work of the Athletic Scientific Laboratory at Charlottenburg.**—Nicolai and Zuntz have made a special study of the filling and emptying of the heart under stress, especially in sports. An important premise is as follows: All sudden changes in the size of the heart depend upon previous changes in the blood vessels. We must differentiate between acute and chronic conditions. Military service and hard mechanical labor are known to increase the size of the heart, and the same thing happens to race horses and coursing hounds. The wild animal of many species has a larger heart than his domesticated brother, and in some birds this is conditioned by rarefaction of the upper air. The ski runner and the swimmer show a gradual enlargement of the heart. Recent work along these lines has been carried out chiefly by means of the *x*-ray, and the general conclusion has been that in the single efforts the heart enlarges not during but after the latter. The authors studied numerous subjects in regard to the period of effort, the immediately subsequent period and the period half an hour after the effort. The subject studied worked on a sort of treadmill, with *x*-rays photographing the heart. It is easily seen that during the exertion the heart enlarges, and also that as soon as the exercise terminates the heart suddenly resumes its normal size. In heart strain in general there is always a blood reserve, the organ is not entirely emptied. This reserve is available in sudden demands upon the heart's activity.

**The Proteolytic Enzyme in the Serum of Normal and Diseased Subjects.**—Saxl, in a brief report on this subject, sums up the work of some recent investigators, notably Sörensen, in this field. He regards the action of autolytic enzymes as *nil*. He has tested the sera of the healthy, the pregnant, the mildly ill, and severely ill for evidence of proteolytic and peptolytic enzymes. It is probable that in the cases of cancer and gestation, ferments of tryptic-creptic character exist in the serum; and that in other subjects pepsin like enzymes predominate. As a rule, tested by Witte peptone, the serum possesses proteolytic activities. The author will continue this line of research.

**Possible Prevention of Paresis by Salvarsan Medication.**—Wechselmann reports a case which is at the same time a retort to Oppenheim's recent assertion that certain alleged claims of recovery from metasyphilis in the Lankwitz clinic were unfounded. The patient in question, already treated with salvarsan and Hg, had been abandoned to his fate in an asylum. The author, at the request of the family, sought him out and found him isolated and raving, pulse bad. After an injection of salvarsan there was marked rapid improvement, which, of course, could be accounted for as a spontaneous remission. Leaving this possibility out of consideration the author proceeded to a second and third injection, and after each one further improvement was noted. At the end of two months the pupillary and patellar reflexes were normal, there was good speech and reckoning, no Romberg and only slight tremor of tongue and fingers. Psyche normal. Wassermann reaction negative. Later patient with other symptoms in abeyance, developed epileptic attacks, some being atypical in character. Salvarsan was resumed. The attacks abated in number and severity. Suggestion of a focal lesion. The Wassermann reaction remained negative.

*April* 23, 1914.

**Lithogenic Icterus.**—Riedel sums up his article as follows: the icterus which appears after a stone enters the choledochus, is mechanical only to a slight and transitory extent; its causation is almost exclusively inflammation of the bile passages, which is propagated to the liver parenchyma. Inflammatory icterus in the narrower sense arises from the propagation of inflammation from the gall bladder to the overlying liver substance, in acute attacks. It has not been shown that the swollen glands in the ligamentum hepatoduodenal exerts as strong a pressure on the deep bile passage as to give rise to mechanical icterus. A protracted impaction of a stone in the ring of Vater's papilla should be of rare occurrence. Should cholecystotomy come into question a trial incision parallel with the costal arch and some 2 cm. distant therefrom has notable advantages, because it permits prolongation in either side and especially upwards to the angle between the costal arch and base of the ensiform process. Duodenotomy is only exceptionally indicated in stone at or within the papilla. Ordinarily cholecystotomy is quite sufficient.

**Treatment of Syphilis with Combined Hg-Salvarsan.**—Scholtz, after a general summing up, states that when all arguments have been heard, we must still abide by the contention that a combination of salvarsan and mercury, properly administered, gives us surpassing results with no noteworthy risk to the patients. A judgment as to salvarsan, its advantages and drawbacks, can be reached only through an equivalent series of controls; while a judgment of salvarsan purely as a medicament, with its advantages and dangers, cannot be stated summarily, but only has reference to individual forms of treatment.

**Prevention of Afterpains in Local Anesthesia.**—Schlesinger speaks of the intense afterpains in analgesia of the fingers. These are so great as to make "painless operations" a mockery. In all operations on digits injections should be made only where loose tissue exists, naturally in the interdigital webs. One should always avoid injecting into inflamed tissues. This precaution will do away with a large proportion of afterpains. The latter are not due so much to chemical peculiarities of the fluids injected as to its physical properties. Hence there is no chance for a chemical neutralization.

**Serous Cysts of the Pancreas.**—A. and P. Behague state that the diagnosis of this condition is based upon the following symptoms: emaciation, vomiting, the signs of pancreatic insufficiency, celiac neuralgia, and the presence of an immovable tumor surrounded by an area of resonance, above all after insufflation of the stomach.—*Le Bulletin Médical.*

# Insurance Medicine.

## THE LATE DR. J. W. LEWIS.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

THE recent death of Dr. J. W. Lewis, of Hartford, Conn., calls attention to a man who at one time was the most widely known physician in this country. He was not often seen at medical society meetings or noted as the writer of papers in medical journals, but in the private consulting rooms of physicians and surgeons and lawyers, and in conferences, in homes and hotels, he was a very familiar figure. He was born in Greenport, L. I., graduated from New York University in 1853, and in 1861 became Surgeon in the Civil War, and was distinguished as an executive officer both in the hospitals, and in field service.

In 1868 he became connected with the Travelers Insurance Company of Hartford, as a Medical Director and Adjuster in the claims department. The Travelers was among the first to take out accident insurance in this country, and its policies sold everywhere. Hosts of disreputable men holding policies claimed all sorts of injuries and accidents, and the effort of the company to discriminate between the real and the false was a great task at first. Dr. Lewis displayed a very acute analytical mind and diagnostic skill in medical and surgical problems. Almost innumerable questions were constantly raised along medicolegal lines, which required the highest kind of inductive and deductive reasoning, as well as acquaintances with law and medicine and its applications to the events of everyday life. These facts were not settled in the office of the company. Dr. Lewis went out and made personal examinations, particularly of the doctors who certified to the injuries, as well as interviewed the claimants. This he did in a most quiet, unofficial way, making free notes of the facts and opinions, gathering about the case and estimating them with a detective skill of Monsieur Lecoq or Allen Pinkerton. Surgeons were astonished at the exhaustive studies made of disputed cases and attorneys were overwhelmed with confusion to find superior information and more exact deductions from groupings of facts which they thought they had understood. Dr. Lewis combined a certain judicial temperament in the grouping of facts with a detective skill to know where they could be found. He also made himself familiar with the work of all the leading surgeons of the country, particularly on questions where there was responsibility and obligation, and in this he was recognized as an eminently just, and fair man, never taking advantage to advance the interests of the company.

Thus, year after year, this mild, gentle, soft-spoken man traveled about the country, unobserved, gathering facts and data, and laying the basis for a life-insurance medical jurisprudence, which before his time was in a very chaotic state. He established rules for the examination of disputed claims, and indicated ways and means in which fraudulent claims could be detected; and with this made an enormous personal acquaintance with active working medical men, all over the country, and particularly those, whose work came in question by the insurance companies. In this field he was a pioneer, and although rarely seen in court, his work was shown in most critical exhaustive studies of facts real and alleged. He was a very close observer and kept copious notes of all the facts, and thus was able to verify the conclusions that he reached.

Dr. Lewis's life was full of most romantic incidents in which he figured as a physician, detective, and judge in a remarkable way. He has left very tender memories among his associates and the friends who knew him.

---

**When a Physician Is Claimant for Accident Insurance, Is Self-Treatment Allowable.**—The conditions of insurance of most of the German accident companies render the claim and payment of the insured's daily stipend dependent on the fact that the medical treatment is continued, and that persistence of a restriction of ability to work resulting from the accident does not in itself suffice for the maintenance of such a claim. One may now ask what is to be understood in regard to continuance of treatment; whether by others, or, in case the claimant is a physician, by self-treatment?

On March 22, 1913, a County Court judge found for the defendant company on the following grounds: There is no doubt that the complainant, as physician, and by reason of the court's knowledge of his personality, and of his official status as county physician, has bestowed upon himself the self-treatment in question, to his best knowledge and conscience, and had made an estimate of his inability to work. There is involved here a principal issue, which must be applicable to all questions of the kind. Section 5, No. 2, of Insurance Conditions, requires first of all that the insured must without delay, and thereafter continuously until cured, call in a physician. Section 8 determines that the compensation will be reckoned at the end of each month on submission of medical attests as to the degree of disability and the uninterrupted duration of medical treatment.

These provisions interpose between the insurer and insured a third disinterested person, specially educated to judge of the facts upon which the compensation is reckoned.

Suppose the insured to have this training himself, self-treatment and self-appraisement of occupational disability, the participation of the disinterested third person will be eliminated.

This is, however, just as little to be approved of as the converse, viz., that the insurer, having eliminated the insured, should, through its own medical staff, undertake the treatment of the insured and permit itself to determine the occupational disability of the same. Therefore the self-treatment of the claimant does not suffice him to sustain a claim for compensation. The circumstance is also not changed, that the treatment from May 5 on was relatively simple, and that the claimant as physician could judge technically as to the further course of the treatment as confirmed by the witness, Dr. A. The proof that complainant from May 5, 1912, was under the continuous treatment of Dr. A. was not forthcoming, for the latter only announced that complainant had said to him after May, 1912, on occasion, that the injured hand was still partly unfit for use; he, witness, however, did not know whether Dr. A. merely asked his opinion as to the interval between May 5 and July 1, or wanted his advice as a physician. This question of Dr. A. by complainant, as to continuance of the prescriptions before May 5 cannot be regarded as persistence of medical treatment. It was this point which decided against the plaintiff.—*Ztschr. f. Versicherungsmedizin*, August, 1913.

# Book Reviews.

Die Auffindung von Arzneimitteln. Festrede gehalten am Stiftungstage der Kaiser Wilhelms-Akademie für das militarärztliche Bildungswesen, 2. Dezember, 1913. Von Arthur Heffter. Price 1 mark. Berlin: Verlag von August Hirschwald, 1914.

This address takes cognizance of the changes that have taken place in our knowledge of drugs in the last few decades, the remarkable contributions made to the pharmacopœia by the rise of the pharmaceutical-chemical industry, how remedial agents are discovered, how humanity has attained possession of its drugs, and how it has augmented these. Our knowledge of medicines is epitomized from the dawn of history to the present time.

Diagnostic Methods. A Guide for History Taking, Making of Routine Physical Examinations, and the Usual Laboratory Tests Necessary for Students in Clinical Pathology, Hospital Internes, and Practising Physicians. By Herbert Thomas Brooks, A.B., M.D., Professor of Pathology, University of Tennessee, College of Medicine, Memphis, Tenn. Second Edition. Revised and Rewritten. Price $1.00. St. Louis: C. V. Mosby Company, 1914.

This excellent little book is intended for medical students, hospital internes, and physicians who have limited amount of time to give to laboratory work. Up-to-date and reliable laboratory tests have been incorporated in a clear, concise manner. The Wassermann reaction and the complement fixation test for gonorrhea are included, besides the usual topics on sputum, blood, gastric and intestinal contents, serous fluids, tuberculin diagnosis, etc.

Ulcer of the Stomach. By Charles Bolton, M.D., D.Sc. (Lond.), F.R.C.P. (Lond.), Director of Pathological Studies and Research, and Lecturer in General Pathology, in University College Hospital Medical School; Physician (with charge of out-patients) to University College Hospital. Price $4.20 net. New York: Longmans, Green & Co.; London: Edward Arnold, 1914.

The subject of ulcer of the stomach presents many problems from the clinical and experimental viewpoints. The theories that have been advanced to explain the origin of gastric ulcer are legion. The author has broken new ground in the study of this subject and has combined with his bedside observations those of the consulting room, the out-patient clinic and the laboratory. The result of his extensive studies is a substantial volume of 396 pages, in which every phase of ulcer of the stomach is discussed in detail. The author purposely excludes the subject of duodenal ulcer on the ground that the latter condition differs from gastric ulcer in having a different origin, in being exposed to different influences, in having its own typical clinical history, and in responding in a different manner to treatment. In discussing the causes that give rise to the initial lesion that precedes the formation of an acute ulcer of the stomach, the author finds that bacterial infection of the body accounts for a large number of acute gastric ulcers. Many of these are due to terminal infection. Other causes are cutaneous burns and irritant substances introduced by the mouth. Alcohol and acid foods excite a gastritis which is a common cause of acute ulcer. Venous congestion of the stomach is an undoubted cause, while aseptic plugging of an artery is a rare cause of acute ulcer. This condition also results from pressure necrosis by a tumor, and also from injury to the epigastrium. It is possible that endogenous poisons of metabolic or other origin may be responsible for some of the ulcers occurring in kidney and liver diseases. As a result of a series of experiments the author has found that acute ulcer failed to appear if the gastric juice were put out of action. A hyperacid gastric juice produced a more extensive ulceration than a juice of the normal acidity. The gastric juice is unable to attack the healthy wall of the stomach. It is only the damaged tissue that is affected by the gastric juice. These are but a few of the facts which the author has gleaned and collated in a section of this work, comprising nearly 100 pages. The symptomatology of acute and of chronic ulcer, their diagnosis and prognosis, and their medical and surgical treatment are all accorded similarly full attention. The complications and sequelæ, such as cicatricial contraction, gastric adhesions, subphrenic abscess, gastric fistulæ, and cancer are all given ample discussion. To each section there is appended an extensive bibliography. The book contains a series of thirty-five photographic plates and fifteen figures in the text. It is well written and represents the latest word on the subject of ulcer of the stomach. The typography, paper, and binding are fully in keeping with the importance of this work.

Das Schicksal von Patienten mit Keratitis Parenchymatosa auf Hereditarluetischer Grundlage. (Syphilis und Auge. VIII. Mitteilung.) Von Priv.-Doz. Dr. Igersheimer, Oberarzt der Universitats-Augenklinik zu Halle a. S. Price Mks. 1.50. Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1913.

This article by Dr. Igersheimer occupies 52 pages. The subject is considered under four headings: First, the history of the eye affected by interstitial keratitis; second, the history of the condition of other parts of the body; third, the result of interstitial keratitis; fourth, the prophylaxis. The work is based on an exhaustive study of quite a large number of cases. The various aspects of the condition have been carefully considered and ably presented. As a review of this manifestation of syphilis the brochure is of much interest. It may be read with profit by all who are engaged in studying the subject.

Defective Ocular Movements and Their Diagnosis. By E. M. Landolt (Paris). Translated by Alfred Roemmele, M.B., Ch.B., and Elmore W. Brewerton, F.R.C.S. Price $2.00. London: Henry Frowde, Oxford University Press, Hodder & Stoughton; New York: Oxford University Press, American Branch, 1913.

This little volume of 100 pages presents a careful study of defective ocular movements and their diagnosis. Pathology is preceded by a short summary on anatomy and physiology. The various anomalies of the ocular muscles are discussed. The methods of examination employed for the diagnosis of strabismus are described and illustrated. About 40 pages of the work are devoted to a discussion of the causes of defective ocular movements. This work is most admirable. It may be read with profit by all who are engaged in the study and treatment of anomolies of the ocular muscles.

The Practical Medicine Series, Volume X., Nervous and Mental Diseases. Edited by Hugh T. Patrick, M.D., Professor of Neurology in the Chicago Policlinic, Clinical Professor of Nervous Diseases in the Northwestern University Medical School, ex-President Chicago Neurological Society, and Peter Bassoe, M.D., Assistant Professor of Nervous and Mental Diseases, Rush Medical School. Price $1.35. Chicago: The Year Book Publishers, 1913.

The book serves the usual valuable purpose of the series by affording the busy man a concise statement of the recent advances made in the diagnosis and treatment of nervous and mental diseases. Many interesting cases have been cited.

The Practical Medicine Series, Volume IX., Skin and Venereal Diseases, Miscellaneous Topics. Edited by W. L. Baum, M.D., and Harold W. Moyer, M.D. Price $1.35. Chicago: The Year Book Publishers, 1913.

In addition to a résumé of the year's literature of skin and venereal diseases, the book devotes some space to the consideration of such general subjects as Medical History, Medical Economics, Sociology and Eugenics. The volume proves both interesting and instructive.

L'Enfant et Son Médecin. Guide Pratique de L'Hygiene et des Maladies de L'Enfance, de o à 15 Ans. Par le Dr. Albert B. Ball, Ancien Interne des Hôpitaux de Paris, Assistant de la Consultation de l'Hôpital Trousseau; Inspecteur de la protection des enfants du 1er age; Médecin des établissements scolaires de Paris; Laureat de la Faculté de Médecine. Deuxieme édition, revue et considerablement augmentée. Price 6.50 francs. Paris: A. Maloine, 1914.

This small volume is printed on thin paper, so that the 375 pages form a thickness of only three-eighths of an inch. The type is small, with the result that considerable matter is comprised within the text. This deals with the subject of pediatric therapeutics and indications, dosage, methods of examination, hygiene, cludes the management of emergencies, therapeutic infeeding, general therapeutics, and surgical definitions.

## Special Article.

# THE DISTRIBUTION OF DUTIES AMONG THE DEPARTMENT OF HEALTH, THE DEPARTMENT OF PUBLIC CHARITIES, AND BELLEVUE AND ALLIED HOSPITALS.*

By S. S. GOLDWATER, M.D.,

NEW YORK.

COMMISSIONER OF HEALTH.

THOSE duties and functions of the Department of Health which are entirely apart from the management of institutions may be assumed properly to belong to the Department of Health, and to be outside of the scope of the present discussion.

A borderline question is the proposal that hospital "social service" should be expanded, enabling hospitals to undertake the duty of instructing the public in matters of hygiene. This proposal arises from the inadequacy of the educational work heretofore performed by the Department of Health. The institution of adequate preventive work by the Department of Health would render unnecessary the establishment by the hospitals of the proposed "health centers."

The health center plan, conceived as an extension of hospital activity, is not broad enough to meet the requirements of preventive medicine. Conditions which contribute to the causation of disease can be adequately controlled only under a system which includes: (1) Factory, store, and office supervision; (2) regulation of dwelling construction; (3) universal periodic physical examination of individuals for the detection of disease in its incipiency.

The development of a comprehensive program of preventive medicine does not lie within the scope of hospital management as such, although it might conceivably be entrusted to the same authority which exercises supervision over hospitals.

In the present discussion we must confine ourselves to a consideration of the principles of the management, by the municipality, of institutions for the treatment of the sick. The question which should primarily engage our attention is not "the proper distribution of duties among the Department of Health, the Department of Charities, and the Board of Trustees of Bellevue and Allied Hospitals," but rather the question of the proper organization and the efficient management of hospitals.

It is conceivable that either a large board of trustees, a smaller board, or a single commissioner, might satisfactorily administer the city's hospitals. Nine ideally organized hospitals, distributed among three city departments in three groups of three hospitals each, would serve the city far better than a group of nine hospitals, improperly organized, but under single control. Central control offers certain economic advantages, and tends to produce uniformity of method. But uniformity may be established on a low plane as well as on a high one, and is not an end in itself.

I do not appear in this discussion as the champion of the Health Department as against other departments of the city government; and I do not urge the continued control of institutions by the Department of Health merely because such institutions have been heretofore managed by that department. In fact, I see no good reason why any hospital need actually be administered by the Department of Health.

The primary function of the Department of Health is to prevent, not to treat disease. In the case of contagious diseases, there is an obvious relationship between hospital isolation and the prevention of epidemics, but the sanitary requirements could be met quite as satisfactorily in contagious wards attached to general hospitals as in the "contagious" hospitals of the Department of Health. For example, the Kingston Avenue Hospital for contagious diseases is contiguous to the Kings County Hospital. Now, if Kingston Avenue Hospital were a subdivision of Kings County Hospital, the public would be just as effectually protected as under the present arrangement, always provided that the rules necessary for the prevention of infection were enforced as effectually as they are to-day. The sanitary supervision of contagious wards in general hospitals should always be entrusted to the Department of Health; but beyond the exercise of such supervision, the Department of Health need not enter the institutional field. If, then, there is no valid reason for assigning to the Department of Health the actual administration of hospitals, we are free to consider the organization, distribution, and correlation of hospitals, without regard to the Department of Health.

Before considering the main question it is proper to ask what we expect the hospitals of the city to accomplish, and to inquire what form of hospital organization will be most likely to yield the best results. The mere supervision of the hospitals is of secondary importance.

The primary function of the hospital is to cure disease; failure to cure is unavoidable in some cases, and in such cases it is the business of the hospital to relieve suffering. A hospital which fails to cure a patient who is theoretically curable, fails to that extent to perform its proper function; a hospital which does not give relief where relief is possible, likewise fails in its duty.

The essential resources of a hospital for dealing with disease are the physical plant, the medical staff and the nursing staff. While it is impossible, within the limits of this discussion, to consider these resources in detail, we may say: (1) that the hospital must be of sanitary construction, and must be amply equipped with appliances for the investigation and treatment of disease; (2) that the medical staff must be so constituted as to be able to give to each patient the benefit of all the scientific and technical resources of modern medicine, and these resources must be immediately and actually available; (3) that the nursing staff must be sufficient in number and of the best quality.

If, as I believe, there is not a single municipal hospital in the City of New York to-day, which is so organized that it is able to meet these requirements, an "improved plan of hospital organization" for the City of New York must address itself rather to the fundamental question of internal hospital organization, than to the question whether it is best to lodge hospital control in the Charities Commissioner, a Health Commissioner or the Board of Trustees of Bellevue and Allied Hospitals.

The subject of hospital treatment is the patient and not the disease; and therefore the hospital must include in its physical equipment and in its medical organization the means of dealing with any physical condition, with any complication of diseases, expected or unexpected, in any individual patient. In medical practice there is no sharp line of demarcation between medicine and surgery, nor between regional and systemic infection. A hospital which can treat a straight case of typhoid fever, but which is powerless to bring swift surgical relief when perforation of the intestine occurs, is a poor instrument for the treatment of disease, unworthy to represent modern medicine. Obviously, such a hospital is not a safe refuge for a patient who has typhoid fever. Similarly, a hospital is defective if its staff includes only expert otologists; for the patient with ear disease may have an infection of his knee, or an ulcer of the stomach, or pneumonia, or a mental obsession—conditions which otologists are admittedly incompetent to deal with. Time is lacking for further illustration, and so I shall simply state, in relation to this point, that no hospital can give satisfactory service, in all emergencies, which is not a full-fledged, general hospital, representing in its clinical organization, in its laboratory organization, in its therapeutic equipment, all that modern medicine is able to contribute of technical skill and expert knowledge to the investigation and treatment of disease.

Modern medicine thrives best in the atmosphere of a general hospital; the medical student is best educated in a general hospital; the hospital patient fares best in the general hospital; hence the typical hospital unit of the proposed "better system" which the city aims to establish, must be a general hospital. The recognition of this truth is a prerequisite to effective hospital reform. The establishment of real general hospitals will quicken medical investigation, will place adequately equipped laboratories, which small hospitals cannot afford, at the disposal of clinicians generally, will tend to correct the specialists' tendency toward narrowness, will facilitate sound medical teaching, will insure a more adequate training of nurses, will abolish the stigma which now attaches to infectious diseases, will improve the clinical work and the nursing service in contagious wards, will promote the standardization of hospital construction, equipment and administration, will develop a trained body of hospital administrators, will discourage the multiplication of poorly equipped special hospitals, and will aid in the standardiza-

* An outline of remarks made at the New York City Conference of Charities and Correction, Wednesday, May 20, 1914.

tion and proper utilization of morbidity statistics.

If the central feature of the improved hospital system is to be the general hospital, will there be no place left for any other type of institution? For chronic diseases and for convalescents, yes; for acute diseases, no. There are so many thousands of persons suffering from tuberculosis that to attempt to provide for them in general hospitals would be to increase unduly the size of such hospitals, and so to complicate their administration that more would be sacrificed by the patients of the hospital generally than would be gained by the tuberculous patient who, in exceptional circumstances only, requiries such services as only a general hospital can give. The same is true of the insane, whose large and increasing numbers make their care in general hospitals impossible, though general medicine and the public would profit by the inclusion in general hospitals, of observation wards for mental diseases. Nor is there any question that the incurable insane, as well as others, occasionally need the services of a general hospital—the demands upon the infirmary at Ward's Island amply testify to this.

For the tuberculous, for the insane, for the incurable, for crippled children, and for convalescents, special institutions may properly be provided, but not for gynecological cases, not for eye cases, not for diseases of the nervous system, nor for other regional or systemic specialties too numerous to mention; for all of these, suitable units, forming coordinated parts of the general hospital, should be provided.

The ideal general hospital will be large enough to accommodate all branches of medicine and surgery, and the clinical units will be of sufficient size to permit of economical construction and administration and of the grouping of different classes of patients in a manner favorable to clinical research. So large the general hospital should be, but no larger. When a general hospital planned on these lines is fully occupied, the demand for additional beds should be met, not by increasing the size of the hospital already built, but by erecting a new one. The number of institutions to be thus provided by the city will be considerable.

In proposing what I believe to be the best type of hospital, I do not mean that nothing is to be left to individual initiative, nor that special genius for organization and administration shall have no opportunity to manifest itself. The hospitals of the city will thrive best if to each institution is left a large measure of autonomy. It is one of the peculiarities of institutional management that no institution can thrive which is wholly governed from without. This point I wish especially to emphasize, because it has apparently escaped the attention of those who have hitherto contributed to the discussion of the question.

Paris, with its large number of district hospitals, presenting an almost perfect system on paper, affords a striking illustration of a company of institutions which languish under rigid rules, promulgated by central authority. No central authority, whether commissioner or board, can ever take the place of a number of local authorities, each actually engaged in the conduct of a given institution, feeling its stresses day by day, contributing to its success, answerable for and conscious of its failures, studious of the achievements of its rivals, independent, aggressive, ambitious, constructive, but above all else, responsible.

The way to improve the hospitals of the city is to place them in the hands of the Commissioner of Charities if he is ready to accept the foregoing principles, or in the hands of the Board of Trustees of Bellevue and Allied Hospitals, if they will subscribe to what is here set down as the fundamental basis of effectual hospital organization. If neither of these departments will agree, then the Department of Health, notwithstanding its present burdens, is willing to be regarded as a receptive candidate.

---

**Grouped Comedones.**—J. M. H. McLeod reports the case of a girl, aged two years. An eruption began when the child was aged one, and was probably the result of camphorated oil and turpentine which had been rubbed on the skin by the mother, as the child suffered from bronchitis. The eruption was present chiefly on the upper part of the back, on the shoulders, and on the chest, and to a less extent on the forehead and cheeks. The lesions consisted of grouped comedones, acne pustules, white pitted scars, and minute fibrous thickenings dotted over with pits.—*Proceedings of the Royal Society of Medicine.*

### SECTION ON PEDIATRICS.

*Thursday, April 29—Third Day.*

**Presentation of Cases of Sporadic Cretinism.**—Dr. CHARLES HERRMAN of New York presented this paper in which he gave a summary of forty-one cases of sporadic cretinism that had come under his attention during the past fifteen years. He also presented a number of illustrative cases. He stated that in this series of 41 cases, 30 were females and 11 males. A large number of the patients in this series were observed at a very early age, 16 being under two years of age, and 8 of these under one year. Dr. Herrman expressed the belief that in the majority of cases the disease was congenital, because so many cases came under observation with distinct symptoms before the end of the first year, and because so many coming under observation later gave a history of having had significant symptoms since birth. He did not believe that the mother's milk contained substances which counterbalanced the deficit of thyroid in these infants, because a number of the patients showed distinct symptoms while at the breast. All cases of myxedema were not necessarily due to absence of thyroid gland. In a case in which both Hochdinger and Kassowitz had made the diagnosis of myxedema due to congenital absence of the thyroid gland as no thyroid could be felt, the patient died, and at autopsy the thyroid was found to be present, but markedly infiltrated by a growth of new connective tissue. This case also illustrated how difficult it was to palpate the thyroid gland. In this series twenty-five of the patients were Russian Hebrews. Making allowance for the fact that at a number of the clinics in which these cases were observed a large percentage of the patients were Hebrews, still the large proportion was striking. The series offered an unusual opportunity for studying the effect of long treatment, for thirteen were under observation for more than five years and of these seven were observed for from ten to eighteen years. As to consanguinity, in only four cases were the parents related, and three of these cases were in one family. A distinct history of constitutional disease in the family was not common. The Binet-Simon test was of very great value but had its limitations, being only applicable to children whose intelligence corresponded to that of a child of four years. The results obtained by this method compared with the intellectual development as shown by the patient's grading in school corresponded pretty accurately. The data presented in respect to physical development, mental development, retardation of mental and physical development, and the age at which treatment was begun seemed to justify the following conclusions: (1) Under thyroid treatment, if begun early, the physical development might reach normal. (2) When treatment was begun late the physical as well as the mental development might remain much below the normal. (3) The improvement in the mental development was never as great as in the physical development. (4) The earlier the treatment was begun the better the result as far as mental development was concerned. (5) In congenital cases, if the treatment was begun after the first year, a marked intellectual retardation persisted. The later the treatment was begun the more marked would be the retardation. (6) In order to obtain good results the treatment must be regular and continuous. A case presented well illustrated this point. While the treatment was regular the increase in height was three and one-half inches in a year, whereas during the periods when it was irregular it was as low as three-quarters of an inch in a year. (7) In the acquired as against the congenital form, the intellectual development was less retarded than the physical development.

Dr. WALTER W. STRANG of New York said Dr. Herrman had been very fortunate to have had the opportunity of observing so many cases of this kind. Dr. Herrman had shown that the mental development in

these cases was not what they had been led to hope for in the earlier papers on this subject. One thing that was very disappointing in dispensary work was the inability to keep the patients under treatment. In the Hospital for the Ruptured and Crippled they divided these patients into two classes, the severe, and the less severe or hyperthyroid cases. The increase in the physical development in the latter class was extremely marked. It was doubtful if anyone else had seen so many cases and there was no doubt but that this paper would be a great help in making the literature of this subject.

Dr. Charles Herrman of New York called attention to the first patient presented who was now twenty-two years of age and had been under observation for eighteen years. His physical development was retarded five years and his mental development ten years. Few cases had been under observation for such a length of time.

**Recurrent Bronchitis in Children.**—Dr. Charles Gilmore Kerley of New York presented this paper. He called attention to the fact that in children subject to recurrent attacks of bronchitis there was an underlying condition which was common to the difficult feeding cases, eczema, recurrent vomiting, and bilious attacks, and that these children were frequently the offspring of parents who suffered from disturbed metabolism. They frequently bore cow's milk and sugar badly, and exhibited a lessened resistance. Recurrent bronchitis was much like other recurrent conditions. It was more apt to come on during cold months when the eliminative functions of the body were less active. It had been found that 41 per cent. of the cases of recurrent vomiting suffered from recurrent colds. A diet having an excess of fats and carbohydrates seemed generally responsible for recurrent bronchitis in children. When the carbohydrate content of the diet was cut down in such cases a marked improvement usually ensued. Milk and sugar were not necessary to the child after the age of one year or fifteen months. Cane sugar was not recognized as a food until three hundred years ago. Countless millions of human beings had lived their span of life without it. The author reviewed the history of cane sugar since 325 B. C. to show that it had only been recognized in medicine and as a condiment until the sixteenth century, and that it was in no sense a necessary ingredient of food. Dr. Kerley presented a number of children whose histories showed that they had been reduced to a state of chronic invalidism by recurrent attacks of bronchitis and who were restored to a normal healthy childhood by proper regulation of the diet. It was his custom to reduce the amount of carbohydrate in the diet by cutting off the cow's milk entirely or else giving only a pint daily of skimmed milk. Sugar was forbidden and the fat content of the diet greatly reduced. Many of the parents feared that the children were being starved, but, on the contrary, they very generally gained in weight quite rapidly after the removal of the sugar and fat from their food. These children were of the so-called lithemic type and so he gave them some alkali (usually salicylate of bicarbonate) and kept the bowels open. There was a certain class of cases in which thyroid extract seemed to be indicated and these he gave one-half grain twice a day.

Dr. Charles Herrman of New York said that in 1905 Czerny of Berlin had described under the title of "Exudative Diathesis" a congenital constitutional anomaly, the chief characteristic of which was a peculiar sensibility of the skin and mucous membrane to an exudative inflammatory condition which manifested itself in the form of eczema, intertrigo, papular urticaria, a geographical tongue, rhinitis, laryngitis, and bronchitis of the recurring asthmatic type. He later added manifestations in the gastrointestinal and urinary tract. Dr. Herrman believed it would be better to consider these attacks of recurrent bronchitis as simply one manifestation of the exudative diathesis. The condition might also in some respects be compared to measles, the difference in appearance being due to the difference in structure of the tissues involved and to the different manner in which they reached to the same irritating agent. The speaker called attention to the fact that in a paper read before the American Pediatric Society in 1911 he had described recurring attacks of loose mucous stools in patients presenting the other symptoms of the exudative diathesis. In the same paper he had called attention to the frequency of sprue in infants who later showed the other manifestations of this diathesis. Finally the blood showed a distinct eosinophilia in those patients who presented cutaneous manifestations and in those with attacks of bronchitis of the recurrent and asthmatic type. Czerny in his original paper outlined the diet as follows: In young infants breast feeding should be continued if possible; if cow's milk must be given it should be in smaller quantities and low in fat. No sugar should be added. Cereals and broths should be given early. For older children cereals and vegetables were allowed but very little milk, no cream, no butter, no sugar, or eggs. Eppinger and Hess included the manifestations of the exudative diathesis in infants as due to vagotonia and on this basis Krasnogorski had given atropine with excellent results, especially in those cases with eczema and recurrent bronchitis. It was necessary to give this drug until distinct physiological effects were observed. He had used this treatment in a few cases with satisfactory results. After the removal of adenoids or tonsils in children with this diathesis the dietetic and hygienic treatment was most important if one hoped to prevent a recurrence. The good effect of thyroid therapy in these cases was due to its marked stimulating effect on the metabolism.

Dr. Anna W. Williams of New York asked if these children with recurrent bronchitis showed a tendency to follicle formation in the conjunctiva as in the nasopharynx.

Dr. DeWitt H. Sherman of Buffalo said it was interesting to learn of the influence of toxicity due to gastrointestinal fermentation upon the upper air passages. The focal point seemed to center in the follicles, with changes in the mucous membrane not inflammatory in type. In those cases which had come under his attention a reduction of sugars or fats, either one, was productive of good. Was it not possible that the same chronic bronchitis was a misnomer? Did not the trouble lie more in the follicles at the base of the tongue or in other adjacent parts. This might be possible since local treatment was so beneficial. Dr. Kerley mentioned rheumatic pains as being relieved by the reduction of fats and sugars, allowing a moderate amount of skimmed milk. Did he consider these rheumatic pains to be relieved by the rather high protein diet he seemed to give or by the alkalies and salicylates given in association with the diet?

Dr. Thomas S. Southworth of New York said Dr. Kerley had spoken of older children with chronic bronchitis having asthma. He was not speaking of the older children, but in very young children asthma might be due to cow's milk. Such a case had come under his observation last summer in an infant fed partly on breast milk and partly on cow's milk. As soon as the cow's milk was removed from the diet the asthma disappeared. Such cases were undoubtedly extremely rare.

Dr. C. G. Kerley of New York said that in reply to Dr. Sherman he would say that the diet employed was not a high protein diet. With the milk skimmed and the quantity reduced the protein content of the diet was reduced. Red meat was allowed three times a week, chicken twice, and fish once. As to the inhalations, they were used in the acute period, and only for two or three nights. The cases he had discussed were chronic cases that had been going on for years, so the inhalations were not responsible for the cures. In reply to Dr. Williams' question, Dr. Kerley said he had not found these children more subject to conjunctivitis than others. As to the coated tongue at the times of the attacks of bronchitis there was no evidence of intestinal disturbance. The urine was negative and there was normal bowel action. The tongue had been found coated regardless of whether there was constipation or not.

**Causes and Treatment of Chronic Conjunctival Affections in Childhood.**—Dr. Anna Wessels Williams of New York presented this communication in which she reviewed the results of the bacteriological study of conjunctival infections in the lower east side of New York. She stated that they had summarized their studies as follows: (1) The written descriptions of trachoma did not agree as to a clinical or a pathological entity. (2) Among the children of sixty public schools in the crowded lower east side of New York City (supposed to be a hot bed of trachoma) during the past four years they had found no cases of conjunctival affections answering in their entirety to the classic description of trachoma. (3) None of the 3,000 and more cases of follicular affections in these children had developed cicatrical changes due to infection; on the contrary, the great majority of them now present

normal conjunctivas. These results were attributed chiefly to the following measures. (1) The carrying out of preventive methods of treatment such as ophthalmia schools and school clinics, summer camps, mothers' demonstration classes, home instructions, and "follow-up" work. (2) More minute care of acute as well as of chronic cases, including the specific treatment given at clinics and the follow-up work in the homes. (3) Non-operative procedures in a large number of cases formerly operated upon. (4) Trachoma inclusions were nests of growing bacteria in epithelial cells hemoglobinophilic bacilli in certain cases of papillary conjunctivitis, gonococci in certain cases of gonorrheal conjunctivitis, and possibly other bacteria in certain other cases of conjunctivitis. (5) If trachoma was present or should be introduced among our school children it might be controlled by methods which were within practical limits.

Dr. ANNA I. VON SHOLLY of New York said that in dea ing with the problem of "sore eyes" in the lower east side of New York they had found that the method of excluding the children from school was an inadequate one. The children used the excuse "sore eyes" for remaining out of school and when not in school there was difficulty in getting them to submit to regular treatment. The important factor in eliminating this infection was to get the children early and to keep them under constant treatment. In order to accomplish this a special ophthalmic class was formed where all children excluded from other schools in that neighborhood were segregated. In addition to this school they had a clinic for eye diseases twice a week during school hours so that the treatment formed part of the routine school work. In some instances the children were segregated in the class room. When this was done special care was exercised in regard to cleanliness of the school room, desks, etc. By keeping the children under supervision they were not only able to treat them continuously but were able to give instruction in personal hygiene and the prevention of the spread of the infection. During the school year 1912-1913 they had had 312 pupils in the special classes, while during the year 1913-1914 they had had only 155 pupils. It was too soon, however, to say that the incidence of the disease had decreased.

Dr. LOUIS C. AGER of Brooklyn said that several years ago he had been inclined to think that many of the children excluded from school for trachoma did not have that disease, but enthusiasm centered on trachoma. He was glad that the research work had shown that trachoma was not as prevalent as it was thought to be. He also expressed the opinion that the very vigorous treatment used in some cases of conjunctivitis was unnecessary and was responsible for some superficial cicatricial contractions.

Dr. ANNA W. WILLIAMS of New York said they did not exclude the cases of folliculosis or of follicular conjunctivitis and not those with papillary conjunctivitis unless there was a secretion.

**Subacute and Chronic Intestinal Infections.**—Dr. ELIAS H. BARTLEY of Brooklyn presented this paper in which he discussed that class of intestinal infections that usually came on late in the summer and secondary to one or more acute attacks of diarrhea. Infection usually occurred sooner or later in these cases. One form of infection of the intestinal canal had been but slightly studied and that was the streptococcus infection. The author divided these cases into three classes: (1) Those in which there was chiefly carbohydrate fermentation with the production of organic acids, much flatus, colic, and a tendency to diarrhea. (2) Those in which the proteoclastic organisms had gained the ascendancy, and the lactic and butyric organisms had failed to keep pace with them. The intestinal contents were alkaline, there was less flatus and colic, but more fever and toxic symptoms, and more profound nervous disturbance. (3) The cases of streptococcus infection and perhaps other highly toxic infections. The subject of treatment he summed up as follows: To change the intestinal culture medium he used a lactofarinaceous diet. If one wished quickly to disinfect the digestive canal calomel would accomplish this best. If one wished a long-continued effect in diminishing the activity of the intestinal bacteria one should select hydrochloric acid, menthol, thymol, or bismuth subgallate if the trouble was conceived to be in the stomach. If one conceived the chief trouble to be in the intestines salacetin, ichthalbin, ichthoform, thymol, or small doses of calomel with benzoate of sodium might be selected. For the removal of the bacteria and their toxins in conjunction with the above antiseptics an emulsion of castor oil or olive oil might be used. Out-door air, a high dry climate and other hygienic measures with tonics would be helpful for improving the appetite and invigorating the system generally.

Dr. H. A. GRIBBON of Poughkeepsie said that in regard to the acute cases Dr. Bartley had covered the ground well. He did not use so many drugs and he did not believe Dr. Bartley did. He took exception to the salacetin. Some of these cases of continued diarrhea following acute infection were not true infection but anaphylaxis due to primary sensitization to cow's milk. In many cases children were sensitized to the proteid of cow's milk and it was hard to get over it. Sometimes a diarrhea was toxic through absorption. It was not advisable to withhold nourishment too long. They must try to find the right time to recontinue feeding. *Eiwciss milch* gave very satisfactory results because the children stood the casein proteid, with the exception of those who had been sensitized. Boiled skimmed milk was often tolerated after five or six days. If the case was one of long standing then one had to wait longer before giving it. He had had fairly good results with the *Bacillus bulgaricus*, especially among poor people, as it was something that they could give and drugs were of little effect.

Dr. DEWITT H. SHERMAN of Buffalo said that Dr. Bartley had referred to the cases of streptococcus infection but did not mention the use of vaccines or serums. They had used vaccines in Buffalo, not only without good results, but often with decidedly bad results, the condition of tetany occurring in two or three instances. As regarded the use of serums the results were different. While they were not as useful as in selected cases of tonsillitis, yet they seemed often to turn the tide and to assist in a much more rapid recovery. He felt that in proper cases they were deserving of serious consideration.

Dr. JOSEPH ROBY of Rochester said it had occurred to him that possibly the use of gentian violet might be effective where the infection was due to Gram positive organisms. The effect of gentian violet on Gram positive organisms in the test tube was so remarkable that we might in the future hope something from it; however, it did not do so well in the presence of blood serum as in the agar tube.

Dr. W. MORGAN HARTSHORN of New York said that he wished to emphasize the value of *Eiweiss milch* in acute and subacute toxic cases. At Roosevelt Hospital they had used it in cases that had resisted the usual treatment. The protein milk obtained from fat free milk, prepared by the Walker Gordon Company, was followed by immediate and striking effect.

Dr. THOMAS S. SOUTHWORTH of New York said he had found that Keller's malt soup had a definite place in the treatment of subacute and chronic cases. Made up in fat-free milk it supplied the lack of fats and carbohydrates. Aside from the *Eiweiss milch* there was nothing that changed the bacterial content of the intestinal tract more quickly where there was a putrefactive process present. It was well borne in the mucoid type of disease. In the group of cases classed as colitis it was well not to permit the child to get to the extreme point of reduction that formerly prevailed, and this could be to a large extent prevented by giving proper food and not waiting too long before giving the types of food necessary to keep the fat of the body up to a reasonable point.

Dr. ELIAS H. BARTLEY of Brooklyn said he had tried the *Eiweiss milch* but got no better results from one form of fat-free milk than from another. In regard to the vaccines he did not try the serum but had used autogenous vaccines from hemolytic streptococci and got no benefit.

**The Early Diagnosis of Congenital Syphilis.**—Dr. CARL G. LEO-WOLF of Niagara Falls read this paper which was based on work done at the Orphan Asylum of the City of Berlin under Professor Finkelstein. He confined himself chiefly to those symptoms of congenital syphilis which were often overlooked, but which if found in the first few days or weeks of the child's life were of great diagnostic importance. He stated that those instances in which the mother was infected during pregnancy and transmitted the disease to the fetus through the placenta or at the time of parturition had not attracted attention to the extent that other modes of transmission had done. He concerned himself especially with those children who were born apparently clean, but in whom one could find on care-

ful examination changes in different organs; also with those in whom the intrauterine course of the disease had run out and who were born apparently healthy so that one could not find anything abnormal with any of the organs, but who were weakly and did not thrive and who would later on have relapses of the disease, and finally with those children who were born healthy but in whom the disease would appear sooner or later. The author called attention to the dilated coronary vein, the vein at the bridge of the nose, the saddle nose, the rhinitis and the optic neuritis as symptoms of congenital syphilis. This latter symptom he said would be found with relative frequency. Japha had found it in 66 per cent. of the infants with congenital lues, and Heine in 83 per cent. He called attention to the diffuse infiltrations like leucocyte infiltrations found in inflammatory conditions. This infiltration sometimes led to the formation of rhagades and sometimes to a swelling paralleling the border of the lips, the color of which was an opaque white. This form of infiltration would be found on the trunk also, but its most frequent location was on the palms of the hands and the soles of the feet. It was of the greatest importance to differentiate this infiltration from the decubitis frequently found on the feet of infants, and here again especially on the heels. They further found this infiltration around the roots of the nails. The color of luetic infants was a peculiar gray which could be easily recognized when compared with the rosy complexion of a healthy infant. After the sixth week of life the skin was apt to present the familiar *"café au lait"* color. Another symptom which might not be called an early one was macular exanthema which appeared first on the soles of the feet and which consisted of brownish purple, lentil-sized, deep-seated spots which were better seen from a distance; later this exanthemata spread over the entire body. At the umbilicus one saw in some cases a thickening and reddening remaining after the falling off of the cord and which developed into a deep-seated, sharp-edged, dirty looking ulcer, which readily yielded to antisypilitic treatment. The *x*-ray would show in the long bones and indistinct epiphyseal line. Another symptom of importance was the swelling of the cubital glands, which were not as easy to find as the text books would have one believe. The two neighboring nerves might be affected, causing the child considerable pain. The author called attention to the pseudo-paralysis of Parrot which was frequently seen in the elbow but might be found in the shoulders and the legs. It must be differentiated from brachial plexus paralysis due to birth injury. Syphilitis periostitis was not often found in the first phalanges of the fingers and the toes, but also affected the bones of the skull. One symptom which should always make one consider the diagnosis of congenital syphilis was eclamptic seizures in infants under three months of age, especially if they did not yield to antispasmodic sedatives. An enlarged spleen was one of the most constant symptoms. A rare early symptom was albumin in the urine without a general condition which would generally be expected in such a seemingly grave condition, and a prompt disappearance of this symptom on the administration of potassium iodide. Another infrequent symptom was hoarseness without any pathological findings in the pharynx or larynx. Still another early symptom was infiltration of the testes, a true orchitis, while tuberculous infection caused an epididymitis. In that class of infants mentioned which did not thrive under the best of care it might be found that they would thrive on antisyphilitic treatment without any other change. In the first few weeks of life the Wassermann reaction might fail one.

Dr. THOMAS F. ELLIS of Brooklyn called attention to the frequency of involvement of the central nervous system in cases showing optic neuritis. The spirochetæ had been found in the brain in infants but the late infections of the central nervous system in infants had not been carefully studied. In infant tabes the normal findings in the spinal fluid were essentially different from tabes established in the quaternary disease.

Dr. GEORGE DOW SCOTT of New York thought that perhaps Dr. Leo-Wolf had not laid enough stress on these cases born with apparently nothing the matter with them, excepting an indisposition to nurse, pale skin and mucous membranes, or a slightly crinkly skin. These cases were apt to be overlooked by the general practitioner. In such cases antisyphilitic treatment for the mother might be beneficial and also for the infant, even if the Wassermann was negative during the first few weeks.

Dr. LEO-WOLF said he thought he had spoken considerably on the subject of optic neuritis. There was a new ophthalmoscope in which one could get a view of the optic nerve so that any one could see it; this would give one an opportunity to detect cases which had hitherto passed unobserved.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held March* 23, 1914.

THE PRESIDENT, DR. T. PASSMORE BERENS, IN THE CHAIR.

**Report of the Committee on Legislation.**—Dr. CHARLES H. CHETWOOD, in behalf of the Committee, presented this report, which stated that this Committee, in line with the State Legislative Committee, had been endeavoring to arouse active opposition to prevent the passage of bad legislation bearing upon matters in which the medical profession was interested. There seldom had issued from any Legislature such a number of foolish, and in many instances, pernicious bills of this character, as had appeared at this session. They had effectively opposed the cocaine and kindred drug legislation, with the expectation of getting a bill that they could afford to support. They were especially interested at this time in raising their voices in opposition to Assembly Bill 465, Senate Bill 281, and Senate Bill 710, known respectively as the Osteopathic Bill, the Naturopathic Bill, and the Chiropractic Act. Both the State and the County Legislative Committee had sent out circular letters to all of their members. They had furnished a list of every district, with the names of the Assemblymen and Senators, and had furnished printed postals to be sent to each of them. There should be no difficulty in anyone finding out the number of his respective district, and then, by consulting the list, the names of the Senator and Assemblymen could be determined. In appealing for personal activity on the part of the members, they had received some satisfactory responses. It had been stated that the Osteopaths would not obtain any more legislation this session, but the Naturopath Bill and the Chiropractic Act were still more objectionable, and were another move toward tearing down the standards raised during the past few years. It would seem that the argument in form of a Pure Food Law and Drug Act, requiring the proper labeling of packages and merchandise sold to the public, should alone be sufficient to kill such legislation as attempted to foist upon the public fake doctors in the guise of regularly licensed practitioners. Dr. Chetwood read a letter from Dr. Paul Z. Bebert relating his experience in endeavoring to use his influence with the Assemblyman from his district. After considerable discussion this Assemblyman admitted that all he knew about the bill was that it had been recommended to him by a friend of his who said he had been cured by the method. He said that if the bill was not genuine he would not give his support to it, and was of the opinion that the bill would not pass the House. Senator Boylan in an interview maintained with great courtesy that the Chiropractic Act could not interfere with the practice of medicine, as the Act prohibited the Chiropractors from using drugs, medicines, or surgical instruments. He also urged that many eminent men whom he knew were taking the treatment and were benefited by it. On the morning of March 23 a telegram was sent to the Hon. Robert F. Wagner which read: "In the interest of good legislation and of the public at large we respectfully protest against the Naturopath and Chiropractic Bills." (Signed) T. Passmore Berens, President; John Van Doren Young, Secretary; Charles H. Chetwood, Chairman Legislative Committee. Another telegram was also sent at 8 o'clock in the evening from the Medical Society of the County of New York, at that time in session, conveying the serious protest of the Society against the passage of the Naturopath and Chiropractic bills.

**Antityphoid Vaccination in the Army During 1913.**—Major FREDERICK F. RUSSELL, U. S. A., presented this communication. He declared that the results with antityphoid vaccine during former years had led them to expect much from the measure, but that the remarkable records of the past year had far surpassed expectations. In the entire army of over ninety thousand

men only three cases of typhoid fever, with no fatalities, had occurred during the year 1913. The year 1912 marked the beginning of compulsory vaccination in the army for all persons under forty-five years of age, but the full effect of such vaccination was not immediately seen since five times as many cases occurred during that year as during 1913 and it was very possible that the rate had now reached an irreducible minimum. Major Russell exhibited a number of charts showing the gradually diminishing morbidity and mortality rates from typhoid fever from the time of its introduction in 1909 until the present time and also showing the effectiveness of sanitary measures previous to the introduction of vaccination. The best record obtained by sanitary measures was noticed in 1908; vaccination beginning in 1909 had steadily diminished the number of cases until in 1913 the rate was reduced to five cases per 100,000 men. What this signified might be appreciated when one realized that the civil death rate (not case rate) in the registration area of the United States was 16.5 per 100,000 of population for the year 1912, the last for which the statistics had been published. There was in the year 1913 only one one-hundred-sixty-seventh of the loss of time from duty because of typhoid fever which occurred during the record year 1908, before the introduction of vaccination. These charts were absolute proof of the efficacy of the typhoid prophylactic. In answer to the question as to whether there had been any harmful effects produced by this typhoid prophylactic it might be definitely and decisively answered by the plain statement that no harmful effects had been produced. In the surgeon general's annual report were records not only of typhoid fever, but of all other diseases affecting the soldier's health. Since these records could be consulted by all only two points would be considered. First, the diseases which were more prevalent during 1912 than during the decade ending 1911, and, second, what, if any, had been the effect of vaccination on the rates for tuberculosis? In the surgeon general's report only eight statistical groups of diseases showed an increase in the case rates per 1,000; these were eruptive fevers, other than measles, smallpox, and typhoid fever; diphtheria, mumps, cancer, and other malignant growths; diseases of the brain and spinal cord; pleurisy, tonsillitis, and other diseases of the pharynx, and appendicitis. There was no reason for believing that the antityphoid vaccination was in any way responsible for these changes. In answer to the second question, it was found that the case rate for tuberculosis of all kinds showed a decrease from 4.51 per thousand for the decennial period ending in 1911 to 4.49 for the year 1912, a decrease of .44 per cent. That it was also shown that tuberculosis not only had not increased since the introduction of typhoid vaccination, but that it had actually decreased, a result due no doubt to the improved sanitation and to the care exercised in the physical examination of recruits. In the annals of medicine there was only one other campaign with which to compare this, and that was the practical extermination of smallpox by vaccination. It had been pointed out that in the suppression of infectious diseases, sanitarians encountered two types of infection, one requiring an intermediate host for the completion of the life cycle of the parasite, or its conveyance from the infected to new victims, and the other composed of diseases of mankind only, the disease passing directly or indirectly from one human being to another. Typhoid fever belonged to the latter class of diseases and for this reason the results here given should only be compared to the results obtained against other diseases of the same class.

**The Practical Application of Vaccines and Serums.**—Dr. JAMES GARFIELD DWYER read this paper. He said that he had treated from 300 to 400 cases of various kinds with autogenous vaccines, including about sixty cases of tuberculosis treated with tuberculin. He had also treated between 300 and 350 cases with the Hiss leucocyte extract. The cases treated with vaccines comprised many different kinds and infections with many different organisms. Vaccines were made up of organisms that had generally been looked upon as saprophytes, but which had been found so constantly in such conditions as chronic discharging ears, chronic tonsillitis, etc. They had in vaccines and serum the first practical remedies that had been put in use to any great extent that approached the treatment of infections along thoroughly rational and logical grounds. The first essential in the use of such therapeutic measures was to make an absolutely accurate and careful bacteriological diagnosis, that was, the causal organism must be identified and a vaccine used made from this organism. That was why so many condemned the use of vaccines and did not get good results because they were probably using a stock vaccine which did not contain the specific organism. In a true septicemia he was not in the habit of not using autogenous vaccines as, according to their present understanding of opsonins, the use of such was contraindicated. In locally acute, subacute, and chronic infections the vaccines found their greatest field of activity. In some systemic infections, where the organisms were simply feeding into the circulation, probably the guarded use of vaccines was indicated, but it was hard to draw the line. In the systematically acute cases, the very acute, the use of leucocyte extract was indicated, and had in his hands given very encouraging results, especially in lobar pneumonia, septicemia, and in erysipelas. Reports on erysipelas and the treatment of other infections had already been published in various journals. (See MEDICAL RECORD, September 13, 1913.) During the last five years Dr. Dwyer had treated a series of cases with autogenous vaccines and also a series with the Hiss leucocyte extract and he said he would report shortly on the practical points that had impressed him as time went on. The series treated with vaccines now comprised about 400 cases or more in the vaccine list, and with the leucocyte extract over 400. Under the vaccine list he had placed those treated with tuberculin. The list comprised the following, classified according to the offending organism: Tubercle bacillus, 60; the staphylococcus group, comprising the aureus, albus, and citreus, over 200; streptococcus, 70; gonococcus, 5; pneumococcus, 17; *Bacillus pyogenes*, 27; *Bacillus mucosus capsulatus*, 20; *Micrococcus catarrhalis*, 14; bacillus of Morax-Axenfeld, 10; acne bacillus, 12; *Bacillus coli*, 6; mixed infections with such organisms as pseudodiphtheria, proteus, etc., about 40, the latter comprising such organisms as were found in chronic discharging ears. They reported only such cases as persisted in the treatment. Analyzing the cases they found that the series treated with tuberculin comprised cases of chronic tuberculosis of the lungs, of the intestines, cervical glands, larynx, iris, cornea, and also cases of episcleritis, phlectenular keratitis, and conjunctivitis. They generally used the bacillus emulsion of tuberculin and started with a dose as low as 1-100,000 and then gradually worked up, according to the serial dilution method. On the whole, the results had been very encouraging and although the treatment continued over a period of months, he thought that the results were better and more lasting than obtained with other methods, and he referred especially to such conditions as cervical adenitis. He gave a typical history of such a case. Briefly the conclusions to be deduced were the following: (1) In acute constitutional disease, such as pyemia, septicemia, and sapremia, the vaccines were contraindicated. In such cases, the leucocyte extract found its greatest field of usefulness and would often save cases which were apparently hopeless. Some authorities did not use vaccines in such cases, with the admonition to avoid the negative phase by proper dosage and very guarded administration. This sounded easy, but it was an entirely different matter to apply such to a case. Therefore, use the extract of leucocytes in such cases and avoid vaccines calling for active immunization. (2) In the locally acute, without systemic symptoms, subacute and chronic cases, the vaccines found their greatest field of usefulness and would be found to act almost as a specific. He had had no experience with the leucocyte extracts in such cases, but they should be effective, especially in the subacute and the locally acute and certain types of chronic cases, in which the diseased focus was not walled off by a firm, hard, fibrous wall. However, the results had been so good with the vaccines that he had not felt the necessity of using any other agent. (3) In all cases use autogenous vaccines in preference to stock ones, as the results would be better and surer, and the administrator knew exactly what he was administering. (4) Make fresh vaccines frequently, so as to insure their greatest potency. (5) Be guided in the administration by the clinical symptoms, but at the same time do not neglect to calculate the opsonic index. In the majority of cases it was just as reliable as a blood count was. (6) Do not use tuberculin in tuberculosis when general constitutional symptoms were present, that was, when the patient was in the pyrexial stage. First, localize the process

as much as possible, and then start the treatment, interrupting it if the condition again becomes general. (7) Give small doses, often repeated, rather than large doses seldom repeated. In all cases start in with a minimal dose and then increase it. (8) Always have in view, even in the simplest case, the danger of anaphylaxis or hypersensitization. This was no negligible quantity. (9) Always combine with the vaccine treatment the other general medicinal and hygienic measures. The vaccine therapy was not a cure-all. (10) If one had a case of septicemia, such as that which followed sinus thrombosis, and surgical measures had been exhausted, do not wait until the patient was in *extremis* or moribund, but start the use of the extract early, so as to give the patient the best chance. The extract was not a miracle worker. Most of the cases he reported were very far gone and were really in the final stage. A more severe test of the efficacy of an agent could not have been devised.

**Statistical Analysis of Erysipelas Cases.**—In the early cases treatment was begun within three days of the appearance of the lesion; in the late cases, treatment was begun later than three days after the appearance of the lesion. The total number of cases treated was 148; 43 recovered, giving a mortality of 3.39 per cent. The average duration of treatment was 3.18 days. The number of recoveries under the age of one year was 8; the percentage of recoveries under one year of age was 66.6. The general mortality rate was 3.39 per cent. (all cases). The mortality among patients over one year of age was 0.99 per cent. The recoveries gave 99.1 per cent.

**Cancer.**—Dr. Francis Carter Wood said that owing to the lateness of the hour, he would confine himself to a discussion of radium therapy of tumors. Much of the published work on this subject was utterly unreliable because of the lack of microscopical examination of the radiumized growths. Without such an examination no case should be considered as of any importance in judging of the value of radium therapy. It was astonishing how few cases of reported cures complied with this criterion. A second point of the greatest importance was the separation of different types of cancer into carcinoma and sarcoma, and a further subdivision into benign and malignant varieties. The medical profession at large did not seem to be aware of the fact that the so-called giant cell sarcoma of the gum was practically a benign tumor, only two to three per cent. recurring after operative removal. Some of the small epitheliomata, especially those of the basal cell type, occasionally remained quiescent for ten to fifteen years, and could hardly be considered as malignant. That these benign types of what was morphologically carcinoma or sarcoma yielded readily to radium in a large number of instances was well known, but occasionally even these forms might be resistant or might be stimulated by the treatment, though the microscopical examination gave no clue to the prognosis. It was generally acknowledged even by those most enthusiastic in the application of radium, that carcinomata of the breast or of the internal organs did not yield to radium, with the sole exception of benign adenocarcinomata of the body of the uterus and of carcinomata of the cervix. Even in the latter instances, however, recent publications in Germany stated that clinically healed cases were recurring after six months or a year. With our present knowledge of radium it seemed far from justifiable to treat any operable malignant tumor with radium. In inoperable cases or recurrences radium was an admirable palliative agent, because it undoubtedly reduced the secondary deposits when they were superficial. The speaker had never observed any effect from radium at a greater depth than one to two inches.

---

## NEW YORK NEUROLOGICAL SOCIETY.

*Stated Meeting, Held March 3, 1914.*

The President, Dr. Smith Ely Jelliffe, in the Chair.

**Diastematomyelia of Henneberg.**—Dr. Jelliffe showed a series of microscopic slides of spinal cord sections illustrating this form of spina bifida. Irregular or abortive types of reduplication of the cord were fairly well known, and in these sections the reduplication was well shown. So far as the work of Sibelius was concerned, we had here a fairly good confirmation of his view regarding the development of the horns of the cord, and the forms of the relative types in cases of this kind.

**Angioma of Brain.**—Dr. Jelliffe also showed microscopical specimens obtained at autopsy. The case was one of epilepsy of long standing, with the final development of the status epilepticus and death, and the anatomical finding of an angioma of the frontal lobe. This case was described in detail by Dr. J. Sweasy Powers of Berlin in Alzheimer and Lewandowsky's *Zeitschrift*, Vol. XVI.

**Paralysis Agitans; Motor Pathology.**—Dr. Jelliffe also presented a series of serial sections from a case of paralysis agitans which illustrated the paucity of the fibers in the internal capsule, especially in that group of fibers which were derived from the development of the cerebello-rubro-spinal system. There were a sufficient number of slides to show the incompleteness of the fibers on one side of the internal capsule. This finding, the speaker suggested, bore upon the development of the present day study of tremors and irregular motor reactions, such as were found in multiple sclerosis, Huntington's chorea, the lenticular degeneration of Wilson, and the group of analomous motor phenomena which had been studied for a number of years and were now regarded as due to disorder or defects in the extrapyramidal tracts.

Dr. I. Abrahamson said that cases of tumor of the midbrain involving this region might show a tremor resembling that of paralysis agitans, but it was decidedly coarser and had greater amplitude—almost like a caricature of that of paralysis agitans.

Dr. Jelliffe said the statement made by Dr. Abrahamson opened up the entire subject of our attitude toward this group of disorders. When we used the term "typical paralysis agitans," the question at once arose, was there such a thing? The condition rather represented a syndrome, a group of symptoms, which, when they came together, we theoretically regarded as paralysis agitans. What we regarded as paralysis agitans was more or less of an arbitrary concept.

Dr. Charles L. Dana said that according to his experience with paralysis agitans, about 90 per cent. of the cases showed the same method of development, they pursued the same course, had the same symptons, and the prognosis was about the same. If this combination did not constitute a clinical type, then the speaker said he was at a loss how to describe one.

Dr. Jelliffe said that in the study of the heredity of Huntington's chorea, three distinct trends had been found, namely, the motor phenomena, the mental phenomena, and the age factor. These trends might appear in different families, but when the three occurred in the same individual, then a typical situation which might be termed Huntington's chorea was present. The speaker said he regarded paralysis agitans in the much the same light; that it represented a syndrome or combination of factors rather than a clinical entity.

**A Modified Instrument for Use in Lumbar Puncture.**—Dr. I. Strauss showed an instrument for lumbar puncture which he had employed for several months with entire satisfaction. He had found the old-style needle rather unreliable, and this instrument contained certain modifications by which the flow of spinal fluid could be regulated.

**Analysis of Some Substitution Reactions.**—Dr. C. P. Oberndorf, in a paper on this subject, said that in 1909 Lowenfeld discussed a topic to which psychiatrists had hitherto devoted little attention; namely, those dreamlike states in which, as he said, "usual impressions, customary sights, and occurrences appear altered to the patient, as though they were unknown, strange, or the product of phantasy, and in which the patient feels as though he were in a dream or half asleep, hypnotized or moving in his sleep." Abraham, approaching this phenomenon from an analytic standpoint, had differentiated three stages of dreaminess, the first of which was dependent upon a phantastic trend of thought; the second, upon an alteration in consciousness, and a further, third stage of emptiness of consciousness which the patient might designate as a standstill of thought. He concluded, as the result of several carefully studied cases, that these states often represent a substitutive activity for masturbation which has been discontinued. Most of the patients in which such symptoms appear, Dr. Oberndorf said, belonged to that class of neurotics who began masturgation early in childhood, and who later engaged in an unrelenting struggle to overcome the tendency. Although failure repeatedly attended their efforts to

relinquish the habit, various expedients, some psychical, some physical, and others again punitive, were invoked to prevent sexual excitation, and more especially ejaculation. Not infrequently such a struggle resulted in an ostensible conquest of the habit, and all physical manifestations might vanish, but unconsciously a demand for some substitution to satisfy the irrepressible libido persisted. This conflict between the wish and repression unconsciously found a solution in the form of a compromise, but the significance of this substitution compromise was either not recognized by the individual, or, if its true nature was suspected, it was either condoned as being less pernicious, or welcomed as being less obvious to outside observers. The substitution reaction was then permitted to proceed unrestrained until it interfered with the individual's normal activities or attracted the attention of his environment as being an abnormality. Dr. Oberndorf then gave a brief analysis of three cases coming under his observation to illustrate the transition to and substitution of dreamy or abstracted mental states, which in two of the cases had been almost conscious, in the process of relinquishing masturbatory activities. The speaker said that whether or not one agreed with the interpretation of the mental states in these cases, they at least indicated that mere elaborate description of these or other neurotic conditions was insufficient without some effort on the part of the neurologist to grasp their origin and explain the motive forces and stipulations which they served to represent.

Dr. I. STRAUSS said that in one of the cases reported in Dr. Oberndorf's paper, the girl who had been in Dr. Sachs' service at Mt. Sinai Hospital and who was afterward treated in the Out-Door Department, the improvement that followed was certainly very marked. In fact, the parents considered the child well.

Dr. JELLIFFE said that in both his private and dispensary work he saw many cases similar to those reported by Dr. Oberndorf, and in the histories they gave he had been struck by the appalling prevalence of cases that had been subjected repeatedly to all the various strictly up-to-date diagnostic procedures, such as *x*-ray examinations, blood cultures, examination of the gastric contents, etc., etc., until he was led to reiterate the remark of Déjerine, "has any one taken the trouble to find out anything about your mental life?" In many of these cases, after a five minutes' talk, the outlines of their mental conditions were laid bare. The trouble in most of these cases did not lie in the intestinal tract, and the speaker said he had utterly failed to trace any connection between their symptoms and an overloaded colon or a gastrointestinal intoxication, nor could he comprehend how an elaborate *x*-ray examination or prolonged chemical tests of the various secretions had anything to do with the mental phenomena which were frequently such a striking example of a mental or psychical conflict which lay at the bottom of the whole difficulty.

**The Relief of States of High Vascular, Muscular, and Mental Tension.**—Dr. WILLIAM J. M. A. MALONEY and Dr. VICTOR E. SORAPURE presented a paper on this subject. The authors stated that according to James and Lange, an emotional state was consequent upon a physical state; that the latter was the immediate source and precursor of the emotion. According to this theory, which was well substantiated, fear developed because our heart quickened; our heart did not quicken because we feared; the tachycardia was the cause of the fear; the fear resulted from the tachycardia, and we feared because we breathed rapidly and irregularly; we did not breathe rapidly and irregularly because we feared; the hurried, shallow, gasping respirations caused the fear; the fear resulted from the hurried, shallow, gasping respiration. Fear without visceral change could not occur. Absence of visceral change implied absence of emotion. To minimize visceral change was to minimize emotion. Deep breathing slowed the heart's action. The changing of hurried, shallow breathing into slow, deep breathing, and the reducing of the heart's rate mitigated or dispelled fear. So long as the breathing was controlled and the heart slow, no considerable fear nor excitement could exist. Every emotion, every thought was externalized in muscular action. Vierordt showed that in the erect posture, the greatest degree of voluntary immobility of any person was accompanied by definite oscillation of the head. He further showed that if a person, standing as motionless as possible, expected to hear something on the right side, the whole body took up a new axis of movement; the whole body now swayed to the right. If the sound was expected from the left, the whole body swayed to the left. Numerous experiments corroborated this, and proved beyond doubt that changes in our stream of consciousness were partly externalized as muscular action. Hence, the attitude of the ataxie was partly an emotional expression—an expression of his uncertainty and fear. Complete muscular relaxation therefore promised still further to tranquilize the anxious tabetic, and, in addition, afford an unconstrained musculature receptive to education in normal movements. Dr. Maloney said he had elaborated for the relief of states of mental and muscular tension certain depressor exercises, which he used as an introduction to the treatment of ataxia by the blindfold method. In tabetics who were practising these exercises he had observed a fall of blood pressure, and the patients had reported to him that at home the exercises often led to sleep. He next observed that in a case of chronic nephritis the exercises led to a fall in the blood pressure from 220 to 192 mm. in fifteen minutes. He communicated these observations to Dr. Sorapure, who soon verified them in over 40 cases and then instructed several physicians in the exercises. These in turn reported equally good results. Altogether, over 300 observations had been made, and in more than 50 cases the effect of these exercises had been studied.

The exercises might be divided into two groups: breathing exercises and relaxation exercises. Breathing exercises: As we seldom used effort to expire, and often needed effort to inspire, expiration, throughout life, was, to a great extent, a passive, mechanical act, whereas inspiration more often was consciously performed. So inspiration was usually better controlled than expiration, and much of the trouble in teaching breathing exercises lay in training patients to govern their expiration. We first instructed the patient to breathe deeply and to pause at the end both of inspiration and of expiration. The breathing should be abdominal and should be done without jerking. One of the purposes of deep breathing was to distract the patient from obsessing thoughts and disturbing ideas; to focus his attention upon the exercises. But deep breathing quickly tired patients. Therefore, after about twelve full breaths, the patient was allowed to pass to breathing of moderate amplitude. Now all imagery was discouraged. The patient was asked to feel only the passage of air through his nasal cavities and the tactile sensations which arose from the movements of the abdominal wall against his clothes. While he was so practising, he was cautioned to keep his attention upon the sensations which accompanied his breathing. After a few minutes of "medium" breathing, the patient was taught to breathe quietly, and to attend only to the accompanying sensations. A bag of sand or shot or other heavy object placed upon the abdomen was useful to increase the muscular effort involved in breathing, so that breathing, during the exercises, might not easily lapse into an unconscious act. Instead of the sand bag, the physician's hand may be used.

Relaxation exercises: To relax the muscles, passive movements in which the muscles were alternately lengthened and shortened, were employed. The scalp, forehead, cheek, and jaw muscles of the recumbent patient were passively moved by the physician, and this was continued until wrinkling diminished or disappeared and muscular spasm was eliminated. Next, a shoulder was relaxed; then an arm. Each was dealt with separately. Each joint was passively moved until all trace of muscular tension vanished. All movements should be first passively made by the physician, and then, where possible—limbs, head and trunk—passively induced by the action of gravity.

The effects of breathing and relaxation exercises: Besides the tranquilizing of excited and anxious states and the general relaxation of the musculature, certain other physiological effects resulted. During the exercises a high blood pressure almost invariably fell. Not only in organic renal diseases, but also in cases of high blood pressure, in which no renal disease could be detected, a fall occurred. A reduction of from 25 to 30 mm. in the systolic blood pressure, as a rule, resulted from the exercises, and even greater reductions occurred. This fall in blood pressure was observed not only in cases of high pressure, but also in normal people, among whom a fall of from 10 to 15 mm. was customary. The fall, as a rule, affected almost equally the systolic and the diastolic pressure in normal peo-

ple, and sometimes there was an equal fall in the systolic and diastolic pressure in persons with organic disease, but in those in whom the blood pressure was abnormally high, the systolic usually fell to a greater degree than the diastolic.

Psychologically, the exercises produced concentration of attention and restriction of consciousness. The physiological effects were relaxation of the voluntary muscles, diminution of muscular reflexes, slowing of the pulse rate, a tendency to re-establish in the pulse the normal rhythm in time and volume, lowering of blood pressure, and a tendency to restore the normal pulse pressure. The exercises should last about twenty minutes at first. If they were continued longer the patient grew restless.

Therapeutic applications: These exercises were originally devised as an aid to the re-education of the ataxic tabetic. Obviously, they were applicable to all cases in which the relief of high vascular, muscular, or mental tension was desired. They were, therefore, taught in cases of high blood pressure, of muscular spasm, of insomnia, and other neurasthenic symptoms.

Dr. WALTER TIMME said the paper presented by Dr. Maloney began on the basis that the rapid heart action produced the fear. Personally, Dr. Timme said, he did not think that the theory was susceptible of proof, but rather the converse. For example, if we took a cat and gave it sufficient atropine to diminish the autoactivity that had control over the heart's action a sudden fright would fail to produce rapid heart action, but still the animal would be frightened. Fright may produce blanching of the sin and diarrhea, due to stimulation of the autonomic nerve ends. In other words, the results of two factors were interwoven, the two factors being the sympathetic and the autonomic systems. Referring to the blood pressure, the speaker said that while in certain cases its reduction might prove beneficial, in other cases the high blood pressure may be compensatory, and its reduction would prove injurious. With a productive inflammation of the kidney a high blood pressure was a purposeful action, by reducing it the kidney could not functionate properly. With functional conditions, of course, the reduction of a high blood pressure was beneficial, but to attempt to reduce it below its physiological limits was of doubtful efficacy. However, our thanks were due to Dr. Maloney for giving us a method which promised so much relief of high tension cases of functional character, for it was just in these cases that a lowered tension was of lasting benefit.

Dr. RICHARD B. KRUNA said he had employed exercises similar to those described by Dr. Maloney in the re-education treatment of infantile paralysis for the past eight years. He had also resorted to them in the treatment of cardiac neuroses, in conditions of disturbed innervation of muscular tissue, of increased muscular activity, such as we found in convulsive tics, and in neurotic tachycardia, and he could subscribe to the fact that by this method we could establish greater regularity of the heart's action, and that in infantile paralysis it improved the innervation of the muscles that were affected by the paralysis springing from certain segments of the cord.

Dr. JELLIFFE said he was glad that the authors of this paper, Dr. Maloney and Dr. Sorapure, had emphasized the value of the psychical element in connection with this method of treatment. He believed, however, that they would have to relinquish their contention that fear was consequent upon the quickened heart's action. If anything had been shown by the recent work on the sympathetic nervous system, it was that the James-Lange theory failed fully to account for these phenomena, and that, after all, we were not afraid because our hearts beat, nor did our hearts beat because we were afraid, but that these phenomena were the result of interrellatory phenomena operating through the sympathetic and the autonomic nervous system, using these terms as Eppinger and Hess had outlined.

Dr. MALONEY, in closing, replying to Dr. Timme, said there was no evidence to substantiate the theory that the kidneys functionated less actively under conditions of lowered blood pressure. At all events, the idea of bringing the pressure down to a danger point in nephritis did not enter into this discussion. In their cases they had noted that the systolic pressure was always lowered to a greater degree than the diastolic, and it was only in the functional conditions that a considerable fall in both the systolic and diastolic occurred.

# State Medical Licensing Boards.

## STATE BOARD EXAMINATION QUESTIONS.

NEW HAMPSHIRE STATE BOARD MEDICAL EXAMINERS.
*January 6 and 7, 1914.*

(*Concluded from page* 919.)

### PATHOLOGY AND DIAGNOSIS.

1. What is the effect on the circulation of increased pericardial pressure?
2. Describe the changes produced in the lungs by mitral stenosis, and how these changes are produced.
3. In what way may arterial disease affect the nutrition of a part?
4. What conditions would influence you in determining the malignity of a tumor?
5. What organ is most commonly affected in visceral syphilis and describe the lesion found in it?
6. Differentiate diagnosis between obstruction in common and cystic biliary ducts.
7. Differentiate between lobar pneumonia and pleurisy with effusion.
8. Symptoms of incipient tuberculosis.
9. Symptoms (*a*) of aortic regurgitation; (*b*) mitral regurgitation; (*c*) mitral stenosis.
10. Differential diagnosis in coma produced by alcohol, opium, uremia, and cerebral hemorrhage.

### OBSTETRICS.

1. Name and describe the ligaments of the uterus.
2. How and when will you use ergot in obstetrical practice?
3. Give indications for the use of hot vaginal douche.
4. Differentiate fibroid, pregnancy, ascites.
5. Mention three causes for retention of the placenta. Give treatment.
6. Discuss intrauterine irrigation following complete abortion.
7. What points should govern the duration of the lying-in period?
8. Diagnose the death of the fetus during the early months.
9. Describe the second stage of labor.
10. Under what conditions do we most often find failure of uterine contraction?

### SURGERY.

1. Enumerate suture materials in general use, and give special value of each.
2. Give technique of first aid to the injured.
3. How would you treat organic stricture of male urethra?
4. Describe and treat postoperative complications in the abdominal wound.
5. What are the indications for trephining in fracture of the skull?
6. Describe a modified circular amputation of the leg.
7. Give diagnosis and treatment of floating kidney.
8. Describe some one surgical procedure in the treatment of hemorrhoids.
9. Give symptoms of bowel obstruction and outline a surgical operation in the treatment of the same.
10. Describe the usual deformity in fracture of the neck of the femur and outline method of treatment.

## ANSWERS.

### PATHOLOGY AND DIAGNOSIS.

1. *Increased pericardial pressure* causes embarrassment of the circulation, through pressure on the auricles and great veins. Less blood goes into the right auricle, right ventricle, and pulmonary artery; the blood pressure in the pulmonary artery falls; less blood reaches the left side of the heart and the aorta, and the aortic blood pressure falls. The venous blood pressure rises.

2. In mitral stenosis the lungs may be congested and edematous, and hemorrhage may occur. These conditions may be due to back pressure or to embolic infarction, the emboli coming from the dilated right side of the heart.

3. *Arterial disease*, such as narrowing, pressure by tumors, sclerosis, aneurysms, and blood clots may hinder the flow of blood to a part and so affect its nutrition.

4. *Malignant tumors* interfere with the general health of the patient, produce a cachexia, tend to spread into

the neighboring tissues, are apt to recur after removal, and show a tendency to metastasis.

5. The organ most commonly affected in visceral syphilis, is the *liver*.

"Syphilis is met with in the form of diffuse infiltration and cirrhosis, or in the form of gummata. Either of these varieties may be found as a result of acquired or of hereditary syphilis. In the diffuse form the liver presents much the same appearances as in atrophic cirrhosis, but the connective-tissue bands are much more pronounced and the liver is prone to be irregularly contracted and lobulated. Gummata may occur in any part of the organ, and may be single or multiple, presenting themselves as rounded, yellowish, or grayish masses, ofttimes showing central necrosis and surrounded by connective-tissue hyperplasia. Complete cicatrization may lead to decided scar-formation. In addition to these forms, congenital syphilis may manifest itself in the form of a uniform, diffuse connective-tissue hyperplasia and round-cell infiltration. The liver-cells are pushed apart and are ill-developed or atrophic."—(Stengel's *Pathology*.)

8. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs:* Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist râles at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

9. In *aortic regurgitation*, there is a diastolic murmur, heard loudest at the midsternum opposite the upper border of the third costal cartilage, and transmitted down the sternum; the murmur is soft, blowing, sometimes rough.

In *mitral regurgitation*, there is a systolic murmur, heard loudest over the apex, and transmitted round to the left axilla and under the left scapula; the murmur is soft and blowing.

In *mitral stenosis*, there is a presystolic murmur, heard loudest over the apex, and not transmitted; the murmur is generally low-pitched, and rough.

10. The following table (from Eisendrath's "Surgical Diagnosis") gives the diagnosis:

| APOPLECTIC COMA | UREMIC COMA | ALCOLOHIC COMA | OPIUM POISONING |
|---|---|---|---|
| Deep coma; sudden onset. If any injury, only a scalp wound. | Deep coma. Slow onset unless convulsions have preceded the coma. | Can be aroused by supra-orbital pressure unless very profound. | Can be aroused unless very deep. |
| Pupils unequal or dilated. Contracted in hemorrhage into the pons. | Albuminuric retinitis. | Pupils normal or somewhat dilated. | Pupils contracted to pin-point size. |
| Pulse full and slow, often arteriosclerotic high-tension pulse. | Pulse rapid. | Pulse more rapid than normal and full. | Pulse rapid, may be irregular. |
| Respiration slow and irregular. | Respiration frequent and irregular. | Regular respiration. | Respiration very slow—may be 6 to 8 per minute. |
| Temperature higher on paralyzed side, but lower in rectum. | | May be low or normal. | |
| Urine contains trace of albumin, but may be same as in uremia. | Urine shows albumin, casts, and low urea percentage. | | |
| Hemiplegia with convulsions on one side. | | | |

6. If the obstruction is in the cystic duct there is usually no jaundice; if the obstruction is in the common bile duct there is usually intense jaundice.

7.

| PLEURISY WITH EFFUSION | LOBAR PNEUMONIA |
|---|---|
| Onset marked by chilliness persisting for a few days. | Onset acute, with rigor, lasting one hour or longer. |
| Cough is irritating; no expectoration, or, if present, catarrhal in character. | Cough more marked, and accompanied by rusty or bloody, tenacious expectoration. |
| Sputum negative; tubercle bacilli rare. | Dense aggregations of pneumococci present. |
| Moderate fever of continuous type; declines by lysis. | Fever, 102° to 104° F.; falls by crisis. |
| Prostration moderate. | Prostration extreme. |
| Unilateral distention of the thorax. | Absent. |
| Countenance pale and anxious. | Mahogany-colored flush of cheeks. |
| Limited expansion at base of chest on the affected side. | Degree of expansion slightly, if at all, inhibited. |
| Tactile fremitus diminished or absent. | Increased over area of consolidation. |
| Interspaces bulging at base of chest. | Absent. |
| Percussion shows flatness, with great resistance to the pleximeter finger. | Dullness with less resistance, and sometimes a tympanitic note. |
| Diminished or absent breath-sounds over effusion the rule. Respiration murmur diffuse, distant, and generally unaccompanied by rales. Bronchial breathing may be present over the entire affected side. | Harsh bronchial breathing and presence of rales in first and third stages, unless a bronchus is plugged. |
| Friction sound heard in early and late stages. | No friction murmur; rales present. |

—(From Anders and Boston's *Medical Diagnosis*).

OBSTETRICS.

1. The LIGAMENTS OF THE UTERUS are: (1) *Broad ligaments*, which extend outward on each side from the side of the uterus to the side of pelvis. (2) *Rectouterine ligaments*, which extend backward from the intraperitoneal portion of the cervix uteri to the peritoneal investment of the rectum. (3) *Round ligaments*, which extend from the uterus just below the Fallopian tubes, through the inguinal canal to the labia majora. (4) The *ovarian ligaments*, which extend from the superior part of the uterus, behind the Fallopian tubes, to the inner end of the ovary. (5) The *uterosacral ligaments*, which extend from the highest part of the cervix uteri to the sides of the sacrum opposite the lower border of the sacroiliac synchondrosis.

2. "The use of ergot favors uterine contraction and retraction. Ergot may be given hourly as a routine, in half dram doses of the fluid extract, until three doses have been taken, or used only when there are signs of relaxation, as a prophylactic against postpartum hemorrhage. Postpartum inertia is not uncommon when the patient has been the subject of hydramnios, twins, etc., or has been subjected to a long general anesthesia, or is exhausted, with a rapid pulse and low blood pressure. Ergot is best used hypodermatically in the form of ergone (25 min.), or ergotole (25 min.), combined with pituitrin (1 ampoule). The generous use of ergot in the puerperium is of value also as a prophylactic against puerperal infection, since it tends to prevent the formation and the prolonged retention of blood clots within the uterus, and by its action on the muscular fibers tends to close the lymphatics and blood vessels against absorption. Moreover, by thus limiting the blood supply it promotes involution."—(Polak's *Obstetrics*).

3. INDICATIONS FOR HOT VAGINAL DOUCHE.—*Before labor:* 1. To induce premature labor. 2. As a prophylactic in cases of suspicious or undoubtedly infective vaginal discharge. *During labor:* As preliminary to version, forceps, or embryotomy. *After labor:* 1. Many obstetricians give a routine douche for the sake of cleanliness. 2. In case of foul lochia. 3. After repair of perineal lacerations. 4. As an element of treatment of puerperal sepsis.—(From Scott's *State Board Obstetrics*).

4. *Pregnancy:* The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor and the general condition of the patient's health may also help in arriving at a diagnosis.

*Uterine fibroid:* Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

*Ascites:* Absence of the signs of pregnancy; the abdomen is distended, but the shape varies with the position of the patient; on lying down there is bulging at the sides, the tumor fluctuates, and percussion shows dullness in the flanks, with resonance in the median line, but the dullness varies according to the position of the patient.

5. RETAINED PLACENTA—*Three causes:* Inertia uteri, endometritis, or morbid adhesion of the placenta to the wall of the uterus. *Treatment:* "A finger—one or two—must be insinuated between the uterus and placenta at some point already partially separated, or, if no partial separation exists, at a point where the placental border is thick, and then passed to and fro, transversely, through the uteroplacental junction, acting like a sort of blunt paper knife, until separation be complete. Another mode is to find or make a margin of separation as before, and then peel up the placenta with the finger-ends, rolling the separated portion toward the palm of the hand upon the surface of the still adherent part. Great care is necessary to avoid peeling up an oblique layer of uterine muscular fiber, which might split deeper and deeper until leading the finger-ends through the uterine wall into the peritoneal cavity. Should such a splitting begin, leave it alone and recommence the separation at some other point on the placental margin. It is sometimes only possible to get the placenta away in pieces. These should be afterward put together and examined to indicate what remnants are left behind. It may be quite impracticable to get out every bit, but small remnants or thin layers too firmly adherent for removal do not distend the womb enough to create hemorrhage from their bulk, and the subsequent danger of septicemia from their decomposition may be obviated by injecting warm (2 per cent.) creolin water into the uterus twice daily, until everything has come away."—(King's *Obstetrics.*)

6. If the abortion is complete, and there is no septic or other pathological condition present there is no need for an intrauterine douche.

7. Points which should govern the duration of the lying-in period, are the character and duration of the labor, the presence or absence of complications, the condition of the uterus, and the strength of the woman.

8. Diagnosis of the death of the fetus during the early months is difficult. The chief signs are that the uterus ceases to grow, the abdomen does not enlarge, the breasts either cease enlarging or become smaller again, the temperature of the cervix ceases to be higher than that of the vagina. The mother experiences vague symptoms of malaise, languor, heaviness, depression, chilly sensations and anorexia.

9. *During the second stage of labor,* examinations should be made only when necessary. In multiparæ the membranes may be ruptured with the finger or with some aseptic instrument. Care should be taken not to injure the child's scalp or the lower uterine segment. The pain may require the administration of chloroform or ether, but not to the extent of complete anesthesia. The expulsive force of the abdominal walls may be increased by directing the patient to pull upon a sheet firmly secured to the foot of the bed. Attempts may be made to prevent laceration of the perineum by making firm backward and upward pressure against the occiput during the pains; by restraining voluntary expulsive efforts during the pains; and by securing expulsion of the head between the pains. The head should be supported when born; the eyes should be cleansed with sterile water; and if the cord is coiled about the neck, it should be loosened or slipped over the head. Delay in delivery of the shoulders may be overcome by stimulating the uterus by friction through the abdominal wall or traction. The cord is ligated and cut when pulsation has ceased, and the child is placed by the mother's side with its face turned away from the maternal discharges.—(*Pockct Cyclopedia.*)

10. *Failure of uterine contraction* may be caused by: "Overdistention of the uterus from plural pregnancy or polyhydramnios; distention of the bladder or rectum; obliquities and displacements of the uterus; thinning of the uterine walls resulting from frequent and quickly repeated labors, or from degeneration of the uterine tissues; precocious or advanced age; general debility or feebleness of the woman from previous diseases, enervating habits, heat of climate, or of season, or the air of a superheated room; exhaustion of the woman from hemorrhage or from lack of sleep or food. Uterine action is sometimes inefficient from uremia, and when there is morbid adhesion between the fetal membranes and uterine wall. Mental emotions: fear, grief, surprise, anxiety, disappointment, and the presence of offensive persons or things will produce it. These last named causes may depend upon idiosyncrasy or unaccountable personal antipathies."—(King's *Manual of Obstetrics.*)

SURGERY.

1. *Suture materials:* (1) Silkworm gut, used only on surfaces, from which it may subsequently be removed. (2) Silk, used in abdominal surgery, for suturing intestines and tying pedicles. (3) Catgut, used for buried sutures. (4) Kangaroo tendon, used for bone, and as an absorbable suture which will last a long time. (5) Silver wire, used for bone.

2. The nature of first aid to the injured will depend upon the injury. If a layman is rendering first aid, his first duty is to keep the crowd away, allow the injured one to get fresh air, see that the injury is not made worse, combat shock, check hemorrhage, place the patient in the most comfortable and safe position, and keep him warm and sheltered.

3. *Organic stricture of the male urethra may be treated* by: Gradual dilatation, continuous dilatation, excision of the stricture, external or internal urethrotomy, urethrectomy, or the operation of Wheelhouse or Cock.

4. *Post-operative complications in an abdominal wound,* are: (1) *Stitch-hole abscess;* the infected sutures should be removed, and their tracts syringed with hydrogen peroxide; this should be done daily; a thick gauze compress soaked with a 1:1000 solution of mercury bichloride is then applied, and covered with the usual dressings. (2) *Suppuration in the wound;* open the abscess, with all blind pouches or cul-de-sacs, irrigate the wound with hydrogen peroxide, and dress as in case of stitch-hole abscess. (3) *Ventral hernia;* this requires either a support or binder, which is merely palliative; or another operation.

5. *Trephining, in cases of fracture of the skull,* is indicated in: Simple fractures with pronounced depression; compound fractures with much depression; punctured fractures; any fracture where there are distinct cerebral symptoms.

6. "*Modified circular amputation of the leg.*—Cut semilunar skin-flaps, lay them back, and cut circularly to the bone at the edge of the turned-up flap. Another method of modified circular amputation is by adding to the circular cut a vertical incision down the front of the leg. In sawing the bones of the leg the surgeon, who stands to the outer side of the right leg or to the inner side of the left leg, divides the fibula first, and at a higher level than the tibia, and bevels the anterior surface of the tibia. In sawing the left fibula the saw points to the floor; in sawing the right fibula it points to the ceiling."—(Da Costa's *Modern Surgery.*)

7. In *floating kidney* the *symptoms* may be entirely absent in some cases. They consist of aching pain in the loin, nausea, vomiting, and constipation. Attacks of renal colic and intermittent hydronephrosis may occur from kinking of the ureter. A movable tumor can be felt in the region of the kidney.

*Treatment* consists in improving the general health and wearing an abdominal belt with a pad. When this fails, or there are attacks of colic or hydronephrosis, nephrorrhaphy should be done.

8. "The application of the ligature is an easy and useful method. It is not so rapid as the cautery, is followed by more pain, healing requires a longer time, and stricture is more common. In this operation, after anesthetizing, stretch the sphincter and treat each hemorrhoid separately. Catch a pile with a pair of forceps or a volsellum, pull it down, and cut a gutter through the skin-margin if the pile is of the mixed variety; tie the small piles without transfixing, but transfix the large piles; tie with silk (coarse silk for the large piles, finer silk for the small piles); cut off

each tumor beyond the thread, and cut the ligatures short. Treat the other piles in the same manner. Irrigate with hot normal salt solution. Do not insert packing. Apply a gauze pad and a T-bandage. Give some morphine to lock up the bowels, and keep the patient on a light diet for three days, at the end of which time a saline may be given. Just before the bowels act remove the dressings and give an enema of warm water or of glycerin. After the movement wash out the rectum first with dilute peroxide of hydrogen and next with hot salt solution, dust with iodoform, and apply a gauze pad over the anus. Irrigate daily until healing is complete. After the tenth day examine with a speculum to see that the ligatures have come away; if any are found in place, remove them."—(Da Costa's *Modern Surgery.*)

9. *Symptoms of acute intestinal obstruction:* "Sudden severe pain referred to the umbilicus comes on, perhaps, after an effort. Shock, evidenced by a weak pulse, a cold, clammy skin, and a subnormal temperature, accompanies the pain. The pain, intermittent at first, becomes continuous. Vomiting is persistent, and soon becomes fecal smelling. The patient becomes exhausted by the vomiting and inability to take food. The abdomen beeomes distended, and if the obstruction is not relieved, perforative peritonitis follows, so that the patient dies in about seven to ten days from the onset. Constipation is usually absolute, though the lower bowel may empty itself at first."

*Treatment:*—"The only thing that can give the patient the chance he ought to have is immediate operation. It is advisable to wash out the stomach before the operation, so that intestinal contents may not be vomited and inhaled during the operation. Three objects are aimed at: (1) To empty the distended bowel above the obstruetion; (2) to relieve the obstruction; (3) to treat the strangulated intestine. In eases that are almost moribund, the abdomen should be opened with cocaine or eucaine anesthesia; a distended coil is pulled out and tapped, a Paul's tube being subsequently tied in. The peritoneal cavity is protected with gauze packing during these manipulations. The bowel is stitched to the abdominal wound after the feces and flatus have drained away. No attempt at relief of the obstruction can be made in these cases till a later date, and, of course, under the circumstances a high death-rate must be expected.

In less severe cases the abdomen should be opened in the midline below the umbilicus, and a systematic search made for the cause of the obstruction. The hernial orifices are first examined, then the cecum. If the cecum is distended, the obstruction lies below it; if collapsed, above it. In the former case the sigmoid should next be examined. If collapsed, the colon must then be traced backwards till the obstruction is found. If the cecum is collapsed, the intestine must be pulled out a foot at a time and examined, beginning with the ileum, and replacing it as each part is done with. If the intestine is much distended, several coils may be tapped and emptied, to facilitate the search."—(*Aids to Surgery.*)

10. If the fracture of the neck of the femur is *intracapsular*, there is very apt to be fibrous union with false joint; if the fracture is *extracapsular*, shortening is very common.

*Treatment of intracapsular fracture:* "Fibrous union nearly always occurs in old people, as the blood supply of the upper fragment depends solely on the obturator branch running in the ligamentum teres. Then, old people often die of hypostatic pneumonia if kept lying long upon the back. If the patient be young, he should be put upon a long Liston splint, with extension, for six weeks. The same should be tried with old people, but the moment the respirations begin to increase the patient must be got up, wearing a Thomas' hip splint. Impaction favors bony union, and so should not be broken down."

*Treatment of extracapsular fracture:* "Unless there is great deformity, it is not advisable to break up impaction. Bony union always occurs. The patient should be anesthetized, and traction kept upon the leg during fixation. A stirrup extension is first put on, and then the leg is firmly bandaged to a long Liston splint, with the eversion corrected. The chest is fixed to the splint by a binder; the foot of the bed is raised, and a weight of eight or ten pounds is put on to the cord of the stirrup extension. Hodgen's splint may also be used. Union occurs in six weeks."—(*Aids to Surgery.*)

BULLETIN OF APPROACHING EXAMINATIONS

**Osteoperiostitis of Upper End of Femur.**—H. A. T. Fairbank reports the case of a girl, aged five years, who was brought to the out-patient department of the Great Ormond Street Hospital in July last with a history of wasting and pain in the right leg. Nothing definite could be made out at first. On subsequent visits complaint was again made of pain in the leg. This pain occurred particularly when the child got up in the morning. Tenderness in the adductor region was notieed, but no swelling or thickening of the femur. In September a skiagram showed a thickening of the upper part of the shaft and neck of the femur. The thickening now present could then be felt in the region of the lesser trochanter. When asked to point to the site of the pain the child always pointed to the inner part of Scarpa's triangle. The child limped slightly. She was admitted to the hospital for rest and investigation. Beyond the thickening and tenderness at the upper part of the femur nothing could be made out. There were no signs of disease elsewhere. The right hip-joint seemed to be normal. No history of specific disease could be obtained and the Wassermann reaction gave a negative result. Mercury and iodides were given without effect. The temperature was never above 99° F. So long as the child was in bed she was free from pain, but as soon as she was allowed to get about again she complained of the pain. Her past history contained the facts that she had "bleeding piles" a few months previously and lost much blood, and that she had pneumonia four years previously. There was no history of traumatism. The skiagrams suggested an inflammatory lesion, not a new growth. The case is reported on account of the obscurity of the cause. It is suggested that an operation should be performed with the object of cutting a deep groove in the affected portion of bone.—*Proceedings of the Royal Society of Medicine.*

### CERTAIN ASPECTS OF THE MIDWIFE PROBLEM IN RELATION TO THE MEDICAL PROFESSION AND THE COMMUNITY.*

By GEO. W. KOSMAK, M.D.,

NEW YORK.

ATTENDING SURGEON, LYING-IN HOSPITAL.

I am very glad, indeed, to respond to this invitation to place before the members of the medical profession in Syracuse certain aspects, both old and new, of this important question. The increasing interest in medical subjects on the part of the lay public has rendered it necessary for the medical profession to recognize and give renewed attention to certain problems which concern not only the profession, but the community. Among these there is scarcely one that is in such great need of our best services and discussion as that connected with the midwife and her activities. The question is one which must be considered from two points of view. One of these deals with the purely medical phases of the situation; the other with the sociological. Each of these constitutes a distinct subject and requires separate consideration. Every community, whether large or small, must sooner or later come face to face with some phase or other of these questions which will require its best efforts at a suitable solution. I shall endeavor to present the matter not from the viewpoint of the metropolis, but will bear in mind the conditions as they exist in the smaller city. Although the details may vary, the general situation is the same, except in degree. It is not my purpose to burden you with a consideration of statistical details. These have already been compiled by others and are readily obtainable in the reports of the American Association for the Prevention of Infant Mortality and from other sources.

The physician usually regards the midwife as a factor in the community whose position is determined by necessity or tolerance. As the custom of employing women during attendance in childbirth is as old as the race, her control or elimination becomes a most difficult question to solve, as those who would be most directly benefited are very apt to accuse physicians of a selfish interest in this matter. It is quite true that the interest displayed by the medical profession is a selfish one, but not in the sense assumed by the laity. The profession at large is desirous of affording to the public the best services acquired by its accumulated knowledge, and no severer critics of the shortcomings of medical men exist than their fellow practitioners. It is this constant aim and desire to improve its knowledge of the body and its ailments that serves to keep the medical profession in the foreground of humane activities.

One of the most essential factors in the practice of medicine is a knowledge of the physiology of reproduction and all that goes with the same. Among physicians this knowledge is acquired only after thorough study and observation, with practical experience in the delivery of pregnant women, whenever this can be obtained. Unfortunately the fact that pregnancy and labor is, or is believed to be, a physiological process has so dominated the lay public, and many physicians, that insufficient thought has been accorded to this important subject. This is shown by the tolerance which has been granted to a certain class of women who practice their calling as attendants in labor simply because the birth act is considered a normal process in the life of women and therefore does not require much attention. Our knowledge of obstetrics, like that of other branches of medicine, is a development of comparatively recent times, and, although the essentials of both theory and practice have not been largely departed from in recent decades, there are other important questions which demand solution and have been accorded increasing attention. If the race is to be perpetuated in a normal and orderly manner, greater thought must be given to breeding of the individual and to the care of women during pregnancy, labor and the puerperium. The statement has been made that over 75 per cent. of gynecological diseases have some relation or other to the generative tract in its relation to the acts of reproduction, and we know well the whole organism bears a very close and intimate relation to this important set of organs. Acknowledging that the above is true, can we as physicians flatter ourselves with the idea that we have accorded to woman as a mother the attention which she deserves? Have we not been satisfied to treat the results and consequences of pregnancy and labor, rather than to do away with the causes? The attendance on a woman during her pregnancy and labor is not considered an agreeable branch of medicine by most practitioners, and the family doctors, so-called, have usually considered it necessary to take care of the confinement cases in order to retain their hold on the family. Fortunately the medical student of the present day is better equipped to do this work because he has been favored with actual clinical experience in obstetrics during his college course or soon after. But even then, in many instances, the importance of the subject is not sufficiently impressed on his mind, and the particular work in obstetrics is often merely taken up because of the requirements of the State Board of Medical Examiners. It would be much better, perhaps, for this requirement to be omitted altogether, rather than have such knowledge acquired under circumstances that do not fit a practitioner for properly carrying out the same.

It is this acquiescence to established customs, in

*Presented at a meeting of the Academy of Medicine of Syracuse, New York, April 7, 1914.

addition to certain economic questions, which has allowed the midwife to gain such an extended foothold. In foreign countries the condition has been much more satisfactorily dealt with than with us, and schools of midwifery have been established under government supervision and aid, which will insure to those people who are compelled to employ them, midwives who have at least had a satisfactory training. Strange to say, although the midwives of most foreign countries are far above the average found in the United States, they are by no means entirely satisfactory to the medical profession. In Germany particularly, where the system has been developed farthest, the lack of initiation and improvement on the part of most midwives is recognized in the movement to compel midwives to take extension courses in obstetrics in order to keep them in touch with the advances in this branch of medicine and to insure their adherence to the same. In comparison, the conditions in our own country must be acknowedged as most deplorable. I need not enter into further details of the subject, except merely to remind you that the control of midwives with us is usually left entirely to the local community, and that no general control is exercised in most States over these women. We are only now beginning to educate candidates for the practise of midwifery in the essentials of obstetrics, and such instruction is still limited to a very few properly organized schools. As the midwives are demanded mostly by our foreign born population, the necessarily large number required can hardly be recruited from these institutions, and we find that the great majority when licensed can obtain the privilege of practising by presenting credentials from foreign or other institutions that are seldom investigated. When a license has once been received, very little attention is paid to subsequently supervising the holder thereof, and, notwithstanding such laudable efforts in the City of New York, the midwife situation, even in this particular community, is certainly not in a condition for favorable comment.

There are certain economic question to be considered as regards the practitioner of medicine that may be briefly referred to in this connection. It is generally claimed that the fee obtainable from poor patients during confinement is not sufficient to repay the regular practitioner for his time, and that, as already stated, in many instances the drudgery of such attendance is assumed in order to retain the family practice. While this is a point of apparently great practical importance and a favorite argument, it is not a logical stand to take, and there is no more reason for shunting off this class of practice than any other which may prove more agreeable. By acquiescing in such a state of affairs the profession lays itself open to great blame for what is actually neglectful treatment of one of the most important functions of a woman's life.

In view of the interest which the public of the present day takes in medical matters, it also seems necessary to accord to the midwife problem greater attention on the part of the laity. The various questions of moral uplift that we find so largely discussed at the present time are not always relished by those for whom they were intended. Among other things, it is a difficult matter to demonstrate to the wage earners the necessity of expert care during pregnancy and labor. Such women are accustomed to regard a certain amount of discomfort and obstetric complications as a part of their lives and accept the results of the complications with equanimity. Unfortunately this does not only concern themselves, however, but if crippled from the results of child bearing, the effect is manifested not only on their own family but on the community, as the latter must put its hands in its pockets to provide such an invalided woman with care and attention which might have been avoided under other circumstances. The conservation of human life and energy should make us regard a mother as a *sine qua non* of our community existence. We most carefully guard against the inroads or spread of contagious diseases, but what do we do, collectively speaking, to combat certain avoidable complications of pregnancy? It is but necessary to remind you of the large number of cases of puerperal fever which occur, notwithstanding our present-day knowledge of asepsis and antisepsis. This is a matter for which the profession is to some extent responsible, and we will have been very remiss in our duty if we fail to properly recognize this unfortunate condition and not inform our fellow citizens accordingly. Puerperal sepsis is not entirely due to the midwife, the doctor must bear a share of this blame. Yet it cannot be gainsaid that the midwife is the direct cause of a great number of such cases in addition to blindness and other avoidable complications of pregnancy.

Having thus briefly outlined the subject for discussion, what shall we do to correct and improve the situation? Shall we eliminate the midwife, educate her, or provide a substitute? The question is one that is not easily answered. It must be approached in a broad, open-minded manner, without personal prejudice for or against this class of women, whom we can only regard as a relic of the days of the barber surgeon. We are dealing with a condition, and not a theory, and, willingly or unwillingly, we must face and treat it. The midwife has a large following among a class of people almost invariably foreign born, who are the muscle and brawn of the nation. They are needed to do our hard and largely unskilled labor. Among such people the custom for centuries to employ only a woman in labor has resulted in a prejudice which it will be difficult to overcome. If the demand is present the supply will follow. Is there no means by which we can overcome this prejudice, by which we can substitute agencies which will afford a satisfactory solution of the problem? I believe it is possible to accomplish this result, but it must be done in a spirit of consistency. The reform, however, must take in the doctor as well as the midwife. It must include a reform in the home, in housing conditions, in the relief of poverty and in the consideration of many other sociological problems. It is a matter of congratulation as regards the doctor, that greater responsibility is now acknowledged by the average physician than a few decades ago in the matter of confinements. Our medical colleges are beginning to supply the need for better obstetrical training of their graduates, especially since the epoch-making report on this subject a few years ago by Prof. J. Whitridge Williams. If this movement of reform among the profession continues we can leave this phase of the question for the present, in the realization that the steps which are necessary to solve the midwife problem will reflect the shortcomings in this field among the members of the medical profession itself.

What shall we do, however, with the midwife system as it is at present constituted? There is no question at all in the minds of thinking persons that our present midwife system can only be regarded as disgraceful. That much being admitted, what shall

we do to overcome this state of affairs. The State must either regulate the activities of these women within its borders, or the individual community must attack the problem as it presents itself. This will require the education of those classes of the population who are liable to patronize the midwife, to the necessity for better care during their pregnancy and confinement. This is necessarily a slow process, but there is no work which can be undertaken by the medical profession that is more deserving of the support of the community. We must either provide a thoroughly educated midwife and keep her educated, or we must provide a suitable substitute agency. In a small community the substitute agency which can be provided in larger cities is often out of the question. A maternity hospital is an expensive thing to manage, and it cannot by any means take care of all those who ought to be reached. The problem can be attacked in another way, however. A pregnancy clinic may be conducted at comparatively small expense, which can be placed in charge of a competent nurse, who shall have received a thorough training in an obstetrical hospital and be prepared to make the necessary antepartum visits, recognize abnormalities, do the ordinary urinalysis and report results to a physician who shall be in direct charge of this work. Now, as to the latter. The increasing attention which is being given to the proper care and delivery of women during pregnancy and childbirth will in time demand the education of specially trained physicians in every community. There is no better way to acquire such training than by actual attendance on an extended series of pregnancy cases. The field is open to the younger physicians recently graduated from medical colleges and hospitals, to take up this branch of the work and limit themselves to a large extent to obstetrics. Two or three young physicians could actually do most of the confinement work in a small city, particularly if antepartum supervision and the greater number of postpartum calls could be left to properly trained nurses supplied by the community.

It is quite generally admitted that the midwife system is largely retained for economic reasons, and one of the great arguments advanced by those who advocate the retention of the midwife is that she gives her services as a nurse in addition to being an attendant during labor. I do not believe that the facts strictly bear out this contention. The midwives of a lower grade undoubtedly supervise the household, bathe the baby, cook and clean after a fashion, if they remain as residents in the house for the time being, but this does not apply to those who consider themselves of a higher status. The latter, as I have observed them, attend a woman in confinement, just as a physician would. They are called when the pains begin; they then examine the patient and usually leave until some time when the pains are stronger. After the delivery of the child and placenta they merely remain to straighten out things and then take their departure, making postpartum calls just as a physician would. This class of women to my knowledge does not look after the household or do any nursing in the sense in which we ordinarily apply this term. If we acknowledge the truth of the contention that certain midwives, however, do act as nurses, it seems to me that a possible solution of the question could be arrived at by furnishing a substitute agency with this in mind. If visiting nurses could be supplied by the community to attend women daily for a fixed charge in order to eliminate the tendency to pauperizing, but free when necessary, one factor in favor of the retention of the midwife would be immediately eliminated, and such nursing by more carefully trained and efficient women could be made to include the prenatal as well as the puerperal period. In this way the patients would be kept under closer observation, and any abnormalities reported immediately to the physician in charge of the service. This might well be regarded as a prophylactic measure and by preventing trouble would save a great deal in the end as the number of cases of eclampsia, puerperal sepsis, etc., would be largely reduced in consequence.

Having briefly referred in the foregoing remarks to a number of the salient features connected with the midwife question in general and its possible solution, you will naturally ask what can be done with the problem as it exists in communities such as Syracuse. As I have already stated, the difference between Syracuse and New York is one of degree only. The actual conditions as regards the clientèle of the midwives, their homes and social status are practically the same and similar remedies may be applied with certain modifications. In this connection I might refer with advantage to a report made at the last (1913) meeting of the American Association for the Prevention of Infant Mortality by Dr. Bennett, of Manchester, N. H. He spoke as follows:

"We have a scheme for eliminating the midwives in the smaller cities. Manchester's industries are largely textile and shoe manufactories. They employ between them about 23,000 operatives. The operatives are largely of foreign extraction—French Canadians, Germans, Greeks, Poles, and other nationalities. The wages paid are small—lower in the textile mills than in the shoe factories. There were last year 2,149 births in the city. Of these 94 were delivered by midwives, of which there are six in our city. Two of these delivered one case each, one delivered 5, and the remaining three delivered 11, 28, and 48, respectively. The midwife who delivered the highest number of cases is the only one in whom we are very much interested. Next year she leaves us, seeking more lucrative fields. She is going to New York City. The agency that has made her business unprofitable is the District Nursing Association. The percentage of mothers who are unable to afford either a family physician or hospital care is approximately 11 per cent.; of these 6.6 per cent. have been delivered by the Nursing Association and the remainder by midwives. The executive head of the obstetrical department of the District Nursing Association is a physician. Patients are required to pay what they are able. The Metropolitan Life Insurance Company has cooperated with us, paying for the mothers who are insured in that company in its Industrial Department. In Boston the criticism was made by Mr. Green that in this we were encouraging industrial insurance among the poor. We think that criticism is not justified. In the first place in an industrial center instalment insurance will prevail, whether there is savings bank insurance or not. The little work we did will not increase in any way the amount of such industrial insurance. We are simply taking care of those mothers who would otherwise go to the midwives. Obstetrical service is given by the younger men as they come to town. They are looked up and their records gone over, and if favorable they are requested to donate to the

association their services, subject to call for two or three months a year, as the case may be. The question was asked (in Boston) how we were able to secure their services. It is simply a matter of custom. The older men began donating their services at the organization of the association, and as their practice increased they simply asked the younger men to do their share. Of course, there are many things that an older man can throw to the younger men in return. It also increases a new man's practice, and ultimately it brings him in good standing with the older men and gives him their stamp of approval in the community. The wage that is paid in cities of this class is low. In Manchester the operatives are employed a larger percentage of the year than in any other shoe or textile city in America; this steady employment to some extent removes the problems of poverty that some of the other cities have to deal with."

This and similar statements may serve as a basis for a propaganda for the work in other cities. The situation in each community should be studied by a committee designated, not as a "committee on midwives," but on "proper obstetric care." If a community will regard this question in the same aspect as certain sanitary requirements now looked upon as of general rather than merely of individual importance, it will place the matter in a different light. A patient with smallpox or scarlet fever must be subjected to certain quarantine and other regulations for the benefit of the community. We insist on properly qualified medical attendance to prevent the spread of contagion, although the individual treatment may be a matter of choice. A woman pregnant should be regarded as an equally uncertain factor in another aspect, unless she receives proper care before, during and after confinement. This is demanded if we assume that a healthy mother is the greatest asset which the community possesses, and that she shall not be subjected to any unnecessary risks in her most essential function of child bearing. But how can we bring about such ideal conditions? Will it not interfere with the great American "liberty of person," and be, accordingly, resented by those whom it would benefit the most? Education of the women is the answer—a knowledge which will lead them to demand for themselves the best care during this period and if their means will not permit, then let the community step in and assist them.

Those classes of our population who can afford to employ a properly trained physician need not be considered here, but the thousands to whom the advent of a baby after the first usually means an increase in care and worry, with consequent neglect of those who have gone before, require our practical sympathy during this critical time. These women naturally turn to a member of their own sex for moral as well as physical aid. Why not educate them to the fact that it is possible to secure both from sources which are reliable. If the entering wedge has once been secured it will be simple enough to do the rest. The local committee on obstetrics already referred to can organize and supply this need with the exercise of a little tact, patience, and —some money. If a maternity bureau were established in a convenient locality under the immediate supervision of a properly trained resident nurse, applications for assistance during pregnancy and labor could be made at certain established hours, and the cases assigned to physicians preferably among the younger men or women practitioners in the community who would agree to attend the woman during her labor for a definitely fixed fee, or, in case the patient is unable to pay, would be reimbursed if possible by the town. If this work is conscientiously carried out by physicians it will soon redound to their individual credit in furnishing them with family practice in other lines and thus aid in their establishment. Assistance during labor when necessary might be secured from the older established physicians in the community, and the district nurse or nurses now so generally found in smaller cities and towns could likewise be called upon to assist at the labor and to make some of the necessary postpartum visits. Help in the household is very essential during the lying-in period and could be supplied by women employed for this purpose by funds furnished from private or municipal sources. Such women should have nothing whatever to do with the obstetrical conduct of the case.

If poor families can by a process of gradual enlightenment be made to understand the value of such services and not be made to feel that they are the subject of charity, the ignorant and otherwise undesirable midwife would soon find herself without an occupation and would gradually disappear from the field. On the other hand, those midwives who are capable and have received a careful training would be compelled to use their best efforts to compete with this movement in order to be retained by families who still insist on their own choice in such matters. In fact the element of competition would be more effective in elevating the status of the midwife than any system of supervision. However, my own impression is that we shall never obtain a sufficient number of such ideal, properly educated midwives in this country or be able to adequately supervise them if we could. After such a class has been developed it will be time enough to consider the altered situation, but in the meanwhile we must deal with actualities and not probabilities. At the present time, for example, there is but one adequate school of instruction for midwives in New York State. During the three years of its existence only a comparatively small number of women have graduated from the same, and a perusal of the necessary qualifications and the course of instruction shows this to be much in advance of the mental qualifications of most women who ordinarily take up this line of activity. I have no desire to decry the very laudable efforts of those who are supporting the Bellevue School of Midwives, but it will take a considerable period of time to test the system. In the meanwhile the situation as it exists to-day must be altered.

In conclusion, there is one factor which I desire to mention that may be of great assistance in the matter—the support of the local press. If a more direct, helpful, and unselfish relation between the press and the work of such agencies could be established a great gain to the community would soon result. Newspaper editors and proprietors are recognizing in daily increasing numbers the value of adequately representing their communities in public health questions and the subservience to patent medicine and similar influences is fortunately lessening. What greater service can they do than by extending their support in such matters in ways to be developed as the occasion may require?

The high ideals referred to in my previous remarks are in reality not as incapable of attainment as would appear from a superficial observation. Education is the key which will open the door to better conditions. We need here, as in other walks, more sensible training in the elementals which go to make

up our life. The problem is largely in the hands of women themselves and in the striving which has now become so widespread toward the newer feminism, attention to the diffusion of knowledge regarding woman and her functions seems to me much more important than the desire for higher political ideals.

23 East Ninety-third Street.

## DEFICIENCY OF CHLORIDE OF SODIUM IN THE ETIOLOGY OF NEURASTHENIA.

By ALEXANDER HAIG, M.A. and D.M. Oxon., F.R.C.P., London, England.

Senior Physician to the Royal Waterloo Hospital for Children and Women; Consulting Physician to the Metropolitan Hospital.

I have long believed that many cases of neurasthenia are due to defective circulation in the brain and great nerve centres, which is caused, amongst other things, by debility of the heart muscle. This I have already pointed out in my book on "Uric Acid in the Clinic," p. 84, *et seq.* It is obvious that chronic underfeeding or starvation is a cause of muscular weakness throughout the body, which eventually affects even the heart muscle. I have elsewhere (Transactions of the Section of Medicine, International Medical Congress at London, 1913) written about underfeeding, but in this paper I wish to point out that deficiency of salt in the body may produce effects more or less identical with those caused by underfeeding, because deficiency of salt leads to ever-increasing failure in the digestion and absorption of food till the nutrition of all the muscles, including that of the heart, suffers.

It seems clear that the cardiac debility, which is the cause of defective cerebral circulation, may be produced by: (1) Chronic underfeeding, which is rather common among many classes in this country at present, and has for years been a failing among vegetarians: (2) non-absorption of food due to (a) improper food; (b) weak heart, which causes imperfect circulation and so imperfect functioning of the digestive organs; (c) deficient chlorine in the body, causing deficiency of hydrochloric acid in gastric digestion.

I will now give notes of the case that drew my attention to the last mentioned cause.

Some eight years ago a patient in the early fifties came to me suffering from what I took to be neurasthenia, his case being like a good many more of this kind recorded in "Uric Acid in the Clinic." He had a very marked and obstinate dyspepsia and was losing weight rapidly; so, as he did not improve on tonics, I advised him to do a rest cure in the country. In two or three months he was able to return to his business. He had been a vegetarian and an abstainer from salt for several years, and had recently been taking some alkali, chiefly sodium bicarbonate, for some rheumatism from which he had often suffered. One symptom noted in this patient, which at the time I by no means understood, was that he used to complain that soon after he had swallowed a meal there came a gurgling which was both felt and heard in the epigastrium and right hypochondrium, and he then suffered from a feeling of emptiness as if his meal had slipped away and been lost. On this he founded the fixed idea that his stomach was contracted and could not contain his food. I now see that this was a sign that gastric acidity was deficient, for it is said (*British Medical Journal*, 1912, Vol. I., p. 1243,) that deficient acidity increases the rapidity with which the stomach passes its contents through the pylorus, and we thus had a sign of a condition which I have little doubt was present in this case—namely, deficient gastric acidity from want of chloride in the body. On several occasions during the worst part of his illness the urine was alkaline and phosphatic, and the same phenomenon was present on one or two occasions in this second illness, so that alkaline and phosphate urine may be an indication of a deficiency of chlorine in the body. When he was being fed up no special point was made of the administration of salt, but he no doubt got some in the cooked foods he was given, which included meat for a time.

Some four or five years later this patient returned saying that he felt as if the same trouble was coming on again. He was losing weight and had some dyspepsia, though this did not apparently cause so much pain and trouble in connection with his gastric digestion as on the previous occasion. There were the ordinary signs of cardiac debility, and I gave, as usual, a heart tonic, but I also had the urine collected for some days and found that urea was falling lower and lower, in spite of a steady supply of easily digestible food, so that at last the ratio of proteid metabolized to proteid taken fell on some occasions nearly 50 per cent.—*i. e.*, out of 1,200 grs. of protein taken only 600, 700, or 800 were converted into urea. I inquired about salt and found that he was still abstaining from it, though it was his habit to take it if he felt a distinct desire for it. When he takes much salt he suffers from nasal catarrh and other signs of chloridism, and had thus concluded that it was not necessary to take it regularly. It then occurred to me that some part of this patient's trouble might be the parallel of that seen in animals when chloride of sodium has been left out of their food, and so I ordered him to take a full supply of salt with his food every day, and to continue it till he got some signs of chloridism. And now we come to a remarkable point, that this patient who was so sensitive to chlorides and had often before got chloridism as soon as he took any salt, on this occasion had no sign of it until he had been on a good daily supply for some five or six weeks. The effect of taking it was a good one in every way, and from the time the salt was put on urea steadily improved till urea obtained was equal to protein swallowed. I now soon left off the heart tonic and trusted entirely to a full allowance of protein and a continuance of salt, and in a month or two recovery was complete—in fact, his nutrition and the condition of his heart became better than they had been for a long time.

Since the above case was under observation I have met a man who was abusing a sect of vegetarians (who, as I know, eat no salt) in no measured terms for having, as he said, nearly killed him. So far as I could gather his symptoms were similar to those in the above case and he had undergone a rest cure for them. He knew nothing about the importance of taking salt, about which I warned him, but no doubt, as in the above case, he got sufficient salt during the cure without its being specially ordered.

I now believe that this has been the cause of not a few breakdowns among vegetarians and others who are ignorant of the facts. In recent years I have kept a watch on salt or its absence as a possible cause of defective nutrition with results resembling those of underfeeding. I have thus seen a considerable number of cases in which an increase of salt has caused a very marked improvement in

nutrition and in the production of urea from the proteins of food. I have also met with some cases of obstinate dyspepsia in which absence or deficiency of salt was the sole cause of trouble.

After these experiences I began to study the literature of salt, and I came upon facts which appeared to suggest that common salt (sodium chloride) is one of the things in the complete absence of which human life does not flourish and will not continue. I say purposely "complete absence" because it is possible to live a considerable time, even a year or two, without swallowing any visible quantity, indeed, it may be quite intentionally left out of all foods, and yet if the body has a small store of this substance in its fluids and tissues sufficient to supply the chlorine required for the hydrochloric acid which is daily excreted into the stomach in gastric digestion, the whole physiology of the body may go on for some time without showing any noticeable departure from the normal.

The quantity of sodium chloride required by a meat eater for the digestion of a day's food is small, and for the purpose of our argument here it may be put down as from 12 to 30 grs., half a teaspoonful at most.

Chlorine is the substance that is wanted; sodium is common enough in all kinds of foods, but chlorine apparently is not so, and amongst vegetable foods almost the only ones which contain it are the nuts, and it is not a little remarkable that it is thus to be found in our natural food. The chlorine which is made use of as hydrochloric acid in the process of digestion is taken up into the blood again along with the products of digestion, and is thus used over and over again. So that as long as the body has 30 to 40 grs. of sodium chloride in its composition available for this purpose all may go well.

But when there is salt in the blood towards the end of the digestive process some part of this will pass out of the body through the kidneys and be lost. We may probably put this minimum daily loss at 8 or 10 grs., so that if 8 or 10 grs. are supplied day by day in the food (and this is a quantity which would quite easily pass unnoticed as regards taste) the body may go on functioning quite well for a considerable time.

Now nuts can supply just such a small daily quantity and a man who eats from 4 to 6 oz. of nuts per diem will thus introduce into his body a small quantity of chloride, enough probably to make up in some cases for the daily loss through the kidneys, so that he may go on well and quite believe that he is living without salt. It seems to me that there is widespread misunderstanding in regard to this matter, and my point in this paper is that apparently there must be some chloride in the human body or life will diminish, flicker, and go out as a lamp does when no more oil is available.

It seems to have been proved that certain alkaline foods tend to sweep chloride out of the body and that animals that live on these foods (herbivora, frugivora) want more sodium chloride than those, like the carnivora, whose food is more acid and does not tend to remove chloride from the body so quickly.

Bunge long ago pointed out that the administration of salts of potassium to man resulted in the removal of considerable quantities of chloride from the body. He also showed that the craving for chloride among all animals is proportional to the potassium in their food. (*Zeitschr. für Biologie*, 1873, Vol. LX, p. 138.) The fact that such a universal crave exists shows that a substance of great importance for the welfare of the body is being removed, and, as I have said, chlorine is the substance which is important and difficult to replace.

Bunge was not able to decide whether all the chlorine could be swept out of the body in this way by potassium salts or vegetable foods containing them, but the facts I now bring forward seem to show that this is possible, and that a fatal result may follow if the chlorine is not replaced within a given time, *i.e.* before nutrition in general, and heart power in particular have diminished to a dangerous extent.

These chemical considerations also explain the well known fact that while a meat eater in this country needs only half a drachm of salt or less, a vegetarian in India may require as much as ½ to 1 oz. per diem.

We learn from this two things: first, that more salt is required in a warm climate than in a cold (a fact also pointed out by Bunge), and second, that more is wanted by a taker of foods rich in potassium (fruit and vegetables) as compared with a taker of foods rich in acids (meat). The native of India, Burmah, etc., thus requires much salt for two reasons, (1) the nature of his food, (2) the heat of his climate, and we know that the same holds as between vegetarians and meat-eaters in this country.

In this also do we find an explanation of the fact that Irish peasants who eat considerable quantities of potato (rich in potassium) are in the habit of taking with them rather large quantities of salt.

On the other hand, various people calling themselves vegetarians, acting on fancy or something they have read, have given up salt, and, so far as they know, have taken none for years. Some of these people do, I believe, now and again get into serious trouble, but many on the other hand, do go on for years without, so far as they know, taking any salt. If nuts form any part of their food this may explain the matter, and many of them do, I believe, get some little salt in their food without knowing it. For instance, I was telling my opinion in regard to this matter to a vegetarian who said that he was quite well and that he had not eaten salt for years, from which he inferred that I must be wrong; but I asked him to tell me his day's food, and when he mentioned 2 or 3 oz. of cheese I asked him how much cheese he could find for me which did not contain salt?

With regard to animals, it is generally stated that they must have chloride or they will die, and, the herbivora, in the Zoological Society's gardens are all provided with salt.

Precisely the same is said of the human animal; he also becomes dyspeptic, failing more and more over the digestion of his food till finally, if he does not get salt, he may die, wasted, invaded by microbes, complaining of gastric pain, gastric neuralgia, even ulceration, with apparently incurable debility, anemia, edema of ankles, and neurasthenia, which may end in heart failure and death. Among minor signs of such alkali dyspepsia is a severe pain limited to the epigastrium and occurring in the morning hours (alkaline tide). Its great characteristic is that it ceases at once on the administration of a little salt or a few drops of a dilute acid, and it soon ceases to recur as salt is given or increased. I do not assert that want of sodium chloride is the cause of all the troubles just mentioned, but I think that further investigation is re-

quired in the light of the facts I am now bringing forward.

In such cases we must estimate both the proteins of the food and the urea produced from them, and, if we find that urea is very deficient, we should not be content to give heart tonics only, but should inquire as to the chlorides and the way in which they have been supplied to or swept out of the body.

To show some of the effects of taking salt I will give the figures from a recent case. The food taken was here equal to about 360 gr. of urea per day. Feb. 1, urea obtained 234 gr. Salt was now increased from ½ dram up to 1½ or 2 drams per day. Feb. 2, urea 281 gr. Feb. 3, 301 gr. Feb. 4, 351 or nearly normal. Salt had here been only slightly deficient and some improvement came quickly. But where the heart has been much debilitated by long-continued neurasthenia or marasmus it is necessary to continue heart tonics for a time and to do all that is possible (by rest after meals or even complete rest in bed) to take work off the heart till it has recovered its nutrition and muscle power and then the fires of life will burn up of themselves, provided that sufficient chlorine is available. So long as salt is deficient attempts to feed up fail and cause only increasing discomfort, flatulent distension, intestinal decomposition with most offensive flatus and other signs of dyspepsia with little or no rise of urea, and all these symptoms gradually subside and disappear as a sufficiency of salt is got into the body. But in cases which are chiefly due to want of chloride if it is given plentifully together with a free supply of protein it may not be necessary to give any heart tonics at all. Thus in the case first mentioned I attribute the good result entirely to the use of increased salt, which improved digestion and the nutrition of the heart and thus removed both factors in the neurasthenia, and not to the heart tonic which was soon left off and had been given apart from salt on a previous occasion without much result. I believe that both attacks in this patient were due to the same cause, and that if he had always eaten some salt or had paid more attention to his salt-crave, when he had it, he would never have suffered from neurasthenia at all. It will, of course, be noted how closely his clinical symptoms paralleled those said to be produced both in animals and man by lack of salt. It is to be noted that this patient had not only been using but little chloride for a considerable time, but he had been taking alkali which would doubtless have the effect of sweeping out the last vestige of this substance from his body.

When he first came to me I believed more or less that it was not possible to live without salt but I had forgotten the fact pointed out by Bunge that the taking of alkaline drugs or foods rich in alkali, such as potato, might precipitate the worst troubles of chloride deficiency by sweeping the body more or less completely clear of it. I believe that the future will demonstrate that my patient, though he sustained much damage from his want of chloride, was comparatively fortunate and that considerable numbers of people lose their lives or their sanity, or first one and then the other, from the cause which produced his severe illnesses.

Of course, if sodium chloride raises the acidity of the urine and of the body fluids, which it probably does to any important extent only when taken in excess of the physiological needs of the body, it will do harm in certain gouty and rheumatic conditions, *e.g.* gouty arthritis, bronchial, nasal, and other forms of catarrh and their sequelæ, and when I see patients who suffer from these troubles I have not hesitated to tell them that they should diminish or leave out salt from their food for a time. The above cases, however, seem to show that it is never wise to tell patients to leave off salt entirely and that they should be told only to reduce it to the physiological minimum, to be at once increased again if any signs of dyspepsia or neurasthenia supervene.

It follows from Bunge's facts that vegetarians, if they do not bear these points in mind, will be more liable to suffer from neurasthenia than meat eaters, for the carnivora will be able to get on with less salt, as owing to their higher acidity they do not pass it out of the body so quickly. It is thus possible that some of the tales current in the profession as to the "inevitable breakdown" which follows perseverance in a non-flesh and uric-acid-free diet for several years have originated in a misunderstanding of cases like the above, for I myself in over thirty years of experience and observation have never met with such cases of breakdown except in those who were deliberately breaking the rule of protein quantity and underfeeding. In the case above-mentioned, however, there was no breaking of the rule of quantity, but failure of nutrition and a breakdown were apparently produced by want of chloride. (See "Health Through Diet" by K. G. Haig, Lippincott, 1914.)

I have been in the habit of considering that the depression and debility produced by alkalies is due to the collemia (excess of uric acid in the blood) and the resultant defective circulation and anemia which they bring about; and it accords with this that these results are very marked when an alkali is administered to a patient who is full of uric acid, but slight if they are given to one who is uric-acid-free. Moreover, if the uric acid in the blood and urine is watched, the effects of an alkali on the circulation and metabolism will be seen to correspond accurately with the quantity of uric acid there present, and when the quantity in these fluids falls to normal the depressing effects of the alkali come to an end, at least for a time. But it now appears that in addition to this effect through collemia, alkali may eventually cause debility in both meat eaters and the uric-acid-free by sweeping chlorine out of the body and thus producing serious, even fatal, digestive failure. Here also may we find the explanation of the very widespread belief that alkalies may induce serious conditions, even ulceration, in the stomach if used too largely or too long continued. The patient mentioned in this paper had marked digestive failure together with some rather severe gastric pain in his first attack which followed a prolonged course of alkali. I am now by no means certain that the diagnosis of "gastric neurasthenia" or melancholia covered the whole of the field and that there was not at one time some organic trouble in his stomach. (See paper on "Gout of the Intestines," MEDICAL RECORD, Oct. 12, 1912.)

On the other hand I believe that some people get a craving for salt which is unnatural and excessive, just as they get a craving for tea, coffee, alcohol, or other drugs which clear the blood of uric acid and thus relieve the depression of mind, body, and metabolism which defective circulation produces. They take it because of its obvious effect, without in the least understanding how this effect is produced. I was once told by a man who had this

crave in a very marked form that it had done him great good and saved him from many diseases, and one can easily understand how this may be the case, at least in comparison with a man who takes food-poisons along with a deficient supply of salt.

But if in a food-poisoned individual salt keeps him free from disease, it does this like many other drugs and some well-known conditions of life, *e.g.* pregnancy, by keeping the blood clear of uric acid so that the capillary circulation is free.

But true freedom from disease is obtained by keeping the body free from uric acid continually, and this is possible only where none is introduced and none retained. Where this is so there is nothing to fear from the future, for the body is free from excess of uric acid through life. On the other hand, where freedom has been attained by means of salt or of other drug or retentive process, a time is sure to come when such retention can no longer be kept up and then there will be collemic troubles to an extent proportional to the quantity retained.

This very marked effect of chlorine on digestion and nutrition has made me wonder how far dilute nitrohydrochloric acid, a trusty remedy for many minor forms of dyspepsia, may have acted merely as an introducer of chlorine into the body? Some forms of the uric-acid-free diet are acid, perhaps as acid as that of the meat-eater, but those whose food contains much alkaline vegetable (*e.g.* potato) may, no doubt, soon require to increase their salt in order to avoid neurasthenia, and still more must those do so who are taking alkali for the treatment of disease.

I believe that those who do not make a habit of eating salt get a crave for it when the body is running short of chloride, and that such crave should on no account be neglected. The same occurs to those who do not take enough salt or who sweep out with alkalies or potatoes more than they put in. People who make a habit of reading or working during meals, thus overlooking the taste of their food, are liable to neglect this crave and then serious results may follow.

Whenever there are signs of a crave salt should be taken and continued till chloridism is produced, and the time taken to do this should be noted.

It follows that not only will vegetables, potatoes, and alkali sweep chloride out of the body, but any condition that increases the alkalinity of the blood will do the same.

Now nearly all wasting diseases such as chronic dyspepsia, vomiting, diarrhea, chronic pulmonary disease, and chronic enteritis of all kinds will do this, hence the marasmus in children, which follows so frequently on diarrhea, vomiting, or any catarrhal trouble of the intestines or bronchi, may be due in part to sweeping of chloride out of the body; and I have found, as a matter of fact, that very many of these cases have weak hearts due to defective muscular nutrition, and this still further interferes with nutrition and hinders recovery, producing in children conditions very closely parallel to neurasthenia in adults.

In my experience such marasmic children do very well and show a most gratifying increase in weight and strength if from 5ss to 5i or more of chloride of sodium is added to their food with a small dose of a heart tonic such as strophanthus. It is now my practice to administer chloride of sodium to all children who are suffering from such troubles, and I use it as a routine treatment in convalescence from summer diarrhea and vomiting.

I have recently also come across a case in which a patient was treated for gout rather energetically, first by alkali and later on by large quantities of potato which he used to eat three times a day. In the course of a few months he began to suffer from well-marked alkali dyspepsia with pain in the epigastrium. (See previous remarks.)

And since I have been using the treatment of the late Dr. Forbes-Ross for cancer,* I have several times met with alkali dyspepsia in patients who had been taking large doses of alkalies, and their pain was generally very promptly relieved by salt or acids. Such alkali dyspepsia is commonly found along with a slightly acid or alkaline urine or with phosphaturia. These patients also may be able to take large quantities of chloride of sodium for weeks together, without getting any signs of chloridism.

The patient who has deficient chloride in the body, will probably also exhibit other well-marked signs, such as debility, subnormal temperature, slow capillary circulation, with more or less dilatation of the heart, and possibly, as a result of this some enlargement of the liver with congestion of the stomach and duodenum, which are also the well-known clinical signs that accompany wasting and marasmus in children. Then the mere administration of salt in sufficient quantity for a few weeks may not only remove the signs of alkali dyspepsia but also the signs of debility and marasmus if the heart is not too weak for its work.

It seems clear that the quantity of salt required in any given case is greatly influenced by such factors as food, climate, and nutrition; by anything, in fact, that affects the alkalinity of the blood and tissue fluids. All factors that increase the alkalinity of the body sweep out increasing quantities of chloride and require an increased dose both to counteract this and to replace the reserve of sodium chloride which has been depleted.

Hence feeble nutrition tends to perpetuate itself if the salt factor is not taken into account, for the more feeble the nutrition the more alkaline the body and the more it will be deprived of its salt reserves.

Patients who suffer from low salt reserves often have a strong crave for sugar, fruit, and acids such as vinegar, and this I think is really a modified salt crave. When the natural salt reserves have been replaced the craves both for salt and acids disappear.

No doubt the sugar or acid does some good by keeping chloride in the body. The great improvement produced in nutrition by sugar may be due in part to its raising the acidity and keeping the salt reserves in the body, as well as to its action in keeping the blood clear of uric acid, *i.e.* improving nutrition at the cost of an increased tendency to gout or rheumatism.

In my opinion salt should be increased in every case of debility, marasmus, wasting disease, rheumatoid arthritis, and chronic catarrh (intestinal and bronchial) and the effects on nutrition and the excretion of urea watched.

It seems to me that the whole subject of malnutrition may require to be reinvestigated in the light of these facts. We have to find out on the one hand how much of our failure to treat chronic wasting disease including tuberculosis† with suc-

*"Cancer, the Problem of Its Genesis and Treatment," by F. W. Forbes Ross. Methuen & Co., London, 1912.

†See also "Metabolism and the Circulation," MEDICAL RECORD, July 12, 1913.

cess is due to the administration of drugs which are often of quite secondary importance, while the salt factor, which is clearly of the utmost importance in nutrition, is either entirely neglected or treated only inadequately with a little hydrochloric or nitrohydrochloric acid. On the other hand we have also to find out how many deaths now attributed to neurasthenia, debility, heart failure, dyspepsia, marasmus, and chronic intestinal catarrh have really been due to want of that important element in food digestion, hydrochloric acid.

## CAN CONSUMPTION BE CURED?*

By HERBERT C. CLAPP, M.D.,

BOSTON.

FORMERLY VISITING PHYSICIAN TO THE MASSACHUSETTS STATE SANATORIUM AT RUTLAND, AND PROFESSOR OF DISEASES OF THE CHEST IN THE BOSTON UNIVERSITY SCHOOL OF MEDICINE.

YES, most decidedly, *yes;* but this answer needs to be explained to prevent misunderstanding. On the one hand, we need to avoid too much pessimism which paralyzes effort, and on the other too much optimism, which leads to carelessness and neglect, which are very often fatal. In looking at the doughnut, we must not forget to see in it the hole. Naturally enough, as a result of the reported successes of recent years, the pendulum has now swung too far the other way, and many people have become too enthusiastic, and now seem to believe that the cure of tuberculosis is as easy as rolling off a log.

On the contrary, it cannot be stated too emphatically that, while in many cases, largely proportionate to the earliness of the stage in which it has been discovered and the proper measures applied, it can be cured; yet to reach this result is not by any means an easy task (with comparatively few exceptions), and generally requires a vigorous fight for many months and often for years, before victory can be won, in which contest certain moral qualities and strength of character play a very important part.

It is extremely desirable, therefore, that the public should entertain a correct view on this subject, in order to encourage sane and rational methods of living and treatment for the benefit of individual cases, as well as to be able to institute proper public measures for the control of the disease, and for the prevention of its spread in the community.

The comparative successes in the treatment of tuberculosis during the last thirty years or more have to such an extent stimulated the enthusiasm and optimism of some members of the medical profession that they have publicly and privately declared their belief in the possibility of the total extermination of the disease in the not-distant future; and some of them have even attempted to set the date approximately, basing their judgment on the progress already made. I confess that I have never been able to sympathize with them in these views, any more than with those who predict that the end of the world is near at hand. Indeed, I doubt if we ever shall rid ourselves entirely of this dread disease, at least as long as human nature remains as it is now, on which subject much might be said. Even smallpox, although wonderfully diminished, has not yet become extinct as predicted as a result of vaccination. Nevertheless, vaccination, if properly performed, and universally adopted, ought to be practically specific against it. But just here comes in the human element, and the mental obliquity which prevents some people from recognizing its efficacy, in spite of demonstrable proof. The difficulties in the way of the complete extermination of tuberculosis for several reasons are ten times as great as those of smallpox. The social evil and its immediate results in disease are apparently no nearer extinction than many years ago, and many moralists confess themselves almost discouraged. The reason is that here the human element and the frailties of human nature play a more prominent part than in the case of tuberculosis, and a thousand times more prominent part than in the case of smallpox.

The estimation of some enthusiasts that tuberculosis would become extinct in twenty or twenty-five years, based on figures already obtained as to its diminution, reminds me of the calculation of the faithful young wife of the impecunious artist, who after many months of fruitless toil had at last sold a picture which took him half a day to paint, for $25. "Splendid," rejoiced the optimistic wife, "$50 a day for 300 working days in the year means $15,000 yearly income. We surely can live on that."

When we consider that among the predisposing causes of consumption are poverty, dissipation, overwork and worry, to say nothing of the rest, is it strange that we should despair of the early and complete eradication of the disease, no matter how enthusiastic we may become as to our wonderful success in treating people who are not too heavily handicapped?

Can consumption be cured? Fifty years ago this question would have been answered in the negative throughout the entire world. People generally considered it a hopeless disease, and the medical profession looked at it with a folding of the hands and a grim contemplation of approaching death, which paralyzed their best efforts. If occasionally a patient got well, it was by the grace of God, and not often as a result of human endeavor. Since then there has been a great change in the outcome of the disease, for the most part owing to modern hygienic, so-called sanatorium methods, which took their real start not far from that time in Goerbersdorf and Falkenstein, in Germany, and which in this country were first heard of to any great extent in the sanatorium in the Adirondacks founded by the illustrious Trudeau thirty years ago. The younger physicians in this country, who have seen many cases get well, cannot possibly have any adequate conception of the comparative feelings of the older ones in this regard, especially of those who have largely treated this disease, how they have risen from the depths of despondency to the joys and enthusiasm of success, even if perfection has not yet been attained.

A large amount of money has been spent in recent years in the antituberculosis campaign, and much time and thought given to it, as well as hard work, and that it has been worth while is attested by the chart published in the recent report (the tenth) of the Boston Association for the Relief and Control of Tuberculosis, which shows that the death rate from the disease *since* the announcement in 1882 of the discovery by Koch of the tubercle bacillus (that is, for the last 32 years), has decreased from 420 to 150 for every 100,000 of Boston's population, while during the 32 years

*Read at the Evans Memorial, Boston, March 24, 1914.

*preceding* this discovery, that is from 1850 to 1882, the decrease was only from 475 to 425.

The great statistician, Frederich L. Hoffman of the Prudential Insurance Co. of Newark, N. J., in an elaborate and lengthy paper read before the National Association for the Study and Prevention of Tuberculosis on May 9, 1913, among other statistics, to illustrate the tendency of the tuberculosis death rate in the United States during a long period of time, brought together the combined mortality of the cities of New York, Philadelphia, and Boston for the 100 years commencing with 1812. From this it appears that there was no decided tendency toward a persistent reduction until 1882. Since that year, however, the tuberculosis death rate has persistently diminished from almost 390 per 100,000 of population in 1881 to 180 in 1912. This shows, he thinks, the most conclusive evidence on record that the deliberate, thoroughly intelligent and nation-wide campaign against tuberculosis on the principle of its being an infectious disease and transmissible from man to man, has been successful beyond expectations. Mr. Hoffman's statistics for a group of 50 large American cities show that there has been in this larger group also a persistent and very considerable decline in the tuberculosis death rate since 1882, that is, from 335 per 100,000 of population in 1881 to 166 in 1911. In England the death rate from tuberculosis has dropped nearly 50 per cent. in 40 years. In London the drop was 33 per cent. between 1901 and 1910. There has likewise been a great drop throughout the civilized world. Much testimony along similar lines could be presented. The greater part of this decline has been owing strictly to antituberculosis work since the modern campaign began. The comparatively small decline in the rate before 1882 was probably mostly due to the general improvement in public sanitation and hygiene. And yet this general improvement goes so much hand in hand with strictly antituberculosis work and is really such an integral part of it, that it is well-nigh impossible to dissociate them. Better construction of houses with reference to light and air, better drainage, better regulation of the hours of labor, better ventilation of factories, better food, less drunkenness and other improvements in the social condition of the people, would naturally tend to lower the tuberculosis death rate, even if this were not the principal object in mind.

One of the best arguments to be brought forward in favor of the curability of consumption, an argument indeed, which is absolutely incontrovertible, is that derived from post-morten examinations of persons who have had the disease and have recovered from it, and have subsequently died of some entirely different disorder, and yet in whose bodies have been found by skillful pathologists unmistakable evidences of healed tuberculous lesions. Such post-mortems are made very frequently abroad, especially on hospital patients, far more frequently indeed than in this country. This evidence has been presented so many, many times, that now it is accepted by all educated physicians, and is a conclusive answer to some scoffers who even at this late day occasionally pretend that a patient, especially in the incipient stage, who claims to have been cured of tuberculosis, never could really have had the disease at all.

Indeed these findings are so common that we are forced to believe that some people have had the disease and have recovered from it spontaneously, perhaps often without knowing that they ever had had it.

Another proof of the curability of consumption, and one which particularly and immediately interests us, comes from the reports of the modern sanatoria for its treatment, which are now so numerous throughout the civilized world, and which all tell essentially the same story, though differing in detail. Many are cured also by the same kind of sanatorium methods either at home or elsewhere outside of a sanatorium; but naturally it is very difficult to get statistics from such. Even from the reports of sanatoria it is not easy to get figures which are comparable with each other and which, therefore, can be conglomerated, for the reason that their bases of comparison are so variant. Some aim to take only incipient cases, some mostly advanced, and some all grades. The classifications of cases and results also differ in various ways, although an attempt at uniformity is being made. For instance, at our Rutland Sanatorium, after some years' trial of its own classification, the adoption of that of the National Association, for the sake of uniformity with other institutions, at once resulted in the dropping of the percentage of "apparently cured" cases discharged, because many of the patients were unwilling to remain during the three months now demanded after the cessation of all their active symptoms. Some of these undoubtedly kept up their good record after they had left, and later reached the desired goal; but of course by the terms of the classification they never became eligible to be recorded in the banner roll of the sanatorium.

The commonest classification of the stages of the disease for the past few years has been *Incipient, Moderately Advanced,* and *Advanced* (or *Far Advanced);* and for results *Apparently Cured, Arrested, Improved,* and *Not Improved.*

In discussing a subject like this a great deal depends on the precise meaning we attach to the word "cured" in this connection. When a person recovers from some diseases, he is in practically just as good condition as before he was sick, and has no further occasion to take anxious thought about the matter in relation to those particular affections. But when he has pulmonary tuberculosis, and it is not immediately fatal, several endings are common, depending largely on the amount of his disease and of his special power of resistance to it, the way it is handled, and on other factors. Some healthy people fortunately have so much lack of susceptibility to tuberculosis or a so-called immunity, either natural or acquired, that they are never touched by it in the slightest degree, in spite of exposure to contagion, and in spite of being surrounded by powerful influences favorable to its production. Half the world in this manner has an immunity against scarlet fever. Others come fairly near this high-water mark with only a *slight* susceptibility to tuberculosis. They are, as it were, struck by bullets which glance off without apparently doing much harm. They often recover spontaneously with a cure which may prove to be permanent, especially if surrounded by favorable influences, whether they are aware of their condition or not. One of the latest theories, which has gained quite a wide acceptance, is that many, if not most, of the common cases of consumption in adult life, really started in early childhood in this way, without attracting much, if any, atten-

tion, and then remained latent for years, finally to be aroused into activity under the fostering influence of overwork, bad air, or any other agency which might reduce the patient's vitality. Cases fired up in this way, including mild infections with slight symptoms, those more severe with well-marked evidences, and even some of the more advanced cases with cavities, may ultimately acquire what is practically a condition of perfect health; or they may reach what is often called an economic cure, where they are able to work to a greater or less extent; or they may drag along for years in a kind of vegetative existence, in various degrees of invalidism, where the question of whether it is worth while often intrudes itself. All of this without dying; but only those who reach perfect health should be called "cured."

The question of individual susceptibility and resistance is a very queer one, but yet it explains many things that are otherwise hard to understand. How one person, for instance, who is infected, seems to be completely overwhelmed, in spite of anything that may be done, perhaps from the very beginning; and how another at the other extreme may go free, scarcely knowing that he has been hit; with all grades between. This difference in susceptibility is seen in animals. Some are very easily infected, like monkeys, rabbits, guinea pigs, swine, and cattle; while others show a great resisting power, like dogs, cats, foxes, lions, and tigers. Some races of men, like the Indians and Negroes, are peculiarly susceptible and fall easy victims to consumption.

All phthisiologists agree that many (perhaps one-quarter or more) of those patients who have been graduated from a sanatorium as "apparently cured," backslide after returning to work, from various causes which will be considered later. This is the reason that they have been called "apparently" cured and not "cured." The adjective added was in the interest of modesty and truth. The backsliding proved either that the cure was apparent and not real, or else that a new and fresh infection had taken place.

It was hoped that this qualifying adjective would so impress the graduates with the precariousness of their condition on leaving, and the danger to them if they neglected to follow out with care the directions for future righteons living, that as little of this backsliding as possible might be expected. But unhappily some probably could not, and some would not, live up to the best light they had. Lately, therefore, many sanatoria have considered it wise to substitute for the phrase "apparently cured" their second-best designation, "arrested." The argument was that if patients on discharge simply considered their disease as arrested, and liable, if they were not careful (especially for two or three years), to flare up again, the importance of hygienic living would be more emphasized.

Whichever way you put it, the practical lesson remains that after discharge from a tuberculosis sanatorium with permission to work, the patient must consider himself constantly on probation, as it were, for at least two or three years, and to a lesser degree for a much longer time. The same principle holds good, of course, if the patient has been "cured" by sanatorium methods outside of a sanatorium. If the word "cure" is used in this disease, it must be restricted to the definition applicable only to tuberculosis. Speaking roughly then, as no absolute accuracy can be attained, statistics from a large number of sanatoria show that of the incipient, the most favorable class of cases, perhaps as an average from one-half to three-quarters on discharge are reported as apparently cured or arrested, and supposedly able to go to work. If then roughly from one-half to three-quarters of *these* stand the strain and remain well without backsliding after a probation of two or three or four years, we have not more than half of these original incipients booked for the ultimate cure, which of course is the only cure to be really considered, as it hardly counts to get folks well if they cannot remain well. If the probationary period were extended, it must be admitted that the percentage of ultimate cures would be somewhat still further reduced.

If we inquire into the results of treatment of the moderately advanced cases, the percentages naturally are a great deal lower, and the advanced or far advanced cases show an exceedingly small proportion of cures, so that if we had only the latter class to deal with, we should feel pretty near being utterly discouraged.

Speaking very roughly then, with not more than one-half of the incipient or best grade of consumption cases ultimately cured; with a very much smaller proportion of the moderately advanced cases ultimately cured, and with very few indeed of the far advanced, the picture is not as bright as it is sometimes painted. Shall we therefore, get discouraged? By no means. For in contrast to the results of fifty years ago, what success we have now is almost phenomenal, and the only way to achieve greater success is to ferret out as patiently as possible present mistakes and to try to eliminate them. We are encouraged in this hope by the fact that in properly selected cases, where there is sufficient intelligence, education, will power, common sense and financial support, our results are already far better than those just given. It behooves us then to inquire into some of the reasons why not more cases are arrested while under Sanatorium treatment, and also why, after they have been arrested, so many of them backslide when they again go out into the big world.

In the *first* place, as has been many times said, too often the diagnosis of the disease before the patient begins treatment has not been made early enough. The old comparison of the difficulty of putting out a large conflagration being so much greater than putting out a small, just-beginning fire, although trite, still holds good. Some improvement in this direction has already been made, but much remains to be done. Physicians are partly at fault, but more blame should be attached to patients, partly on account of ignorance of the first symptoms, which ignorance should be corrected by public education; and partly because, when they do know, they often resolutely refuse to accept the situation or to take the necessary steps. Early cases are arrested very much more quickly and surely. Although our Rutland Sanatorium has generally been specially reserved for Incipient cases, yet such are apt to be in the minority there, simply because they do not go. Often only one-third of the patients there are incipient.

*Secondly*, the stay of patients in the sanatorium is, as a rule, far too short. It now averages about six months. This may be long enough for a few, but not for most. The reason for the short time is at least two-fold; partly because the patient too soon thinks he is all right, and is in a hurry to get

away, and also because the sanatorium is often glad to have him go, because so many outside patients are insistent to have his vacant place as soon as possible. Accommodations even here in Massachusetts are now so few, that it often takes two months or more after acceptance, before a patient can get in, during which time he is apt to get worse.

After a so-called good case has been under treatment for a comparatively short time, he often looks rosy and plump and apparently well. He says he feels well, perhaps as well as he ever did in his life, and yet he is still a sick man, and would almost surely collapse under the strain of competition in the outside world. This we all recognize as the special danger-period for him, whether in the sanatorium or under private treatment outside. It is often very hard to persuade him to keep on with his treatment. If the patient is outside, the conscientious physician has another difficulty to encounter in apparently seeming anxious (for a consideration, of course,) to continue to treat one who looks well and says he feels well, even if he is not well. Another reason for his wanting to leave before he should, and a perfectly natural one, is that stern necessity often seems to compel it. His money is all gone and he needs to go to work, perhaps to support a family. Thus his generous feeling proves his own undoing.

*Thirdly,* before the patient gives up sanatorium treatment the so-called "rest cure" should be followed by a "work cure," to prepare him for the resumption of his work in the outside world. Too much cannot be said in commendation of the wonderful effects of rest in consumption properly applied, and of the judicious regulation and adjustment of rest and exercise. Indeed, those consumptives who egotistically think they "know it all," and who under the mistaken impression that all that is necessary is fresh air and good food, undertake to conduct their own cases, generally with disaster, oftenest fail through lack of knowledge of accurate details about regulating exercise and rest. Healthy people need exercise. Consumptives, especially at first, need rest in generous doses, but the nearer they get to the condition of health, the more exercise they need. Occasionally, to be sure, some become so impressed with the idea of rest as a therapeutic measure, that they want to continue it for the remainder of their lives. They get lazy. These are in the minority, however. But if patients do little or nothing but rest until they leave the Sanatorium, and then try to plunge at once into the competition of life, ill results may follow. The idea is now recognized, therefore, that an additional period of time should be taken, during which the mind and muscles should be so trained, under careful medical supervision as to fit them for life's work, as well as to cultivate a good general resisting power.

Now why does the disease relapse after it has become arrested, and the patient has resumed work of one kind or another? For several reasons, the first of which was given by good old Dr. Isaac Watts in his "Divine and Moral Songs for Children." "Let dogs delight to bark and bite, for God hath made them so"; "Let bears and lions growl and fight, for 'tis their nature to;" and this reason is equally appropriate to the treacherous disease tuberculosis. On this account perhaps a relapse may occasionally be necessary in spite of what anybody can do.

Poverty is another reason. It has been said, "Only the rich can afford to have tuberculosis," and poverty is certainly a great factor in inducing tuberculosis, a hindrance in overcoming it, and especially a big handicap in keeping well after a return to work, although not by any means an insuperable obstacle to permanent recovery. When we think of the homes to which so many have to return, dark, overcrowded, insanitary tenements, with surroundings such as are constantly giving rise to new cases, is it strange that some relapse? Tuberculosis is particularly a house disease and some infected houses, especially in the slums, have claimed victim after victim. Here is an enormous field for private philanthropy, if not for public appropriation, to provide healthy houses, model tenements with roof gardens, and buildings like the Vanderbilt "Home Hospital," 78th St. and John Jay Park, New York. Boards of health should certainly condemn improper buildings, fight the dust and smoke nuisances, supervise lodging houses and compel the sanitation of workshops and factories. Among the poor follow-up work is very important, and the trained visitor to inspect conditions and give advice, and the domestic science caller to teach the proper selection and cooking of food, both systems started by the Boston Association and then turned over to the public authorities, are steps in the right direction.

Improper occupation after discharge is another very effective cause of relapse. And here comes in one rather curious and unexpected fact learned in the school of experience. After an extended trial we find that the majority of patients get along much better if they go back to their former employments, provided they are not distinctly dangerous ones, than if they take up something new, which is theoretically better suited for their condition. From the observation of the remarkable effect of fresh air in the recovery from the disease, the inference was natural that to stay well the same should be continued, and that the work, if formerly sedentary and in-doors, should be changed to out doors. But the practical fact remains that the number of suitable out-door occupations open to graduates is very small, that the extra exposure and unusual strain are apt to be too much for them, that the income for one not especially trained to the new work is also small, and that this smaller income will buy less food and other comforts and necessities of life. These and similar considerations more than overbalance the acknowledged superiority of a longer period in the twenty-four hours in the fresh air. We all find also that the utilization of the worker's off-duty time is more important than that of the on-duty time, and that if the work in a well-ventilated office or shop is suited to his capacity and strength, he will generally get along well, if he has a sufficient number of hours of sleep in the open air, and is not prodigal in the expenditure of vital force in his recreation time. If he is skilled in his former work, he can earn more than in something untried. Formerly the commonest advice was to go out on a farm and work, or drive a livery team, or to deliver groceries and provisions or something of that kind. Generally the giver of this advice knew as little practically about what was involved in this work as the receiver; but on trial, if the job was obtainable, as occasionally happened, the difficulties sometimes loomed up like a great cloud.

Among different occupations recommended, none

has received stronger support than farming, and yet on account of the hard physical work, the long hours of toil and the exposure, few city people could stand the strain as farm hands. The farmer himself needs the work done, has generally too little help, and cannot afford to coddle or favor the worker. If the worker tries to run the farm himself without previous experience, he makes a financial failure of it. Besides, the average city man has no taste for farm work and really dislikes it. Small poultry work is better.

The only real good way to utilize a farm for these people is to have it connected with a sanatorium in the form of a farm colony, and to have graduates or those not far from graduation work on it under medical supervision, each as many hours as is good for him, or not at all some days, if his physical condition demands a rest. This will not be a financial success, but will confer a benefit on the workers, and will test their endurance and prepare them perhaps for other work. For years at Rutland it has been the policy to employ under medical supervision on diminished pay a certain number of graduates, who had not become tough enough to engage in outside competition, to work about the institution, mostly inside with open windows and for them it worked very well. If members of the Legislative Committee were amazed at this large force of workers on the pay roll, the fact was explained as for the benefit and further treatment (work cure) of the patient, which might prevent relapses.

Another very effective influence in favoring relapses is the spirit of *over-confidence* begotten in some of those who have finished the treatment and have gone to work again, apparently believing that they are "cured" so thoroughly, that nothing could ever happen to them again. This spirit tempts them to do all sorts of things antagonistic to their welfare, recklessly to squander their recently repaired physical assets by overwork, too much play and even by dissipation, relaxing also in the principles taught them of the hygienic life. They consider that they are cured in the sense of a cure of measles or of scarlet fever or of typhoid, with no prospect of a return of their disease, and this opinion they hold in spite of proper explanation. If the word "arrested" will make them more careful than the word "apparently cured," by all means let us use it. The great fact for them to remember is that the sanatorium treatment does not "end all," but merely starts them on the road to health, and that they cannot afford to neglect the hygienic life, and should call in extra help if things do not go just right. For this reason we may call attention to the fact that it has not infrequently happened that persons discharged as unarrested have sometimes been more successful in reaching the ultimate cure than the class now under consideration; because they knew they were not cured, and therefore were prepared to continue the fight indefinitely. So some physicians even go so far as to advise all graduates to say, not "I had tuberculosis, and am now cured," but rather, "I have tuberculosis." Human nature is such that it is doubtful if a man's whole conduct could be completely changed by a slight difference in phraseology. What he needs, after proper instruction, is to have his will power, his moral fiber, his whole character strengthened. With these and other important modifications we look to the future for greater successes than in the past.

419 Boylston Street.

## AN ECONOMIC AND SOCIAL STUDY OF FEEBLE-MINDED WOMEN.

By MAX G. SCHLAPP, M.D.,
NEW YORK,
PROFESSOR OF NEUROPATHOLOGY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; DIRECTOR OF THE CLEARING HOUSE FOR MENTAL DEFECTIVES,
AND LETA STETTER HOLLINGWORTH, M.A.,
NEW YORK,
PSYCHOLOGIST TO THE CLEARING HOUSE FOR MENTAL DEFECTIVES.
(From the Clinic of Professor Schlapp.)

THE number of persons recognized as mentally defective is increasing disproportionately in all civilized countries. This increase is due to a complexity of factors, among which, as possible causes, may be mentioned the effects of the modern struggle for existence upon the human organism; the unrestricted and therefore very high birth rate among the feeble minded and mentally inferior at large in the community; improved methods of detecting the feeble minded; and the rising standard of mental efficiency necessary for personal maintenance in the increasingly strenuous and complex competition of modern life.

It is not the immediate purpose of this paper, however, to consider the causes of mental deficiency, but rather to consider its effects. The presence of a large number of feeble minded individuals in the social body constitutes a problem the urgency of which is in inverse ratio to the amount of exact information that is available on the subject. Tredgold* in his work published six years ago points out the need for study of the economic and social aspects of mental deficiency, and notes the paucity of data on the subject. "Until the last few years no reliable, and at the same time extensive, statistics referring to the ament as a citizen have existed. The extremely valuable ones we now possess are due in great measure to the investigations instituted by the Royal Commission of 1904. . . . I know of no similar inquiry or statistics concerning any other country."

Some progress has been made since Tredgold wrote, but as yet there are few accurate statistical accounts, statements being in the majority of cases prefaced with the unsatisfactory phase "it is estimated." This vagueness is undoubtedly due in large measure to the fact that there was formerly very limited opportunity for the collection of exact data. Institutions for the detention of the feeble minded do not include in their histories many facts that are of social and economic interest, these histories being made primarily from the medical point of view. It is also true that great numbers of mentally defective persons never are admitted to institutions because (1) guardians and parents object to their commitment, and there is no law in the majority of states to enforce commitment; (2) the institutions are inadequate for the accommodation of those who do apply; (3) for certain kinds of defectives, notably the moral imbecile, there is at present in most of the states no place of detention unless the individual has already committed a crime and has been through the court. For these various reasons the statistics of institutions of detention are inadequate for the study of the defective in his relation to society, and such studies have not appeared from such institutions.

It is believed by the writers of the present paper that a statistical study of cases which pass through the Clearing House for Mental Defectives in New

*A. Tredgold: "Mental Deficiency," 1908.

York City will be of interest to all who are immediately or remotely concerned with social problems. This Clearing House was established in 1913 as a branch of the Department of Public Charities. It maintains a professional and clerical staff whose work it is to examine mentally, physically, and socially all cases of suspected mental defect that are brought to its clinic, and to record and file the histories thus obtained, together with all available information concerning the individuals examined. Commitments to state and municipal institutions of detention are made through this Clearing House, professional advice is rendered to parents, guardians, probation officers, courts, etc., on all cases, whether commitment is desired or not, and treatment is given in those cases where therapy is indicated. The files of the institution thus become a valuable source of available data for the study of mental deficiency in all its phases. The present paper is limited to the consideration of a single group of the mentally defective, *i.e.* feeble-minded women sixteen years of age and over.

During the year 1913, and through February of 1914, 3,300 cases of suspected mental defect were examined at the Clearing House for Mental Defectives. Among these 3,300 patients, 474 women of child-bearing age (16 years of age and over) were included. One hundred and forty-seven of these women were found to be suffering from some disorder not involving amentia, and there were 46 who failed to return to the clinic for exact diagnosis, or in whose cases for one reason or another no definite diagnosis could be made. This leaves 281 who were definitely diagnosed as feeble-minded, including 113 morons, 105 imbeciles, 26 epileptics (diagnosed primarily as epileptic, but considerably below the limits of the Binet measuring scale), 22 moral imbeciles, and 15 idiots.

The figures show that by far the greatest number of those female aments who survive in the social milieu till womanhood belong among the morons and the imbeciles. These high-grade defectives are much more important from the social point of view than are the low-grade defectives. The latter either die before they reach maturity, or are placed in institutions at an earlier age because they are easily recognized as unmistakably defective, and because they constitute an intolerable burden to their families. The moron and the high-grade imbecile on the other hand are often not recognized by the layman as mentally defective. They do not constitute an intolerable burden to their families because they are able to care for their own physical needs, and because they are able to perform simple menial and manual tasks necessary in the household. Thus they grow to maturity in the family instead of in institutions.

*Nationality.*—The 281 women were first distributed as to their nationality. As would be expected, they are in this respect a very heterogeneous group, coming as they did in the majority of cases from the lower East Side of New York City. In some cases it was impossible to determine definitely the nationality of the patient. Some of them were waifs, picked up by social workers from the streets, and unable to give any intelligent information as to their origin. Others had been "rescued" when infants, and their parentage and birth were completely obscured. There are nineteen nationalities represented. (The Semitics are presented separately.) Eighty of the women had been born in Europe, and had entered this country as immigrants. The following table gives the distribution by nationality.

| *Nationality.* | |

*Sources from Which Cases were Referred.*—The records show that about half of the whole number of cases were referred from hospitals and charitable organizations of various kinds, both public and private. The majority of cases that came from hospitals were referred from the maternity and venereal wards. There can be no doubt that the expense of caring for feeble-minded girls and women in hospitals constitutes a very considerable financial burden. At present there are no exact and extensive statistics available as to the proportion of feeble-minded women among the patients in the venereal and maternity wards.

Next to the hospitals and charitable organizations, the family and houses of refuge furnished the largest numbers. Then follow in order the New York Probation Association; social workers; settlements; courts; private physicians; asylums; the Society for the Prevention of Cruelty to Children; the Joint Application Bureau; churches; nurseries; the Council of Jewish Women; the Salvation Army; the Traveler's Aid Society.

It is seen from these records how this problem of the feeble minded touches and concerns nearly all the institutions of organized society. Particularly the charities, both public and private, are immediately concerned, for upon them falls a heavy share of the burden of these incompetents. Courts, settlements, churches, nurseries, are all involved, both socially and economically, in the problem, since upon each of these institutions rests some share of the burden. The sums of money expended in attempts to aid, to discipline, and to rehabilitate the mentally defective individuals in a community represent a truly enormous economic waste.

*Economic Status.*—An interesting question that always rises when considering this class of defectives is, How had they "floated" in the social milieu for so long? On what economic basis had they maintained themselves or been maintained? Had they been actually maintained by charity for from sixteen to fifty-four years? Or had they found some more or less secure economic basis for survival on their own account? Does our society afford a means of subsistence for the feeble-minded woman? The records reveal the following facts with respect to the economic status of the 281 feeble-minded women here considered.

| | |
|---|---|
| Living at home (usually assisting with simple tasks) | 94 |
| In domestic service (including private families, hotels, and boarding houses) | 67 |
| Engaged in simple factory operations | 21 |
| Living in institutions (orphan asylums, refuges, reformatories, etc.) | 20 |
| Prostitutes | 17 |
| Housework (living with relatives) | 13 |
| Married (supported by husband) | 11 |
| Nursemaids | 8 |
| Living with men, and doing housework (unmarried) | 7 |
| "White Slaves" (working for cadets) | 6 |
| Laundresses | 5 |
| Doing "odd jobs" | 5 |
| Working in stores | 4 |
| Errand girl | 1 |
| Wet nurse | 1 |
| Manicuring | 1 |

It is thus seen that the greatest number surviving on any one economic basis was that surviving in the medium of the family. As has already been noted, the high-grade defective, who is able to care for her own immediate personal needs, and who reaches a mental age of from eight to eleven years, is frequently not recognized as definitely defective. She is able to perform simple household tasks, such as peeling vegetables, washing dishes, sweeping floors, "taking care" of small children, etc., and thus she is of some economic value to her family, and survives in its midst so long as no situations calling for the exercise of judgment, will power, reasoning, or ingenuity arise.

The greatest number employed in wage-yielding pursuits was in domestic service. The average wage of these domestics, where any wage at all was mentioned, was $10 per month (about 30 cents per day). The highest wage received by any one of them at any time was $16 per month; the lowest was $4 per month. Most often they worked "for their board." They were employed in private families, in cheap boarding houses, in hotels, in institutions, and in brothels. Their average mental age was not quite nine years.

Next to domestic service, prostitution offered to this group of women the most frequent means of economic maintenance. This includes those who were on the streets soliciting for themselves, those who were working for cadets, and those who were living with men to whom they were not married and "keeping house." The average mental age of these wage earners was also about nine years. In some instances those working as domestics, factory girls, or nurse maids also earned casual sums by prostitution. Thus for example, one girl earning $15 per month at housework earned also $2 a week by prostitution. (Case 1,970 in the files.) Her actual age was 18 years; her mental age was 9.6 years; she was diagnosed as an imbecile.

A unique case is that of the woman who maintained herself by going out as a wet-nurse. This woman was an immigrant from Ireland. At the time of her appearance at the clearing house she was 36 years old, and had already borne five illegitimate children. This numerous offspring had been placed in foundling asylums, each infant being taken by charity at birth, and the woman being thus left free went out as a wet-nurse. Having had five children in ten years, she was able to employ herself as wet nurse much of the time. She was nevertheless chronically in trouble, and finally reached the Clearing House under the auspices of The State Charities Aid, as destitute and homeless. Her mental age (Binet) was found to be 8.6 years. She was diagnosed as an imbecile, and was recommended for institutional care.

It should be understood that these women practically never *wholly* maintained themselves in the pursuits mentioned. Nearly all of them were intermittently or chronically objects of charity also. Those not working in their own homes were in most cases really wanderers, being unable to keep any "job" for more than a few months or weeks at a time. Thus one woman employed at menial domestic tasks had had sixteen positions in less than four years, spending intervals between "jobs" in a rescue home, where much time and effort had been wasted in trying to rehabilitate her.

*Immediate Cause of Appearance at the Clearing House.*—Another question of interest that presents itself is this: Having survived until maturity, and often until middle age, in the social milieu, what were the accidents and circumstances that finally brought them to the Clearing House? Our study reveals the following immediate causes and combinations of causes that precipitated them:

| | |
|---|---|
| Ill or confined in hospitals | 38 |
| Destitute and unemployed ("lost job again") | 35 |
| Interest of some social worker | 26 |
| Sudden change in home conditions | 23 |
| Parents on own initiative at last decided to bring child | 20 |
| Sexual crimes (soliciting, incest, rape, victimization) | 20 |
| General incorrigibility | 18 |
| Arraigned in court (various misdemeanors) | 11 |
| Pregnancy (illegitimate) | 10 |
| Husband died, deserted, was imprisoned, or fell ill | 10 |
| Complaint of outsiders (neighbors, ministers, etc.) | 6 |
| Fight between mother and daughter | 5 |
| Relatives feared seduction | 5 |
| Reached age limit in children's asylums | 3 |
| Stealing | 3 |
| Grossly abused or neglected their children | 2 |
| Relatives saw the Clearing House Exhibit | 2 |
| Set fire to a mattress | 1 |
| Forged a check | 1 |
| Arrested for carrying concealed weapons | 1 |
| Lost on railroad station | 1 |
| Attacked sister with a knife | 1 |
| Fell on a stove | 1 |
| Accompanied her feeble-minded children to the Clearing House and was noted by the physicians | 1 |
| Drunkenness | 1 |
| Ran away | 1 |
| Kidnapped a child | 1 |
| Went to take an insurance examination | 1 |
| Deserted by men with whom they had been living | 2 |
| Married a man she had never seen before | 1 |
| Married a man who was already married | 1 |

It is seen from these data how accidental are the causes that bring these defectives to the Clearing House. Many of them had survived in society for more than thirty years, and might have survived for many more years had not some crucial situation arisen. Had not a particular minister assumed charge of the parish, had a relative not died, had illness not befallen, these women would still be at large in the community. No one can doubt that there are scores of women as defective as these at large in society to whom such accidents have not happened.

The immediate causes of their appearance, furthermore, constitute a long list of crimes and misdemeanors. The expense to the public, the burden upon charity, the anxiety and suffering of relatives in their attempts to reclaim these incorrigible defectives, the contamination of the normal and the healthy, the sufferings of the incompetents themselves, are all revealed in this list of "causes."

*Immoral Relations.*—This is a matter upon which reliable, complete and definite information is exceedingly difficult to obtain. We may be certain that immoral relations had been sustained in many cases where this was denied by the individuals themselves. Thus the figures given are too small, since immorality is recorded in these statistics only where it has been definitely acknowledged or proved. One hundred and thirty-two of the 281 women were definitely known to have had immoral relations. In 50 more cases immoral relations were strongly suspected, but had not been absolutely proved. Thirty-seven of the women were unmistakably afflicted with venereal disease.

*Offspring.*—Of immediate importance to the

community from both the economic and social points of view is the number of children borne by the feeble-minded. It has been indicated by various writers, especially by Dr. Hastings Hart, that the rate of procreation among defective women is very high, and that for this reason they constitute a peculiarly great social menace. Tredgold gives some statistics from the report of the Royal Commission on the subject of propagation by female aments.

In Manchester Dr. Mellard found that out of 94 women in the maternity wards, 19 were feeble-minded, all the children of these, except 2, being illegitimate. Dr. Potts found at Stoke-on-Trent that of the 17 women giving birth to children during the period of inquiry, 7 were feeble-minded, all the children being illegitimate. In Carnarvon Dr. Parry found that half the inmates of the maternity wards were mentally defective, nearly all their children being illegitimate. "It is clear," says Tredgold, "that the number of children produced every year throughout England and Wales by feeble-minded women must be very great."

The defective women here studied had borne 89 illegitimate children, which were acknowledged and could be somewhat definitely located (so we may say that they had borne *at least* 89 children), and 16 women were illegitimately pregnant at the time of their examination at the Clearing House. Twenty-four of the 281 were married, and these had borne 46 legitimate children. (Some of the illegitimate children had also been borne by those who were married.) Thus 281 feeble-minded women, most of them still under 25 years of age, had already produced at least 135 children, two-thirds of which were illegitimate, and were on the point of adding to this number at least 16 more.

The average mental age (Binet) of these illegitimate mothers was 9 years, the lowest in mentality being an imbecile 26 years old, who was 3.2 years old mentally, and who at this age had already borne 2 illegitimate children. As a matter of fact, 22 of the women had had 2 or more illegitimate children, the highest number borne by one mother being 6. This woman was a native American, who had "floated" in the community until the age of 32 years, maintaining herself by a combination of housework, scrubbing by the day, prostitution, and charitable aid. She finally reached the Clearing House under the auspices of the New York Probation Association, having been turned over by her relatives after the birth of her last child, on the grounds that "six was too many." She was 7.2 years old mentally, according to test, was diagnosed as a moron, and was recommended for institutional care.

It is the plan of the Clearing House to take up as soon as is financially possible the matter of keeping in touch with all this numerous offspring of the child-bearing women who are brought to its clinic, and in this way to trace heredity. At present it cannot be stated what percentage of the 135 children are or will be found to be mentally or morally defective. Nearly all of them are placed while infants in foundling asylums. Not infrequently they are left to charity when the mother goes out from the hospital after confinement. In one way or another they almost invariably become public charges. Many of them are placed by charitable institutions in "free homes," a procedure much to be deplored from the social viewpoint, especially in those cases where full information as to the origin and heredity of the child is withheld from those who take it.

*Summary.*—This concrete statistical study of 281 actual cases yields results that are of interest to all who are immediately or remotely concerned with social and economic matters. Nothing is estimated; nothing is guessed. Every fact recorded here is gleaned from the actual life of individuals. It would be fruitless to go into minute detail regarding each individual case, or to attempt to indicate item by item what these defective women have cost the community in hospital expenses, in court expenses, in funds for foundling asylums, in actual destruction of the life, health, and property of normal citizens; what they have cost relatives in anxiety, suffering, and pain; what they have cost charities, both public and private, in attempts to aid and rehabilitate them. But the most pathetic aspect of the problem is, perhaps, the suffering of the incompetents themselves. They are at the mercy of the vilest and most unscrupulous elements in society, helpless before suggestion, easily coerced into anything. Our data on the matter of economic status reveal that society finds a use for mentally defective females; they are to be found in the kitchens of cheap hotels, as chambermaids in boarding houses, as prostitutes on the streets, as the support of the cadet, as underpaid or unpaid nursegirls, as scrub women in hospitals, office buildings, or institutions. Thus unsegregated and at liberty they are exposed to all those dangers and undesirable contingencies which bring them finally into grave conflict with society and at last to the Clearing House. Crime and misery of all kinds arise as the direct logical consequence of their irresponsible and unprotected condition.

Our data here reveal that illegitimacy, attempted murder, theft, forgery, arson, prostitution, drunkenness, destitution, and disease are salient features of the social careers of these incompetents. It is by no means to be supposed that they reach the Clearing House at the "first offence." Practically without exception, there is in every case a "history" of incorrigibility, misery and waywardness, extending sometimes over ten or fifteen years. It is impossible to estimate just what would have been the economic and social saving to the community had all of these women been apprehended when they were children, and detained in segregation.

Since the investigation of the Royal Commission of Great Britain, appointed in 1904, and since the enactment of the Mental Deficiency Law in England, public interest in the problem of the feeble-minded has been greatly stimulated, and the recent legislation in New York and other States bears witness to the fact that there is a growing realization of the urgency of the matter. It is becoming plainer year by year that the solution of the problems of crime and destitution is inextricably bound up with the solution of the problem of the feeble-minded. To the end that society may apply itself to this problem, it is desirable that exact data should be collected, published, and made available for study by all who are immediately or remotely concerned with social welfare and social economy.

# ANGIONEUROTIC EDEMA.*

By CARL E. MUNGER, M.D., F.A.C.S.,

NEW YORK.

ASSISTANT SURGEON, MANHATTAN EYE, EAR AND THROAT HOSPITAL, NEW YORK; LARYNGOLOGIST AND AURAL SURGEON, WATERBURY HOSPITAL, WATERBURY, CONN.

THAT the condition angioneurotic edema is characterized by a marked inexactitude of knowledge as to its etiology and pathology, is apparent from the numerous names that have been employed in its nomenclature. Angioneurotic edema (the favorite name) edema angionerotica, giant urticaria, blue edema of Charcot, hysterical edema with vasomotor phenomena, Quincke's disease, the hysterical paroxysmal edema of Edgeworth, urticaria edematoma of Hardy, acute circumscribed edema, acute essential edema (Étienne and Gallaird), acute idiopathic edema, acute toxic neuropathic edema (de Calvi), wandering edema, hereditary edema (Fairbanks), etc. Before taking up the consideration of this disease in detail, I desire to relate the history of a case, interesting in its course, startling during its paroxyms and lamentable in its termination.

CASE I.—May 12, 1913, I was called in consultation by Dr. Graves to see a girl six years and ten months old who was suffering from an intense dyspnea which had come on in an apparently healthy child in two hours. There were the usual signs of suffocation and impending dissolution. The outside of the neck was swollen and there was a marked edema of the left side of the throat extending to all tissues inside, the soft palate, uvula and epiglottis. The edema was of enormous proportions, the epiglottis filling up the whole oropharynx. There was no time for discussion of the case, as the demand for relief was instant. An intubation tube with great difficulty was forced past the enormously swollen epiglottis and then into the larynx, where it remained indeed but a short time, but long enough to allow of a very vigorous and thorough scarification of the soft palate and epiglottis. The dyspnea gradually disappeared and the child to all appearances was well in about twenty-four hours. Albumin was found in the urine and persisted for three days only. At the time of the edema of the throat the right arm was swollen from the fingers to the shoulder. This swelling also subsided in a few hours. Here was a child apparently well. She went to school the afternoon of the attack and was at the point of suffocation before six o'clock. Naturally such an attack calls for a history and I am indebted to Dr. F. G. Graves for the following notes and history of the case previous to and following the attack just described.

D. M., girl, age six years ten months, healthy at birth, became marasmatic. At two years shoulder and arm, one side, became suddenly edematous; no pain; lasted one or two days. Had repeated attacks of similar edema twice a year. In July, 1912, she had a more serious spell, when the face was edematous, also the throat. Albumin in urine in July, 1912. Two months later no albumin found. March, 1913, had attacks of edema of face only, lasting two days. No urine examination at that time. May 12: Acute edema on left side of throat, extending to all tissues inside palate, larynx, etc., coming on inside of two hours. Albumin in urine next day; disappeared in three days. Has been fairly well since. June 16: Swelling of right leg. Thirteen ounces of urine in twenty-four hours, with albumin. June 27: Thirty-four ounces urine in twenty-four hours, no albumin; specific gravity, 1006. July 1: Large amount albumin in urine; lasted about three days; no swellings. July 28: Another attack of edema of neck, involving submaxillary glands. Following Saturday both feet and one hand swollen. No albumin showed until Sunday night. August 24: Both hands much swollen. August 25: Albumin found. August 29: Both feet swollen. August 30: Back of neck between shoulders swollen. Examination of urine showed no albumin; specific gravity, 1010. September 5: Had a swollen palate which lasted from 12 until nightfall. September 11, 1913: The patient came to my office, and examination was entirely negative, the child presenting the appearance of absolute health. November 18, 1913: Patient had an attack of swelling of the soft palate, which was apparently mild. Dr. Graves, who saw the case at this time, left. In a few minutes the girl choked up and died before the doctor could get back to the house.

Such in brief is the history of this case. I will also present the history of a fatal case of angioneurotic edema reported by F. Hablitz.

CASE II.—A sailor, twenty years of age, was found dead in his bunk. The head and neck were extremely swollen, lips and tongue edematous, mouth full of frothy fluid. Soft palate so edematous that entrance to pharynx was closed. Patient had had several attacks of swelling of neck and head, attended with difficulty in swallowing. At one time he had a swelling of the right wrist, but at the time of death there was no swelling of the extremities. The last attack began with a swelling about the left eye. A few minutes before death he sat up looking at his face in a mirror. He fell backwards, called for help in a hoarse voice, threw his arms about, frothed at the mouth and died. Post mortem showed the mucous membrane of larynx and trachea edematous and pale. There was no exudate, ulceration or hemorrhage anywhere. The mucous membrane of pharynx was also edematous. Other organs were normal. The family history of this case is interesting. A brother twenty-seven years old had attacks commencing with edema of the face or extremities followed by pain in stomach and vomiting. His first attack was at the age of seven or eight years. For a time he had two or three attacks a year, later more frequently, especially in Autumn and Winter. Aside from these attacks he was healthy. His father had similar attacks and died suddenly. A paternal grandfather and two sisters were also affected.

Etiology.[1] Of the predisposing cause of this condition heredity seems to play an all important rôle. Fritz[2] tells of a family in which eight were affected in three generations. Five died suddenly from suffocation due to edema. In reviewing the hereditary type of this disease Bullock[3] tabulates 170 cases with 36 deaths from edema of the larynx. In speaking of the hereditary factor in this disease Olsen[4] in 1888 described a family in which the disease appeared in five generations and of the 39 members of this family 19 had angioneurotic edema, 2 dying from edema of the glottis. The order of transmission from generation to generation is through affected individuals and not through healthy members of the family or as it has been stated.[5] "This is a disorder of heredity and has been traced sometimes through many generations but so far as can be judged from the recorded families it seems only to pass through individuals who themselves exhibit the liability to attack, so that normal members are not likely to transmit the tendency. When we come to investigate the exciting causes of an attack we are very much at sea. This seems to be a disease or more properly a condition in which the ingested food seems to have but little causative effect. Among the most important exciting causes[6] cold and emotional disturbances, seem to be potent and the cases occur most frequently in early adult male life." Loder states that his study leads him to believe in the presence in the blood of a lymphogogue in pathological quantities and the rapid rise of lymph pressure produces in areas of lessened resistance a sudden and rapid vasomotor paralysis.[7] "Unlike the closely allied condition, urticaria, particular articles of diet do not seem to have any influence in causing the development of angioneurotic edema."[8] Quincke regards the condition as a vasomotor neurosis under the influence of which the permeability of the vessels is suddenly increased. Anxiety, fright and worry may any of them prove

*Read before the Waterbury Medical Association March 12, 1914.

exciting causes, and Birkett reports one case of edema of the uvula and soft palate following an immunizing dose of antitoxin and further quoting this author says: "Angioneurotic edema depends upon an increased irritability of the vasodilator nerves, due either to direct or reflex central or peripheral disturbance, and in the series of cases reported by Osler in 1888 he states that the peculiarity transmitted must be either a morbid susceptibility of tissue or an inherited peculiarity of metabolism or both." In Anders "Practice of Medicine," published in 1913, we find this statement: "The pathology is obscure, the edema is supposed to be due, either to venous stasis or to some nervous influence upon the lymph channels causing them to exude liquids."

In Pembrey and Ritchies' "General Pathology" we find this: "There are certain phenomena which suggest that the endolithia either of the blood or lymph capillaries or of both are under a nervous control which can modify the amount of liquid passing through them, and the morbid condition known as angioneurotic edema, where the edema is of an intense and fleeting character involving a part of the body seems to support this theory though whether the whole nervous system is exerted on the capillary walls to the exclusion of the extravascular tissues has not been ascertained." It seems to be a mooted question whether the edema is due to excess of tissue fluid or deficient removal. When the skin is the seat of the affection the[9] "Edema is most often in the connective tissue of the derma,[10] beneath the papillæ and in the subdermoid tissue." Crocker states that everything points to the disease being primarily a vasomotor disturbance direct or reflex, central or peripheral: that a spasmodic contraction of the vessels is followed by a paralytic dilatation and stasis or retardation of the circulation in the papillary layer of the skin. Serous exudation then ensues producing acute edema. The same thing occurs in the mucous membrane and readily explains the sudden edema and enormous swelling that comes on in a few seconds or minutes. This may occur in the brain, kidney, and probably any organ or tissue in the body. Stellwagon[11] in his last edition of the "Diseases of the Skin" sums up the history of angioneurotic edema as follows: The swelling may present itself without constitutional or other symptoms, though there may be some degree of preliminary malaise, gastrointestinal disturbance, and a feeling of being generally out of sorts, which may usher in and persist through the attack. These gastrointestinal disturbances may be found due to edematous swellings in the gastric walls, or in other cases to toxins which provoke the malady. The swelling itself is acute reaching enormous development in a few seconds or minutes although sometimes one or two hours elapse before the acme is attained. The swelling itself is hard and does not pit like ordinary edema. The duration of the swelling varies, and it may disappear as rapidly as it came on, but more commonly lasts a few hours, in some instances a few days, then rapidly or gradually melts away. There is sometimes itching or burning, but almost always *tension* and *a feeling of stiffness*, and in some instances partial anesthesia has been noted for a short time after the disappearance of the swelling. Jamieson has recorded a case where the lungs were involved, as follows: "A young female was attacked without any preliminary symptoms with great dyspnea which became aggravated to a frightful degree, the extremities were cold, there was a cessation of perspiration, incessant cough, quantities of frothy sputum, pale pink in color. Physical examination showed no dullness, but there were fine crepitations audible without bringing the ear in direct contact with the chest; in a few hours the patient was perfectly well.

Prognosis: Unless the disease attacks mucous membrane it is ordinarily simply a nuisance, although there are cases in which intussusception or appendicitis have been thought present and a laparotomy has been performed, but when the throat is attacked the patient is in imminent danger of suffocation, and as the attack is likely to come on at any time without warning, it behooves us to be prompt in giving attention to the immediate needs of the sufferer. The treatment of angioneurotic edema is unsatisfactory in the extreme and seems to be highly empirical, many drugs have been used, nitroglycerine and the nitrites (Osler claims to have warded off the attacks for months with these), calcium lactate, saline laxatives, antacids, sodium salicylate, sodium benzoate, magnesia salol, arsenic, quinine, Pilocarpine hyperdermatically administered, atropine, ergot, etc. In a case of angioneurotic edema occuring in a syphilitic, Burr used salvarsan with apparently good effect. Of all the drugs that have been used with good result in angioneurotic edema of the throat, injections of adrenalin chloride seem to give the best and quickest relief, and should always be used if possible in a case of suffocative edema. This followed by active catharsis and a general alkaline course of medication seems to be the course from which we may hope the most. One must always be prepared for immediate intubation or tracheotomy in desperate cases. In general it might be said that the treatment of angioneurotic edema is that of urticaria, although the two diseases are not identical, as the following definitions given by Stellwagon will sufficiently show. "Urticaria is an inflammatory affection characterized by evanescent whiteish, pinkish or reddish elevations or wheals, somewhat variable as to size and shape, and attended by itching, stinging and pricking sensations. Angioneurotic edema is an affection characterized by one, several, or more acute circumscribed edematous swellings usually in regions where the tissues are readily distensible as eyelid, ear lobe, lips, tongue, genitals, soft palate, etc."

One is impressed with the decided indefiniteness as to the cause of this condition. Indeed everything is indefinite except the clinical aspect, which is so startlingly apparent; but if one will recall cases of anaphylaxis which are sometimes fatal, after the use of immunizing or secondary injections of antitoxin, in which the edema of the larynx may be extreme, and which come on suddenly after the use of serum, one must be struck with the similarity between the clinical picture of anaphylaxis and that of angioneurotic edema. One may with much reason state the belief that in angioneurotic edema there is inherited passive anaphylaxis, a hereditary anaphylaxis which is the underlying cause of this condition. As we learn more of induced anaphylaxis, we will gain exact knowledge of the condition which we have had under consideration. Weil[12] has stated that "All certainty in the solution of this problem must wait on some exact means of approaching the subject clinically or experimentally, and it may be that by working along the lines of anaphylaxis we may approach something definite."

## TWO NEUROLOGICAL CASES IN PEDIATRIC PRACTISE.*

By MEYER A. RABINOWITZ, M.D.,

BROOKLYN, N. Y.

ATTENDING NEUROLOGIST TO THE JEWISH HOSPITAL DISPENSARY; ASSISTANT NEUROLOGIST TO THE JEWISH HOSPITAL.

### I. SYPHILITIC PSEUDOPARALYSIS OF THE NEWBORN.

Case I.—H. W., male, age seven weeks, was referred to me for diagnosis by Dr. Rivkin on October 6, 1913. Family history: Father alive and well; no personal examination obtained. Mother well except for true epileptic convulsions occurring once every two to four months and dating from the seventh month of her first pregnancy, six years ago; no stillbirths or miscarriages. She has three other children, aged six, five, and three and a half years, respectively. All the children are normal and well developed, though the five-year-old child has markedly decayed teeth, a chronic running ear, and chronic conjunctivitis. Personal history: This child was delivered after a very easy labor of several hours' duration. The child was well developed and to all appearances normal, and took the breast readily. When four weeks old it was noticed that the child did not move his right hand and cried constantly, especially when handled. There was no fever. Within a few weeks, the child did not move any of its limbs, and the restlessness, crying, and sleeplessness continued till brought to the clinic.

Examination: The child was fairly well nourished and lay quietly on table, all four extremities limp and motionless. The skin showed a diffuse, coppery, maculopapular eruption of moist character about the mouth, genitals, and anus. There was a marked scaly eruption of palms and soles; snuffles. Both wrists and both knees showed moderate swellings, which were very tender, corresponding to the ends of the shafts of the lower radii and upper tibiæ at their junction with the epiphyses. There were no atrophy of the muscles, no abnormal reflexes, no active or passive motion of the limbs, and the muscles reacted normally to the galvanic and faradic currents; temperature normal. Diagnosis: On the basis of the early onset, negative obstetrical history, multiple symmetrical swellings at the diaphysoepiphyseal junctions, snuffles, eruptions, absence of atrophy, normal reflexes, and normal electrical reaction a diagnosis was made of syphilitic pseudoparalysis. This was later confirmed by a positive Wassermann reaction with the mother's blood, and the prompt clearing up of the paralysis under treatment by inunctions of dilute mercury ointment once daily of a portion the size of a lima bean. November 26, 1913: The child is well nourished and sleeps well; the skin is absolutely clean all over; there is no scaling of palms or soles; there are no snuffles, and all extremities are moving actively. There is nothing now present to show the original condition except nontender swellings about both wrists and knees.

*Reported to the Brooklyn Pediatric Society Nov. 26, 1913, and the Williamsburg Medical Society, Jan., 1914.

This disease is variously termed: Parrot's disease, syphilitic epiphysitis, syphilitic perichondritis, syphilitic epiphyseal osteochondritis. The pathology present is an osteochondritis of the junction of the shaft with the epiphysis. It usually attacks long bones, is unilateral or bilateral and attacks the upper limbs first. It is usually multiple and symmetrical earlier in life. The bones are involved in the following decreasing order of frequency humerus, radius, ulna, femur both ends, tibia, and fibula lower ends. Symptoms: The child is fretful, cries when handled, a limb is tender and is held as if paralyzed. There is a swelling about the joints due to (1) insertion of muscles dragging on the perichondrium, and (2) moderate thickening of the shaft at the junction with the epiphysis. This swelling is globular, cylindrical. The epiphyseodiaphyseal junction is tender. The soft tissues are not involved. There is rarely suppuration.

Differential Diagnosis: (1) Traumatic separation of epiphysis is single, history of a fall and being picked up, bruises and possibly fracture present. (2) Scurvy occurs after six months, gives a history of improper feeding, and the lower extremities are chiefly involved; gum signs and subcutaneous hemorrhages. (3) Acute articular rheumatism is rare under two years; fever, pain shifts from joint to joints; joints themselves swollen. (4) Rickets is always general and symmetrical; other evidences; more common between sixth month and second year. (5) Birth palsy gives a history of difficult labor; very early onset, no swelling, no pain, no tenderness. (6) Tuberculosis of the bones is rare in infancy; attacks epiphysis and overlying soft parts and ends in suppuration. (7) Acute osteomylitis; the location of the swelling is on the shaft, and the temperature curve is characteristic of sepsis.

### II. RECURRENT MULTIPLE NEURITIS IN A CHILD.

Case II.—J. B., aged 12, female. Family history: Father and mother living and well. She is the oldest of six children; no similar disease in family or grandparents. Past history: Measles at 4; pertussis at 5; no diphtheria, croup, scarlet, or sore throats; no malaria. Previous attack: At age of 9, *i.e.* in spring of 1911, gradual weakness of fingers and both hands developed, which was rapidly followed by weakness of both feet. She had pains in both hands and feet, especially in the latter. This developed without severe constitutional symptoms and without fever or other acute illness. She was unable to use hands or feet; could not walk. There was no trouble with speech or swallowing. This condition was treated by numerous physicians with electricity and massage, gradually grew better, and at the end of one year was all well, as well as before the onset of the trouble. The mother, who is a very intelligent observer, insists that the onset, appearance of the limbs, symmetry of paralysis, and signs of improvement are exactly identical with the present attack.

Present attack: The child was perfectly well during the summer of 1912 and attended school the following winter and spring. In May, 1913, it was noticed she could not hold things in her hands; inside of a few weeks the hands and legs were very bad and painful. There was no fever. In July the condition was marked so that she could not help dress herself, raise her wrists, or walk, or even rise from chair; very infrequent nocturnal enuresis. No cramps or other gastrointestinal disturbances. She was seen September 27, 1913. Habits: Does not and never before drank any liquors, has not been taking any drugs such as arsenic; rooms in which the child's family dwelt had not recently been papered. Her diet is a normal one for her age and her bowels are very regular.

Examination showed a well-nourished pretty girl of 12, practically dragged in by the mother who supported her under armpits. She could not stand on her feet, but sank to the floor if unsupported. Her gait was a peculiar waddle. Her hands and feet were cold, cyanotic, slightly atrophied, and flaccid. There was a

bilateral wrist and foot drop, and an inability to extend wrists or dorsiflex the ankles. The feet were in an equinovarus position due to the peroneal nerve palsy. The tendon reflexes of arms and legs absent. The muscles reacted slightly to galvanic current and failed to react at all to the faradic current. There were no upper motor neuron changes, as spasticity, exaggerated reflexes, ankle clonus, or Babinski. There were no cranial nerve changes, and no mental disturbances; muscles of calves tender. Only one diagnosis of the conditions now present was possible with this history and examination. That the previous attack was one of multiple neuritis is shown by the similarity of history as given by an intelligent, observant mother, by its onset without severe constitutional symptoms, by its perfect symmetrical involvement of the periphery of all extremities, by the inability to use hands or feet, by its perfect recovery without any residual paralysis.

The case is therefore one of recurrent multiple neuritis, *i.e.* there is a marked tendency to repeated attacks of multiple neuritis without definite cause. Multiple neuritis of non-diphtheritic origin is a rarity in children. Starr failed to observe any under the age of 16. Osler mentions only 8 cases of recurrent multiple neuritis at all ages having been collected up to 1898 and reports very few since.

November 26, 1913. The child is very much improved, she can get up without much assistance and walks fairly well. The electrical reaction shows the tendency to recovery. The reaction to the faradic current is still absent, and has increased to the galvanic current. The treatment employed was rest, massage, interrupted combined current, and strychnine. February, 1914, developed a true peripheral palsy of left facial nerve. May, 1914, arms and legs almost complete recovery, while facial palsy much improved.

183 Vernon Avenue.

## Medicolegal Notes.

**Degree of Care and Skill Required—Burden of Proof of Negligence.**—In an action for malpractice for failing to properly diagnose and set an arm which had been fractured near the shoulder, the Colorado Court of Appeals applied certain well established rules determining the liability of a physician and surgeon. In the absence of a special contract otherwise providing, a physician and surgeon employed to treat an injury impliedly contracts that he possesses that reasonable degree of learning and skill ordinarily possessed by others of his profession, that he will use reasonable and ordinary care and diligence in the exercise of his skill and the application of his knowledge to accomplish the purpose for which he is employed, and that he will use his best judgment in the exercise of his skill in deciding upon the nature of the injury and the best mode of treatment. He does not undertake to warrant a cure, and is not responsible for want of success, unless that want results from failure to exercise ordinary care, or from his want of ordinary skill. If he possesses ordinary skill and exercises ordinary care in applying it, he is not responsible for mistake of judgment. The fact that an injured limb is defective after treatment is not, of itself, evidence of negligence on the part of the physician treating it. A patient is bound to submit to such treatment as his surgeon prescribes, provided the treatment be such as a surgeon of ordinary skill would adopt or sanction. If he will not, his neglect is his own wrong or mistake, for which he has no right to hold his surgeon liable. It was also held that the skillfulness of a physician in diagnosis and treatment should be tested by the recognized rules of his own school, and must be determined by resort to the testimony and opinion of experts, not only as to the correct diagnosis, but also as to whether the defendant exercised ordinary care and skill in examining the case and applying the remedies; such opinion to be based upon the facts in evidence.

The defendant requested an instruction that in considering whether in diagnosing and treating the arm he exercised ordinary care and skill, the jury must be guided by the evidence of physicians, and, if they could not determine from such evidence what constituted ordinary care, there was a failure of proof, and the jury could not find for the plaintiff. It was held error to refuse the request, and to instruct so as to permit the jury to find a standard of care from evidence both competent and incompetent.

The evidence showed that the defendant was discharged immediately after the discovery of the fracture, and before he attempted to set the arm. It was held that an instruction that if, when he was discharged from the case, the fractured bones had not united, and that the condition of which the plaintiff complained arose thereafter, without the defendants' negligence, the defendant was not responsible, was erroneous as changing the burden of proof so as to require the defendant to show that the condition hypothesized in the instruction did not exist, and that the bones had not united so as to make it impracticable to comply with the defendant's advice that the fracture be reduced. Judgment for the plaintiff was reversed.—McGraw v. Kerr, 128 Pac. 870.

**Malpractice—Right of Choice of Method in Difficult Cases.**—Action was brought for alleged malpractice in the treatment of two compound fractures of the plaintiff's lower jaw. The injury was a serious one. The segment of the jaw between the two fractures had been drawn out of position by the contraction of the muscles and had been drawn upward. One of the problems facing the surgeon was to restore such segment to its place and to secure it in its proper position. In order to do this, sufficient force had to be applied in some way to overcome the tendency of the contracting muscles. An interdental splint was constructed, with the assistance of an experienced dentist. This was kept in the patient's mouth for five weeks. There was more or less infection present, and the plaintiff became sick with pleurisy. In time a union occurred, and, on the trial, the place of fracture was not readily discoverable by the expert witnesses, although the alignment was more or less imperfect. There was another method known to the profession which might have been adopted by the defendant. This consisted in drilling several holes in the jaw and in each end of the broken segment, and drawing and holding the parts together with the use of a silver wire. This method also had its perils. In case of infection there was danger of necrosis of the bone. The plaintiff contended that it was negligent on the part of the defendant not to use this method, and that his use of the interdental splint was unwarranted. It was held that the adoption of this method by the defendant did not show negligence or want of skill on his part, though the physicians might have adopted a different course of treatment. All experts agree that every difficult case presents a zone wherein the best method becomes largely a question of judgment of the attending surgeon under all the apparent circumstances of each particular case. That the appliance was painful or inconvenient, and that infection resulted, and that the plaintiff's life was in great peril, were all matters incident to the natural results of the original injury. The best of surgical treatment might not be able to avoid them. Judgment for the plaintiff was reversed.—Cozine v. Moore, Iowa Supreme Court, 141 N. W., 424.

**Failing to Report Diphtheria Case—Evidence.**—In a prosecution against a physician for failing to report a suspected case of diphtheria, it appeared that an autopsy had been performed on the sick girl's sister who had died from diphtheria a month and a half previous, and that the accused was present. It was held that the surgeon who performed the autopsy might testify that, in his opinion, the indications of a diphtheritic condition were so plain as to be apparent to an ordinary practitioner, under the rule that inferences from observed facts are admissible when the inferred facts are relevant, and the constituent fact cannot adequately be placed before the jury. In no other way could the surgeon bring before the jury the fact that an ordinary practitioner would have recognized the diphtheritic condition.—State v. Pierce, Vermont Supreme Court, 88 Atl. 740.

**Sale of Cocaine—Burden of Proof of Legality.**—In proceedings for the unlawful sale of cocaine to a negro boy, it was held that proof that the sale was made upon a physician's prescription devolves upon the accused, this being peculiarly within his knowledge.—Miller v. State, Mississippi Supreme Court, 63 So. 269.

## THE ANTAGONISMS OF POISONS.

THE subject of the mutual antagonism of poisons is an extremely interesting one. In its simplest phase this antagonism has been explained as the result either of the chemical interaction of the poisons themselves, or of the specific physiological effect which these poisons may produce. In other words the antagonism may be chemical or it may be physiological. Upon this classification is based the entire system of modern toxicology. According to the recent discoveries of physical chemistry the specific action of poisons has been explained on the basis of the permeability of the cell membranes, of differences in solvent power of these membranes, and of differences in surface area causing differences in absorption. According to J. N. Langley (*The Journal of Physiology*, March 31, 1914) none of these explanations accounts for this specific action adequately. But while advocating the chemical theory as being at present the one most in accordance with the facts, he does not consider it to be more than a tentative explanation. A theory which has had considerable vogue for a long time is that which holds that poisons having a specific action owe this property to their forming chemical compounds with certain tissues. The antagonism between physostigmine and atropine, and that between pilocarpine and atropine are explained by Langley on the hypothesis that such antagonistic poisons form chemical compounds with some constituent in the tissues, that the compounds are reversible, and that the amount of each depends on the relative mass of the two poisons.

Langley subjected this theory to experimental analysis in studying the antagonism of curari and nicotine in skeletal muscles. He found that the antagonism by curari to the fibrillary twitchings and to the tonic contraction caused by nicotine in the neural region of muscles follows different laws. Though curari reduces both effects in proportion to its percentage (*i.e.* in proportion to the concentration of its curarine), the abolition of the twitchings takes place with a definite percentage of curari for a considerable range of variation in the concentration of the nicotine. On the other hand, the abolition of an immediate tonic contraction by curari is strictly dependent on the ratio of the percentage of curari to that of nicotine. These conclusions were based chiefly on observations made on twitchings in the sartorius muscle, and on the tonic contraction in the rectus abdominis. There is a certain ratio between the percentage of curari and that of nicotine with which nicotine just fails to produce an immediate tonic contraction. The action of curari is at its fastest at first, and the rate of action then decreases. Curari does not appreciably antagonize the effect of nicotine on the non-neural portion of the muscle substance: the antagonism is confined to the special substance or mechanism of the neural region. When a muscle is immersed in curari after having been immersed in nicotine, the extent of the relaxation produced depends on several factors; it is less the higher the percentage of the nicotine and, within certain limits, the longer the duration of its action; it is greater the higher the percentage of the curari. Other things being equal, the extent of the relaxation depends on the relative concentration of curarine and nicotine. If the ratio of the percentage of curari to nicotine is below the equivalent percentage ratio the relaxation produced is trivial, and after a certain duration of action of the stronger solutions of nicotine, curari in higher percentage than the equivalent ratio also causes a trivial relaxation only. Thus curari antagonizes the stimulating action of nicotine to a degree which depends upon the relative concentration of curari and nicotine, but it has no certain effect upon the contracture produced by nicotine.

Upon the basis of these experiments the general conclusions are reached that curari and nicotine produce their effects by an action on the neural region of the muscle fiber and not by an action on the nerve endings, so that the explanation of the specific action must depend upon a difference in the neural and non-neural region of the muscle fibers.

## INTRASPINAL INJECTIONS OF MAGNESIUM SULPHATE IN THE TREATMENT OF CHOREA.

THIS method of treatment which is now generally referred to as Marinesco's method was first suggested by the experimental and clinical work of Meltzer and Auer of New York. These investigators had shown that magnesium sulphate in intravenous, subcutaneous, and intraspinal injections, and in local applications to nerve trunks, inhibits the two chief properties of nerve tissue, namely, its excitability and conductivity. On the basis of their experimental work, Meltzer and Auer had suggested that the subcarachnoid injections of magnesium sulphate might be employed with advantage as a substitute for cocaine in producing regional anesthesia. The first important therapeutic application of this method was in the treatment of tetanus. At the present time favorable results from this mode of treatment are being reported from various clinics abroad. Marinesco demonstrated the good effects of magnesium sulphate when injected into the subarachnoid space in sciatica and in the gastric crises and the lightning pains of tabes, and later applied this method in the treatment of Sydenham's chorea. In 1908 he reported four cases of the lat-

ter disease successfully treated by means of the intraspinal injections of magnesium sulphate. Since that time similarly favorable results have been reported by Baduel, Rocaz and others.

The most recent contribution to this subject is that presented by Augusto Natali in the *Rivista Ospedaliera*, March 31, 1914. He employed the so-called Marinesco method in the treatment of eight severe cases of chorea, one of which was a chronic case in an adult. The technique consisted in the performance of lumbar puncture in the usual manner, the evacuation of a certain amount of the cerebrospinal fluid, and the injection of a solution of magnesium sulphate. The strength of the latter varied from 7 to 25 per cent., and the amount injected consisted of 1 cubic centimeter for every 25 pounds of body weight. Of the author's eight cases, following the first injection, there was a rapid improvement in two cases, an appreciable improvement in two cases, and a slow improvement in two others. No benefit was derived in the two remaining cases which included one instance of the chronic type of the disease. The importance of these results is revealed by the fact that all of the cases were severe ones, and had failed to respond to the usual methods of treatment. Natali points out that it is of advantage to follow the intraspinal treatment by means of a brief course of arsenical medication. As regards the rationale of the action of the magnesium sulphate Natali is probably correct in stating that this drug acts not as a specific but merely as a symptomatic remedy, diminishing the excitability of the nerve centers.

## THE PANCREAS AND SILICA METABOLISM.

So many functions have been imputed to the external and internal secretions of the pancreas, and so many relationships have been traced between the active principles of the gland and diseases of different types that the etymology of the word itself, "all flesh," seems to be in a measure realized by the manifold activities of the gland already demonstrable, with the additional possibilities about to be mentioned.

In 1902 Rohden, writing of the metabolism of silica in the human body, made the announcement that "the pancreas is a sort of reservoir for silicic acid in the organism." Four years earlier, however, Kall made two studies of silica metabolism in cancerous subjects, and found an amount of silica in the pancreas which was double the normal content, as determined later by others. The amount excreted by the urine is correspondingly lessened. Exactly the opposite relationship is seen in tuberculosis, in which affection the pancreas may contain no silica at all.

The silica metabolism of the organism is discussed in full in two separate articles published in the *Muenchener medizinische Wochenschrift*, April 7, by Kahle and Rössle respectively. These deal chiefly with the silica metabolism in tuberculosis, and appear to show that this substance is logically indicated in the treatment of this disease, not only because of the waste of silica which is noted in the disease, but also because this substance is reputed to possess the power of stimulating connective tissue growth. Of even more interest, perhaps, is the fact that in cancer the silica metabolism is retarded and the mineral undergoes retention in the pancreas. This relationship at once suggests the theory of Beard that cancer is related to the failure of the pancreas to suppress the trophoblast. In either case there is a relationship between pancreatic insufficiency and cancer.

The authors quoted make no mention of silica as an old empirical remedy for superficial cancer. Even today Czerny employs it for this purpose. In theory it should be contraindicated, at least if cancer is regarded as a general disease. In superficial epitheliomata, however, it may facilitate recovery by promoting cicatrization. Kahle asserts that after extirpation of carcinomata, the amount of silica which has accumulated in the pancreas is rapidly dissipated. As pancreas substance is able to lower the antitryptic index in cancer, it is possible that it is also able to mobilize the stored up silica in the gland, and it is to be hoped that the Jena savants will test this possibility.

## The Immunization of Lake and River Seamen Against Typhoid Fever.

Typhoid fever is prevalent among the seamen of the U. S. merchant marine of the lakes and rivers. Their calling in itself renders them subject to insanitary dangers over which they have practically no control. Further, either during the period of a seamen's illness from typhoid or subsequent to recovery as a "carrier" he acts as a focus for the spread of the disease to his fellow shipmates and to the public at large. Surgeon-General Robert Blue of the U. S. Public Health Service draws attention to these obvious facts in Public Health Reports for March 20, 1914, and urges that the practice of immunization against typhoid be encouraged aboard ship. He points out that this method of prevention has long since passed beyond the theoretical and experimental stages as evidenced by the results obtained in the armies and navies of the United States and Europe. Surgeon-General Blue states that the U. S. Public Health Service is ready and willing to render every assistance and advice, and at all relief stations throughout the country service officers are instructed to administer the typhoid prophylactic to all sailors applying for the same.

## Relation of Public Health to Industrial Welfare.

It goes without saying that the relationship between public health and industrial welfare is a very intimate one. In fact, industrial welfare must flag and eventually wither unless those engaged in industrial pursuits are in good health. Thus the protection of the working classes from disease is an economic measure which concerns the nation, the state, and the employer. Samuel G. Dixon, Commissioner of Health for the State of Pennsylvania, gave an address on the subject before the Welfare Efficiency Conference held at Harrisburg in October, 1913, in which he drew attention to the importance to the community of conserving the health of the working population. He showed how the State of Pennsylvania had grappled with the

arduous task of looking after the physical well being of 8,000,000 persons, and pointed out that when individuals and communities were brought to a full realization of the fact that disease is not a mysterious visitation without tangible cause, but the result of sanitary indiscretions or the failure to observe certain readily definable precautions, a tremendous step forward will have been accomplished. *Salus populi suprema lex* is an axiom the significance of which is beginning to be appreciated throughout the civilized world.

### Determination of Sex.

A paper on this subject by Poll was read recently before the Berlin Gynecological Society (*Berliner klinische Wochenschrift,* March 23) and aroused much interest. Long before an individual has been evolved from the germinal plasm, or keimanlage, Poll said, certain cells may be distinguished by their size which are to develop into the future genital glands. These cells possess an independence, and their behavior in respect to staining differs from that of the surrounding elements. These primitive genital cells already represent a sex. If two male cells of different types unite, one will be a heterochromosome; if two female cells, both will be heterochromosomes. In other words, two types of male cell are common; while two types of female cell certainly exist to some extent. But two kinds of male cell suffice alone for sex differentiation. Of great interest in this connection is the parallelism between a creature like the common fly and mankind in respect to the eyes. Some of these insects have red, others white eyes. By crossing, either sort of eye may be produced at will. It is a question of sex. In mankind, color blindness shows the same laws of inheritance, while it can be produced at will by special mating. If the sexual products of a male are injected into a castrated female of the same species, secondary male characteristics reappear in the latter, notably the male color of the feathers. Another subject highly pertinent here is that of familial hermaphroditism.

## News of the Week.

**Civil Service Examinations.**—The New York State Civil Service Commission will hold examinations on June 20, 1914, for the purpose of filling the following vacancies:

Assistant medical officer, health officer's department, port of New York, at a salary of $1,500. This position is in the detention and hospital service at the quarantine station, Staten Island, and a knowledge of cholera, plague, yellow fever, smallpox, and epidemic cerebrospinal meningitis is required. The examination is open only to licensed medical practitioners of the State of New York.

Laboratory assistant, State department of health, $720 to $1,200. Open to both men and women. The duties of this position are to assist in the work of the laboratory.

Physician, Bronx county jail, $1,000 per annum. Candidates must be legally licensed medical practitioners and residents of Bronx County.

Further details and application blanks will be furnished upon request by the State Civil Service Commission, Albany, N. Y.

The United States Civil Service Commission announces an open competitive examination for men only, to be held on July 6, 1914, for the purpose of filling vacancies in the position of assistant epidemiologist in the Public Health Service, at salaries ranging from $2,000 to $2,500 a year. An educational training equivalent to that required for graduation from a recognized medical school, and at least three years experience in epidemiological work under federal, State, or local authorities, and experience in laboratory technique, especially in regard to typhoid fever, are prerequisites for consideration for this position. Applicants will be rated on the following subjects: General education and medical training, 25 points; laboratory experience, 30 points; experience in epidemiological work, 35 points; publications or thesis, 10 points. Application for the examination should be made to the United States Civil Service Commission, Washington, D. C.

**Dr. Harry S. Bernstein,** director of the Bender Hygienic Laboratory, Albany, N. Y., has been appointed pathologist and bacteriologist to the Rhode Island Board of Health, and will take up his new duties on September 1. The position which he will fill is a new one, having been authorized by an act passed at the last General Assembly of the State, and carries a salary of $4,000.

**A Loving Cup to Dr. Tucker.**—At the annual dinner of the alumni of Albany Medical College, held May 26, a silver loving cup was presented to Acting Dean Willis G. Tucker, who retired on January 1 last after a service of nearly thirty-two years as registrar of the college. The presentation was made by Danforth E. Ainsworth and addresses were made by Governor Glynn, Dr. Albert Vander Veer, and others.

**Grant to Yale Medical School.**—The General Education Board at a meeting on May 29 made a grant of $500,000 to Yale University as an endowment for the medical school, it being a condition of the gift that the school procure complete teaching and medical control of the New Haven Hospital, and that the teachers in the main clinical branches be placed on a full-time or university basis. On similar conditions the board last year made a grant of $500,000 to the Johns Hopkins Medical School, Baltimore, and a grant of $750,000 to the Washington University Medical School, St. Louis.

**School for Public Health Officers.**—The proposal to the General Education Board that it establish schools for the training of public health officers, has been under consideration by a committee, which reported on May 29 that as no such schools existed at present it seemed clear that they should be established in one or two centers, such as New York and Boston, at least, in connection with the medical and engineering departments of universities, and co-operating through field work with city and State health departments. Before formulating a definite scheme for the creation of such schools of public health the board resolved to authorize a study of training for public health service and of the organization of such services in the different countries of Europe. When the facts have been ascertained a concrete scheme will be formulated for schools of public health.

**New Hospitals.**—Work was begun on May 18 on the new building for the Union Benevolent Association Hospital of Grand Rapids, Mich., a gift to the city from Mr. John W. Blodgett of Grand Rapids. The plans call for a steel and concrete building to be erected at a cost of about half a million dollars.

The Abington Hospital, Abington, Pa., was opened for public inspection on May 15 and 16. The hospital was erected by Mr. George W. Elkins in memory of his wife, Stella McIntire Elkins, and has been endowed by him to the amount of $200,000. Efforts are now being made to increase the endowment fund to $500,000.

At a meeting of the supporters of the Har Moriah Hospital, New York, held recently, it was voted to begin at once on the collection of a fund of $100,000 with which to erect a new hospital building. The present Har Moriah hospital is situated on East Second street and is supported by the Galician Jews of this city. During the last year the hospital cared for 1,006 patients, 1,658 being refused for lack of room. In the dispensary 22,856 patients received treatment.

The German Hospital of Jersey City, N. J., was dedicated on May 30. The hospital contains twenty-four beds and has been erected at a cost of $35,000 by the German Hospital and Dispensary Association.

**Public Health Education.**—The New York City Department of Health has recently created a new Bureau of Public Education and this has been put under the direction of Dr. Charles Bolduan, assistant sanitary inspector. The first attempt to educate the public in methods of preserving health will consist of exhibitions of moving pictures.

**City Death Rate.**—During the week ending May 23 there were reported in New York City a total of 1,592 deaths, giving a death rate of 14.88 per 1,000 of population, as against 1,572 deaths and a rate of 15.27 for the same week of 1913. This is an absolute increase of 20 deaths and a decrease of 0.39 in the weekly rate, which is equivalent to a relative decrease of 42 deaths. For the first twenty-one weeks of 1914 the death rate was 15.33 per 1,000, as against 15.55 for the corresponding period of last year.

**Homeopathic Medical College.**—Forty-one students were graduated from the New York Homeopathic Medical College and Flower Hospital at the commencement exercises on May 27.

**Nursery Building Opened.**—The Hebrew Kindergarten and Day Nursery Association opened its new building on May 28. It is four stories high, and contains an auditorium, large dining room, and accommodations for 500 children.

**Plans for "Baby Week."**—With the approval of Mayor Mitchel the New York City Department of Health is laying plans to keep one week in June as "Baby Week," and during that time to interest everyone in the public and private agencies which care for babies during the summer months and are cooperating in the effort to reduce infant mortality. It is pointed out that the death rate of infants has fallen in the last seven years from 135.8 per 1,000 to 101.9 and that a still lower rate is possible.

**Fever at Auburn.**—A large number of cases of scarlet fever have occurred recently at the State Prison at Auburn, N. Y., and it has been found necessary to place a strict quarantine on the entire institution. The State Commissioner of Health has taken charge of the situation and has put one of his deputies in the prison to direct the efforts being made to control the epidemic.

**Gifts to Charities.**—By the will of the late Miss Elizabeth Shippen of Philadelphia, the Pennsylvania Hospital of that city, and the Pottsville Hospital of Pottsville receive bequests of $50,000 each. The S. R. Smith Infirmary, Tompkinsville, Staten Island, N. Y., receives a bequest of $30,000 by the will of the late Miss Sarah J. Farrar of New York.

**Marriage License Requirements.**—The Medico-Psychological Association at its meeting in Baltimore on May 21, refused to pass a resolution recommending the enactment of laws requiring a "clean bill of health and evidence of normal mind before the issuance of a marriage license." It was believed that the passage of such a resolution would be the cause of much ill-considered legislation, and that the number of marriages would be considerably reduced by such an attempt to raise the standard. Eugenics, it was agreed, was a phase of an ideal state of society not yet attained, and improvement would come rather through popular education than through statute.

**College of Physicians and Surgeons.**—At the meeting of the Trustees of Columbia University on June 1, Dr. Warfield T. Longcope was appointed, on the recommendation of the Medical Faculty, Bard Professor of the Practice of Medicine at the College of Physicians and Surgeons, succeeding Dr. Theodore C. Janeway. Professor Longcope was also nominated as medical director of the Presbyterian Hospital. At the same time the department of therapeutics at the college was merged with the department of medicine, and Dean Samuel W. Lambert, professor of therapeutics, was made professor of clinical medicine. There was also established a new department of pharmacology under the direction of Dr. Charles C. Lieb, assistant professor of pharmacology. Dr. William Darrach, associate in surgery, was made assistant professor of surgery. Announcement was made also of the gift of $2,400 from various donors for the purpose of establishing a scholarship at the College of Physicians and surgeons in memory of the late Dr. Frank A. Hartley, professor of clinical surgery.

**American College of Surgeons.**—The second convocation of the American College of Surgeons will be held on Monday evening, June 22, in the ballroom of the Bellevue-Stratford, Philadelphia, when it is expected that between five and seven hundred additional fellowships will be conferred upon applicants who have been accepted since the last convocation in Chicago.

**Medical Elections.**—Missouri State Medical Association: Annual meeting on May 12 to 14. Officers elected: *President*, Dr. Henry C. Shuttee, Westplains; *Vice-Presidents*, Dr. J. A. McComb, Lebanon; Dr. G. O. Cuppidge, Moberly; Dr. W. G. Estill, Lawson; Dr. T. A. Coffee, Springfield; Dr. W. A. Clark, Jefferson City; *Treasurer*, Dr. J. S. Welch, Salisbury; *Secretary*, Dr. E. J. Goodwin, St. Louis. The 1915 meeting of the society will be held at St. Joseph.

Connecticut State Medical Society: Twenty-second annual meeting in New Haven on May 21. Officers elected: *President*, Dr. Oliver Cotton Smith, Hartford; *Vice-Presidents*, Dr. Stephen J. Maher, New Haven, and Dr. John B. Kent, Putnam; *Secretary*, Dr. Marvin McR. Scarbrough, New Haven; *Treasurer*, Dr. Joseph H. Townsend, New Haven.

Kentucky State Homeopathic Medical Society: Twenty-sixth annual meeting at Lexington on May 20 and 21. Officers elected: *President*, Dr. Charles H. Struble, Dayton; *Vice-President*, Dr. E. B. Smith, Shelbyville; *Secretary*, Dr. H. P. Fischbach, Newport; *Treasurer*, Dr. Paul E. Kerkow, Covington.

**Obituary Notes.**—Dr. Arthur Warton Swann of New York, a graduate of the College of Physi-

cians and Surgeons, New York, in 1907, assistant visiting physician to the Presbyterian Hospital, and instructor in clinical medicine and in clinical pathology at the College of Physicians and Surgeons, died at the Manhattan Eye and Ear Hospital, New York, after a short illness, on May 28, aged 34 years.

Dr. William James Dugan of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1896, a member of the Medical Society of the State of Pennsylvania, the Philadelphia County Medical Society, the Philadelphia Neurological Society, and the Philadelphia Pathological Society, and instructor in electrotherapeutics at the Jefferson Medical College, died at his home on May 21, aged 45 years.

Dr. Philip B. Housekeeper of North East, Md., a graduate of the Jefferson Medical College, Philadelphia, in 1868, and a member of the Medical and Chirurgical Faculty of Medicine and the Cecil County Medical Society, died at his home on May 17, aged 68 years.

Dr. James Henry M. Karsner of Oroville, Cal., a graduate of the Jefferson Medical College, Philadelphia, in 1868, a veteran of the Civil War and a member of the Medical Society of the State of California and the Butte County Medical Society, died at his home from ptomaine poisoning on May 15, aged 69 years.

Dr. William M. S. Curtiss of Bristol, Conn., a graduate of the Baltimore University School of Medicine in 1893, and a member of the Connecticut State and Hartford County Medical Societies, died at his home, from Bright's disease, after a long illness, on May 17, aged 44 years.

Dr. Horatio S. Brewer of Chicago, Ill., a graduate of the Bennett Medical College, Chicago, in 1879, and for many years a surgeon of the Chicago, Milwaukee, and St. Paul Railroad, died at his home on May 19, aged 68 years.

Dr. John M. Dunn of Richmond, Ark., a graduate of the Medical School of Washington University, St. Louis, in 1861, died at his home on May 20, aged 81 years.

Dr. John Byron Thomas of Colorado Springs, Col., a graduate of the Indiana University School of Medicine, Indianapolis, in 1909, and recently house physician at Bethel-El Hospital, Colorado Springs, died at Wabash, Ind., on May 20, aged 27 years.

Dr. John Frank Alcorn of Pittsburgh, Pa., a graduate of the University of Pittsburgh, Medical Department, in 1900, and a member of the Medical Society of the State of Pennsylvania and the Allegheny County Medical Society, died at his home after a short illness on May 25, aged 44 years.

## Obituary.

### EMIL GRUENING, M.D.,

NEW YORK.

Dr. Emil Gruening, emeritus professor of ophthalmology at the New York Polyclinic Medical School, died at his home from cerebral endarteritis, after a short illness, on May 30, aged 71 years. Dr. Gruening was born October 2, 1842, in Hohensalza, Prussia, and came to this country when twenty years of age. He entered the College of Physicians and Surgeons, New York, but interrupted his course to enlist in the Seventh New Jersey Volunteer Infantry, serving through the Civil War. He then returned to college and was graduated in 1867. He studied abroad three years and began practice in New York in 1870. In 1871 he was appointed an assistant surgeon to the New York Ophthalmic and Aural Institute, in 1879 ophthalmic surgeon to Mount Sinai Hospital, his connection with the latter institution continuing until his death. He also served for twenty-three years as ophthalmic surgeon to the German Hospital. At the time of his death he was consulting ophthalmic surgeon to these two hospitals and to the New York Eye and Ear Infirmary and the New York Infirmary for Women and Children. He was a member of the New York Ophthalmological Society, the New York Otological Society, the New York Academy of Medicine, the New York State and County Medical Societies, the American Laryngological, Rhinological, and Otological Society, the American Ophthalmological Society, the American Otological Society, and the Association of the Alumni of the College of Physicians and Surgeons.

Dr. Gruening began practising when ophthalmology was in its infancy and otology in embryo. In the last two decades both these branches of medicine have become highly specialized and separate and most physicians who undertook both have since dropped one or the other. Dr. Gruening, however, practised both ophthalmology and otology and achieved the highest distinction in each branch, namely, the presidency of the American Ophthalmological Society and the presidency of the American Otological Society. He had also been president of the New York Ophthalmological Society, the New York Otological Society, twice president of the section of Ophthalmology of the New York Academy of Medicine, president of the section of Otology of the New York Academy of Medicine, a director of the New York Eye and Ear Infirmary, and president of the Society for the Relief of the Widows and Orphans of Medical Men. Perhaps his greatest achievement was the development of the mastoid operation as it is performed in this country today. He was the first to point out the dangers of blindness from wood alcohol poisoning. He contributed voluminously to medical journals on subjects connected with the eye and ear. In the system of "Diseases of the Eye," edited by Norris and Oliver, he wrote the chapter on "Injuries to the Eyes."

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

OPHTHALMOLOGICAL CONGRESS—INTRODUCTORY ADDRESS—PIGMENT OF IRIS—DISSEMINATED SCLEROSIS—POSTOPERATIVE COMPLICATIONS OF CATARACT EXTENSIONS.

London, May 15, 1914.

The annual meeting of our Ophthalmological Society assumes the dignity of a congress, naming itself so, extending over three days, with a special clinical meeting at the Central Ophthalmological Hospital and a welcome to visitors interested in the important discussions provided. This year the congress occupied April 23, 24, and 25, and among distinguished visitors were Professors' Landolt of Paris, Straub of Amsterdam, and Uhthoff of Breslau.

The proceedings opened with a brief introductory address by the president, Mr. Richardson

Cross, who welcomed visitors, congratulated the Royal Society of Medicine (in the rooms of which they were assembled) on the success achieved by their section of ophthalmology, and reminded the congress of the valuable work of his predecessors in that honorable office. He referred to the investigations he had himself undertaken at the request of the Royal College of Surgeons on the question of factory lighting, thanking those members residing in industrial localities who had helped him by replying to his inquiries, which showed that few ailments were really due to insufficient or bad lighting of factories. The inquiry, however, did not include some special work as glassmaking, exposure to red or white hot metal, etc. Injury done by excessive artificial lighting seemed from the ultra-violet rays, but wearing glasses was a great protection from them. That all sorts of variations in the blood or general health might bring on intraocular changes was remarked by the president, who mentioned a suggestion of Mr. Hughes to rename rheumatic iritis as "metastatic" iritis. He also spoke of bacteria and their evolutionary developments, antitoxins, hormons and sera. Referring to the history of the society the president observed if the advice tendered to governments by its committee thirty years ago had been followed many disasters would have been prevented. So if another of its investigations had been recognized and the advice offered adopted a large number of persons would have been spared the calamity of blindness.

On the conclusion of the address Mr. W. H. Jessop read a paper on the "Prognosis of Incipient Opacities of the Lens" in which he deprecated naming them cataract to the patient who too often was injured by the terror to which he was thus subjected, and he mentioned a case of one who for years lived in such fear, although his sight continued good, except for a slowly progressing presbyopia, to the age of 86. Professor Landolt supported Mr. Jessop and thought the term cataract should be restricted to serious impairment of sight, which would ultimately require removal of the lens. Similar views were expressed by members representing the English, Scottish, and Irish schools.

Mr. Harman then read a paper on the "Appearance of Pigment in the Iris of the Child." After this "Flat Sarcoma of the Choroid, with Multiple Metastases" was the subject of one by Dr. G. Holmes and Mr. R. A. Greeves. It was a safe beginning with analysis of external rectus going on to severe pain in the forehead (right side) and sensory loss in the right trigeminal nerve (101 division). Later tactile insensibility and partial paralysis in region of right oculmotor nerve. He died five and a half years from the onset.

Mr. Paton read a paper on "Papilledema in Disseminated Sclerosis"; out of 100 cases 5 gave evidence of former iritis. In one he had found normal vision 18 months after neuritis.

Lt.-Col. R. H. Elliot had a paper on dressings and antiseptic methods in eye operations, enforcing minutest details and commenting on some carelessness he had observed. Referring to Herbert's advice to irrigate the conjunctiva with 1 in 3,000 perchloride he said he had not had a case of post-operative panophthalmitis since 1907. Professor Landolt observed that boiling cutting instruments spoilt their edge, so he used dry heat for 20 minutes—up to 150° F.—and he believed he had never had a case of infection from them. For atropine he used a fresh ampulla each time, objecting to an irrigator. Professor Straub said most operative infections arose from organisms resident in the eye beforehand. He carried out sterilizing methods for three days preceding operation.

Mr. Wray's paper on "Dislocated Lens," objecting to needling, but in great displacements justifying iridectomy, was discussed by Messrs. Landolt, Story, Priestley, Smith, Elliot, Rowan, Straub and Clegg.

The second day was perhaps the most generally interesting to the largest number, for while the afternoon was devoted to the clinical exhibition already mentioned, the whole of the morning was given up to the discussion of the postoperative complications of cataract extractions. This was opened by Mr. Treacher Collins, who directed attention to differences of incision by different operations. He favored that which aimed at the cutting of a conjunctival flap. If the wound did not readily heal a downgrowth of epithelium might take place and even spread all over the anterior chamber and cause glaucoma. Prolapse of the iris might lead to a late suppurative state of the uveal tract, appearing months or years afterwards. Astigmatism varied enormously in amount after extraction. Suppurative inflammation of the cornea was mostly caused by the pneumococcus and has been greatly diminished by aseptic precautions and sterilization of instruments. Sometimes posterior synechiæ developed in quiet eyes, but he did not regard them as septic; so keratitis punctata, which was certainly non-septic, would be found in cases going on normally, if these dots were carefully looked for. It was a fallacy to regard the mere presence of soft lens matter in the anterior chamber as capable of setting up iritis, but if mixed with aqueous it was a good medium for organisms, if any, were present. He had seen sympathetic ophthalmitis benefit under salvarsan. Information was often obtained from a blood count. He considered how glaucoma was produced after an extraction or a needling and the proper treatment. Further expulsive hemorrhage, detached choroid, opaque membranes, vitreous opacities, and detachment of the retina.

Lt.-Col. Herbert said infection was the chief danger; in India it had been almost abolished by thorough irrigation with mercurial perchloride, 1 in 3,000. It had one drawback, it irritated the conjunctiva and later led to further development of microorganisms; but by that time the wound had healed, though it must be considered, if any further operation were contemplated within two weeks, *e.g.* very early needling.

Sir A. Critchett said Mr. Collins had set on firm pathological ground a number of questions. Collins' procedure was best when the pupil had been drawn up into the wound or there was a dense capsular membrane.

Mr. S. Browning communicated an interesting fact for bacteriologists—that out of hundreds of cases examined at Moorfield Hospital before operation only one was declared clean and that became infected after operation. He suggested that causes for sepsis be searched for beyond the eye itself—say in the gums, nose, throat, etc. The practice of bandaging in advance to see if pus appeared on the bandage he condemned, for he had seen an increase of organisms so caused.

Mr. C. Killick had had a series of 101, of which only one suppurated. He had had only three suppurate out of 1,000 cases in three years. He had

needled twenty-eight times in all for capsular proliferation. Mr. C. A. Worth thought hemorrhage into anterior chamber five days after operation as peculiar to the conjunctival flap method, not having met with it after the corneal incision. Mr. Ormond related two cases of endogenous infection. Mr. Story had assisted some infections by electrocautery to edges of wound and subconjunctival injection of cyanide of mercury. Infection was mostly exogenous, and he carefully searched not only eye but nose and mouth, and if many organisms were present postponed operation and carried out cleansing treatment. Dr. Alexander spoke of the great instruction he had found in Lt.-Col. Elliot's clinique at Madras, and Lt.-Col. Elliott spoke in the highest terms of Mr. Collins' paper and supported his views. Prof. Landolt had always doubted the value of preliminary bandaging for he assumed no conjunctival sac was free from germs and danger of infection was present as long as the wound was open.

Dr. Mackay favored a weaker solution than the perchloride—argyrol or boric lotion were useful. Dr. Henderson said adhesion of iris or capsule did not lead to pathological results so long as they did not make a bridge for organisms. Professors Uhthoff and Straub described their methods. The latter had not seen inflammation begin in the second week when the toilet after operation had been carefully carried out. He warned against the danger of squeezing the eye, which sometimes caused its loss. The president said every one of them felt the essential condition of success was absolute asepsis or antisepsis. Most cases of sepsis, he held, were exogenous, but a few were endogenous, as those from the mouth and from metastatic inflammation.

South Wales University has accepted a gift of £70,000 from an anonymous donor, to build a complete school of preventive medicine in connection with physiological block given by Sir W. J. Thomas.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

BETTER MORTALITY FIGURES—HOSPITALS AND DISPENSARIES AS PEACE AGENCIES—IMPROVED TRANSPORTATION FACILITATING THE SPREAD OF DISEASE —BACTERIOLOGY OF LEPROSY—FILARIASIS.

MANILA, P. I., April 24, 1914.

THE mortality figures for the city of Manila again show marked reduction. The lowest record for any March since American occupation has been reached this year. The rate for the city of Manila was 20.39 per thousand. In March, 1913, it was 22.66 per thousand. A review of the death rates that have prevailed during the past ten years in Manila shows that a steady decline has taken place, and it is believed to be fair to attribute the results largely to the improved hygiene and sanitation that have been brought about. In 1904, for instance, the death rate for March was 40.23 per thousand, so that the results a decade later show practically an improvement of 50 per cent. If the mortality of Manila were compared with that of the principal American cities upon all deaths above one year of age, the rate would be found to be about the same as that of New York. The prospects for April, however, are threatened by the fact that there is again a marked shortage in the Manila water supply and, beginning March 30 some water was pumped from the badly polluted Mariquina River. It is hoped, however, to offset this danger by placing calcium hypochlorite in the water in the strength of 1 to 2,000,000.

The policy of establishing hospitals and dispensaries among the Moros apparently is bringing about peace conditions much more rapidly than could have been hoped for by the promoters of this scheme. Reports recently received from Mindanao show that not only the outpatient dispensaries but the hospitals are being patronized by the Moro women. Extensive experience in dealing with the uncivilized peoples of the Philippines has shown that whenever the wild man is willing to bring his women folks into the presence of the white man he is really peaceably disposed and that his confidence has been gained. The attendance at the hospital, which was recently opened at Dansalan in the Lanao District, is increasing week by week and the Constabulary officers report that it is very noticeable that as the medical men come more and more in touch with the Moros in remote districts peace conditions steadily improve.

With the improvement of transportation and the carrying out of large projects in the Philippine Islands, there is now much greater danger of communicable disease being conveyed to portions of the Islands that have not yet been affected thereby. The opening of the San José Sugar Estates in the Island of Mindoro was responsible for the introduction of the malarial fever of Mindoro into new towns and provinces in which it was not present theretofore, on account of the workmen who were employed there returning to their homes. A similar experience is now being had with regard to the construction of the new line of railway through Tayabas Province. Up to the present time the island of Cebu has practically not been infected with malaria. At present large numbers of laborers are recruited from that island and are being transferred to Tayabas, where many hundreds of them are contracting the disease. It has been the experience that as soon as they feel themselves ill, if at all able to travel, they immediately return to their homes in Cebu. This has been responsible for infecting the mosquitos of Cebu. The Bureau of Health is making every effort to locate these cases as soon as they arrive from Tayabas, with the hope of minimizing the danger as much as possible. Several million doses of quinine are also being distributed in Cebu, which will also probably have some influence in keeping down the incidence of the disease.

The regular monthly meeting of the Manila Medical Society was held on April 6 at 8:30 P.M. in the amphitheater of the College of Medicine and Surgery of the University of the Philippines. Among other papers read was one entitled "A Contribution to the Bacteriology of Leprosy," by Dr. John A. Johnston of the Bureau of Science. The paper of Dr. Johnston was particularly interesting on account of the fact that he is apparently on the way of cultivating the true leprosy bacillus. He has succeeded in isolating a streptothrix from the spleen of a person who died of leprosy and in culture producing acid-fast rods from the original streptothrix. He inoculated a rabbit with a culture of an acid-fast rod which he recovered from the spleen of a person dead of leprosy and which he cultivated. One year after the inoculation took place the rabbit died and the pathological lesions were those of typical leprosy. Another paper read was entitled "Clinical Notes on Filariasis in Bilibid Prison," by Dr. J. W. Smith, the Chief of the Prison Sanitation Division of the Bureau of Health. Dr. Smith gave a record of over 700 cases of filariasis which he found among the 3,000 odd prisoners of Bilibid. He tried the

usual treatments recommended in standard textbooks, but apparently the therapeutic measures employed had no effect on the disease. Close observation over a period of seven years indicates that none of these cases were contracted in the prison; in other words, it is not probable that the disease is transmitted from infected prisoners to healthy ones while they are in Bilibid.

Dr. Bernstein of the German Navy showed an interesting series of colored lantern slides that were taken with the three-color process on Lumière plates of the various stages of leprosy which he found among the inmates of the San Lazaro Leper Hospital at Manila. The lantern slides as projected on the screen gave an excellent color reproduction of the lesions and even the erythemas of leprosy could be plainly seen.

6. Report on Leucocytic Inclusion Bodies. L. Webb Hill.
7. Poor Health in the Child: Some Developmental Influences and Their Importance to the Adult. J. Bryant.

**2. The Diagnosis of Tuberculosis in Children.**—J. B. Hawes states that in the absence of advanced tuberculosis or a recent infection with some acute disease which might cause a negative reaction a diagnosis of tuberculosis is rarely justified unless there is a positive skin tuberculin reaction. Constitutional signs and symptoms are usually present and require careful study and investigation. If such symptoms are absent, a definite diagnosis is unwise, although this should not interfere with placing the child under proper treatment. Signs referred to the chest and lungs are of interest and value, if present; if absent their absence should not preclude a definite diagnosis. If present without constitutional disturbance, one should look out for chronic influenza and pneumococcus infections. Positive *x*-ray evidence is of value in conjunction with other evidence. Diagnoses based on the *x*-ray alone are apt to be wrong and are unjust to the patient.

**3. Lateral Curvature of the Spine.**—Z. B. Adams notes that a careful *x*-ray study of each case is indispensable before treatment. Fourteen of the author's twenty-two cases in the clinic showed congenital lesions at the lumbosacral junction. The fact that the age (ten to fourteen) when the anterior lumbar curve becomes constant, is the age when scoliosis develops in a large number of cases is interesting. At this age the weight of the upper trunk is increasing most rapidly and the epiphyses of the iliac crest have not appeared. The vertebral sacral angle varies widely, but is great in females. The increased tipping throws greater strain (both downward and forward) on the articular processes, and as the angle of inclination increases the horizontal thrust becomes more vertical and the strains tend to unite. Hence, when these processes are defective scoliosis develops. Many of the cases should be operated upon either before correction is attempted or after correction is obtained. A knowledge of the character of the lesion allows a prognosis. This knowledge explains some of the many failures of the past.

**7. Some Developmental Influences and Their Importance to the Adult.**—J. Bryant concludes that adhesions, ptoses, and other demonstrable physical defects are of very common occurrence at all ages in both sexes, but the frequency of these defects in the adult is not markedly greater than in the child. It is not improbable that such defects may stand in a causal relation to some at least of the disabilities of the child and the adult. An anomalous ligament of Treitz may be a factor in obstruction of the duodenum. The treatment of developmental defects is primarily non-surgical, and if properly carried out in the child is preventive, in that it will result in creating an adult not only personally more efficient, but one who may entertain the hope of having physically more perfect children. "The problem is comprehensive enough to accept all the assistance it can through gymnastics, bandages, regulation of diet, and habits, and still furnish an abundant percentage of human wreckage (Lane) for the surgeon to attempt to reclaim."

12. A New Psychosis. S. Block.

**2. The Inlay Bone Graft in Fresh Fractures.**—F. H. Albee states that one can secure union of the fragments, even when there is actual separation or loss of bone substance, by the inlay graft method; that angulation of the fragments can be corrected; and that the presence of the graft inlaid in the fragments stimulates the osteogenetic function, not only of the recipient fragments, but on the part of the graft itself, thus doubly assuring the formation of bone callus. The fact that the author's last one hundred cases, including old and ununited fractures, when the inlay bone graft was used, produced one hundred per cent. of successful results, strengthens his conviction that this method of dealing with fresh fractures should be equally successful. The technique of application differs but slightly in treating fresh fractures by the inlay graft method from that already used so successfully in the ununited fractures, and is much easier, as in old ununited cases the angulation and overriding of fragments and eburnation of the fractured ends present often greater obstacles to correction of alignment and implantation of the graft than would be looked for in recent cases.

**3. High Vascular, Muscular, and Mental Tension.**—W. J. M. A. Maloney and V. E. Sorapure state that the former has elaborated for the relief of states of mental and muscular tension certain depressor exercises which he used as an introduction to the cure of ataxia by his blindfold method. In tabetics who were practising these exercises he observed a fall of blood pressure, and patients reported to him that at home the exercises often led to sleep. He next observed in a case of chronic nephritis that by such exercises the systolic blood pressure was reduced from 220 to 192 mm. in fifteen minutes. The exercises may be divided into two groups, breathing exercises and relaxation exercises. They first instruct the patient to breathe deeply and to pause at the end both of inspiration and of expiration. The breathing should be abdominal

and should be done without jerking. One of the purposes of deep breathing is to distract the patient from obsessing thoughts and disturbing ideas, to focus his attention upon the exercises. To relax the muscles passive movements, in which the muscles are alternately lengthened and shortened, are employed. The scalp, forehead, cheek and jaw muscles of the recumbent patient are passively moved by the physician, till wrinkling diminishes or disappears and muscular spasm is eliminated. Next, a shoulder is relaxed, then an arm. Each limb is dealt with separately. Each joint is passively moved until all trace of muscular tension vanishes. When the joints of a part are free from all muscular constraint, the part lies motionless or flaccid or falls limply from any unsupported position. After a part is relaxed, those previously and those newly relaxed should be briefly dealt with again and in the order in which they were first relaxed. Thus, after relaxing the first limb, the physician turns again to the scalp, forehead, cheeks and jaw, relaxes these, and then again relaxes the limb. This linking of parts previously to parts newly relaxed is helpful in bringing the whole to a satisfactory state of relaxation. Besides the tranquillizing of excited and anxious states and the general relaxation of the musculature, certain other physiological effects result from these exercises. Among these effects is a reduced frequency of the movements of the eyelids. At the beginning of a treatment the eyelids quiver. As tranquillity is gained, the quivering grows less, until often the lids lie motionless. When distractions arise the lids begin to flicker, or if flickering was present before, it now increases. During the exercises a high blood pressure almost invariably falls.

**7. The Albumin Reaction in the Sputum.**—W. M. Lewis concludes that the demonstration of albumin in the sputum depends upon the presence either of albumins *per se*, derived from the blood serum, or of corresponding substances which have been liberated as a result of cellular destruction. Should this assumption be correct, one would expect to find albumin present in the sputum from practically every pathological condition involving either primarily or secondarily any portion of the respiratory tract, also in those essential normal individuals who are the victims of the so-called American catarrh. The writer concludes, therefore, that an examination of the sputum for albumin is of no practical importance, so far, at least, as the diagnosis of tuberculosis is concerned.

**8. X-Ray Treatment of Hyperthyroidism.**—E. Birdsall notes that hyperthyroidism is proving to be a most fruitful field for *x*-ray therapy. Surgery, however, has pointed the way to this form of therapy by demonstrating that a reduction in the size of the gland, thus decreasing the amount of secretion, will produce a cure. The therapeutic action of the rays on the thyroid gland is a reduction of secretory activity, induced by the atrophic changes and the obliterating endarteritis, resulting in a lessened blood supply to the gland. Thus the same results are obtained as by removal, but with this difference, that with Roentgen treatment the amount of the secretions can be reduced to normal with accuracy, while the surgeon never knows exactly how much of the gland it is necessary to remove to accomplish the same results. The tachycardia receives the first benefit, even before there is any noticeable reduction in the size of the gland.

**11. Autoserotherapy in Fibrinoserous Pleurisy.**—H. M. Fisher states that to Gilbert of Geneva is generally credited the first suggestion of treating serous effusion into the pleural cavity by the injection under the skin of the patient of portions of his pleural serum, and at the International Congress at Rome, in 1894, this author reported a number of cases he had treated in this way and recommended its more general use on account of the good results he had obtained. A little later Enriquez and Gaultier explained and recommended the same treatment. Gilbert recommended the autoinoculation of one or two c.c. of the serum at intervals of one or two days and advised, in all, six inoculation. The results obtained from this treatment are, it is said, almost immediate sensations of relief, notably from dyspnea and oppression often observed within the first twenty-four hours, a great increase in the secretion of urine and, along with this, a marked and rapid diminution in the serous exudation, and lastly a complete resorption of the fluid, sometimes within six to ten days, sometimes more gradually. From a review of the literature of this subject the author concludes that there can be little doubt that autoserotherapy in serous pleural effusion does have in most cases a very distinct effect in decreasing effusions. Whether this is due to the absorption of the "specific antibodies from the effusion into the general circulation, or of autolytic products of cell metabolism"—the increased diuresis seems to be a fact proved by the experience of many careful observers. But, as eighty per cent. of all cases of simple fibrinoserous pleurisy show a tendency to spontaneous cure, it seems that the treatment might well be reserved for those cases where there have been repeated reaccumulations of the fluid after tapping. Paracentesis still seems to be the treatment necessary in cases of large effusions accompanied by great difficulty of breathing. The relief afforded to great and alarming dyspnea by autoserotherapy does not appear to be sufficiently rapid. If Schnutgen's observations as to the lessened danger of thickening of the pleura from fibrinous exudations where autoserotherapy is used, are generally confirmed, this treatment will probably be tried in many cases which would hitherto have been treated by paracentesis.

1. The Causes and Treatment of Chronic Backache. With a Consideration of the Diagnosis of Sacroiliac "Relaxation." R. W. Lovett.
2. The Use of Cholesterin Antigen in the Wassermann Reaction. C. W. Field.
3. Fatal Attack of Filarial Lymphangitis Simulating Bubonic Plague. I. G. Martinez.
4. Diseases Connected with Meckel's Diverticulum, with Especial Reference to Diverticulitis. J. P. C. Griffith.
5. Supraclavicular Anesthetization of the Brachial Plexus. A Case of Collapse Following its Administration. H Neuhof.
6. Best Methods of Discouraging the Activity of Inoperable Cancer. A Study of Heat in Cancer. J. F. Percy.
7. Deep Wound of the Brain. F. H. Gunn and H. C. Fairbrother.

**1. Causes and Treatment of Chronic Backache.**—R. W. Lovett makes a plea for a careful etiological study of each case of chronic backache or lameness of the back, and presents a classification which has worked out satisfactorily in practice. Cases are cited to show the variety of symptoms and the way in which treatment has or has not been successful. The populaar diagnosis of "sacroiliac relaxation" is commented on, and attention is called to the fact that adhesive plaster straps on the skin cannot possibly "immobilize" relaxed sacroiliac joints which at every step must bear the weight of the trunk as a downward thrust, and the fact that treatment of this sort often relieves symptoms is fair evidence that the diagnosis in such cases is incorrect.

**4. Meckel's Diverticulum.**—J. P. C. Griffith notes that localization of the pain and tenderness is not so often at McBurney's point as somewhat higher and to the right of the umbilicus, or even about it, or in some

entirely different regions. There is an area of puffiness or of firm resistance in this region. There is an absence or a slight degree of meteorism, at least early in the attack. There is blood in the stools and in the vomited matter. There is often an earlier appearance of an umbilical fistula, or of some malformation elsewhere in the body.

6. **The Effect of Heat on Inoperable Cancer.**—J. F. Percy points out the widening of the field of investigation regarding the vulnerability of the cancer cells to the effects of heat. It will be of particular interest to make further observations as to the relation of the reaction producing heat in the body, following the injections of toxins, serums and vaccines in the destruction of carcinoma. If the primary gross mass of cancer which is usually accessible can be rendered innocuous by raising the temperature through the medium of an electric heating-iron, and the remaining small amount of lymphatic involvement be reached by thermic-raising, artificially produced toxins, serums or vaccines, as is emphasized by Vidal, then the cure of cancer may be realized. Finally, it becomes necessary to develop the application of heat by a method which is at once efficient and harmless, and the author believes that he has done this by the technic which he has developed. He also believes that he has accomplished this in such a way as to make it highly probable that many forms of carcinomatous growths may be eradicated.

1. **Development of the Heart in Man.**—D. Waterston summarizes his conclusions as follows: In the first stage of its development the heart is a self-regulating organ. Its rhythmic activity is shown by peristaltic waves of contraction which sweep over it from end to end, and at this stage it possesses a continuous muscular coat. It is quite independent of the central nervous system. In the next stage, i.e., when the primitive chambers are being divided, a new mechanism arises in the form of a node of specialized tissue situated at the junction of the sinus venosus and the atrium, which node passes thence to the dorsal wall of the atrium and the region of the pulmonary veins. This is the first of the nodal tissues to appear, and is the precursor of the sinuatrial node of the adult heart. The *a.v.* bundle and node make their appearance about the time of the further division of the chambers of the heart, as a bundle of fibers lying under the posterior endocardial cushion of the atrial canal, and extending from the atrial wall to the ventricular muscular septum. The evidence goes to show that this bundle is derived from the tissue in which it appears, and that from the first it is surrounded by a sheath of loose connective tissue. Fibers and cells from the central nervous system invade this bundle and also go to other portions of the heart wall, but the intrinsic regulating mechanism appears to arise independently of the nervous system, and is connected only secondarily through that system with other parts of the body.

3. **Dietetic Disorders in Infants.**—E. Pritchard states that within recent years attention has been directed to a condition in infants which has been called rumination, in which a very tractable form of regurgitation or vomiting persists. It is supposed to be due to some abnormal or perverted coordination of the neuromuscular mechanisms of the esophagus. Cases of cardiospasm in infants are much more common than is generally supposed and the few published cases in no way represent the true frequency of the condition. Intractable vomiting is by no means common in infants, and may be due to obstruction to the onward flow of the food current at any point in the alimentary canal. The obstruction may be due to the persistent muscular spasms, or to other causes. Pyloric spasm is one of the commonest causes, if not the most common of vomiting of this kind. Diarrhea is often wrongly attributed to some indigestible quality of the food, when the true explanation is hypersensitiveness of the neuromuscular mechanism concerned in the locomotion of food through the intestinal canal, a condition commonly known as lienteric diarrhea. The author has observed many cases of diarrhea with so-called undigested curds in the motions which are regarded as due to indigestion, but which are in fact due to starvation. Diarrhea is often attributed to some fault in the character of the food, when the true etiological explanation is that the hypersensitive neuromuscular mechanisms of the bowel are stimulated into activity by some preceding event—as, for instance, by forcible sucking at a relatively dry breast or at some artificial nipple which is pierced with too small a hole. There are three common causes of constipation in infants, although the number of occasional causes is almost infinite. The common causes are :(1) dulling or disorganisation of the rectal reflex by previous overstimulation and exhaustion of the nerve centers (purgative medicines, enemata, suppositories, and previously existing diarrheas); (2) overfeeding, especially with fat, and (3) underfeeding (chiefly in the case of breastfed infants). So-called colic in infants is nearly always due to some spasm of a sphincter or of a group of intestinal muscles which interferes with the normal locomotion of food through the alimentary system.

6. **Operative Treatment of Exophthalmic Goiter.**—A. J. Walton states that of late years evidence has been accumulating as to the value of surgical treatment in cases of Graves' disease. This line of treatment is theoretically indicated owing to the evidence that has been brought forward in support of the following conclusions: (1) The disease is due to an excess of thyroid secretion. (2) The results of medical treatment are unsatisfactory. (3) The operative mortality is not necessarily high. (4) The results of surgical treatment are very satisfactory. (5) The danger of postoperative myxedema is slight. Success in operating to a large extent depends upon a careful consideration of the time at which the operation should be performed. In the more common varieties of the disease it is very important to realize that the symptoms show very considerable variation in their severity. If possible such cases must be watched and operative treatment carried out in one of the intervals between the exacerbations. In addition to this fluctuation in the symptoms the length of time that the disease has existed is also of importance. Plummer has pointed out that the greatest height of intoxication is reached during the latter half of the first year and then rapidly drops, so that operation is more likely to be successful if performed early in the disease or at a later period. The danger of performing operations on other parts of the body in patients suffering from Graves' disease must also be kept in mind. He regards right hemithyroidectomy as the operation of choice.

8. **The Influence of X-Rays on Persistent Suppuration.**—E. P. Cumberbatch two years ago tried the effect of *x*-rays upon a case of chronic suppuration of very long duration, which had resisted other forms of treatment, including surgical operation. The suppuration was arrested, the part was healed, and the cure has lasted to the present time. Three other cases of a similar kind were then treated, and equally good results were obtained. During the past year other cases have been treated with the view of investigating the action of the *x*-rays upon chronic suppuration, and the results show that this form of treatment has an influence upon its progress, lessening it in some cases, and in other permanently arresting it.

2. **Spasm of Cerebral Vessels.**—W. Russell discusses certain points bearing upon the blood circulation in the brain and upon phenomena due to disturbances of that circulation. Owing to the position of the brain within the cranial cavity, local disturbances of the circulation are difficult of proof; they can only be assumed from the clinical phenomena which may be present and from one's knowledge of the dependence of local function upon an efficient local blood supply. The special condition to which the author alludes is spasm-constriction of the arterial channels in localized areas of the brain; the term "cerebral angiospasm" is given to the condition. Although the cerebral vessels cannot be seen the vessels of the retina can be examined by means of the opthalmoscope, and it has been clearly established that angiospasm occurs in these vessels. Various observers have noted that a temporary loss of vision of one-half of the retinæ may be associated with marked diminution in the size of the retinal vessels corresponding to the blind field, and that vision returns with the relaxation of the constricted vessels and the reestablishment of the normal blood supply to the part. From these observations alone it is fair to postulate that corresponding constriction can take place in the arteries in localized areas of the brain. It is a well-established clinical fact that in migraine such disturbance of vision as has just been referred to is by no means uncommon, and that it can be shown to be associated with the change in the retinal vessels referred to. In migraine, however, there are other temporary phenomena which must have their origin in the brain. Of these perhaps one of the commonest is partial or complete loss of power of one side of the face, of one limb, or of both limbs on one side. Another set of phenomena may be explained on the same hypothesis, namely, the loss of memory of recent actions which ordinarily imply not only active volition but conscious volition. This set of phenomena is illustrated by what frequently occurs in old people. The next type of cerebral phenomena is characterized by a complaint of sleepiness, of entire want of energy, and of marked forgetfulness. Such symptoms are the result of grave disturbances of the circulation in certain brain areas.

4. **Epilepsy and Tuberculosis.**—B. H. Shaw states that a high epileptic ratio is constantly associated with a high tuberculosis incidence and vice versa. The death rate from tuberculosis amongst the non-epileptic is directly proportional to length of sanatorium residence, which does not obtain amongst the epileptics. The number of positive and suspiciously positive reactions to tuberculin amongst epileptics is 95 per cent. Only 50 per cent. of non-epileptic patients associated intimately with the epileptics show a similar reaction. Associated with a high ratio of epileptics in urban relatively to rural districts is a similarly high infantile and early childhood mortality from tuberculosis, convulsions, atrophy, debility, and marasmus and also a correspondingly high proportion of occupied married women, which it would be well for employers of female labor to bear in mind. Except in terminal cases of active tuberculosis, loss of weight is not a valuable criterion of the presence of tuberculosis in epileptics. It is contended that epilepsy may be an evidence of tuberculous infection in childhood, probably affecting the bronchial glands initially, and that the convulsions are due either to reflex irritation so set up or to the resulting toxemia acting on an unstable nervous system, either inherited or acquired. Further, the constantly recurring seizures not only establish a vicious habit as far as the nervous system is concerned, but also effect tuberculin autoinoculation, thus tending to keep the tuberculous process in check, so that instead of a fatal termination epilepsy results. Consequently, the advisability of carefully searching for tuberculous foci in children the moment epileptic fits develop, and also the immediate use of tuberculin in their treatment, should receive consideration.

5. **Strychnine-Tuberculin Treatment of Hospital Tuberculous Cases.**—J. H. Whelan has recently called attention to the good results obtainable in the different forms of tuberculosis by the combination of tuberculin and strychnine, the former given weekly, the latter practically daily, by intramuscular injection in large single doses. Since then he has given larger doses of strychnine with improved results. He gives the strychnine injections to all of his tuberculous patients, including cases in which tuberculous injections are contraindicated, with the best results. The author gives strychnine in acute and chronic cases, in the pyrexial and the apyrexial, in the early stages and in the most advanced, and with invariably good results. It always improves the appetitite and general condition. Patients who have a loathing for food soon regain their appetite under its influence. Strychnine will frequently do away with the painful necessity of adopting Debove's gastric lavage and over-alimentation. But the drug must be given by intramuscular or subcutaneous injection, preferably the former. Administered by the mouth it has not the same effects and in large doses will cause tormina and diarrhea, with possible disastrous results in advanced cases. These effects are never produced by the injection.

6. **The von Pirquet Reaction.**—A. J. B. Leckie arrives at the following conclusions: The cutaneous reaction is of no prognostic or diagnostic value. Results are more frequently obtained in women and children than in men. The older the individual the less likely is the reaction to be obtained, and old-standing lesions, as distinguished from advanced cases, usually fail to produce the reaction. Cases of rheumatism give more positive results than do tuberculous individuals. Late and early reactions have no clinical significance.

**Maize Poisoning.**—Gosio, chiefly in connection with pellagra, reviews the past and recent status of this subject. Recently two Americans, Alsberg and Black,

of the U. S. Department of Agriculture, have written on maize deterioration, with especial reference to certain forms of fungi found therein. In 1896 the author published his discovery of fungi in maize which can transform the fatty matter into aromatic substances, including a striking production of phenylic acid. Later he followed up the activities of the *Penicillium glaucum*, the fungus most extensively present. The product of the latter could be expressed by the element formula $C_9 H_{10} O_2$, representing the ferment-metabolic substance. With this were compared the products of cultures *in vitro* of the penicillium and similar fungi. These were found to be tetanisants for some small animals. The ferment product in maize, however, behaved negatively in this respect. The two Americans having taken up the work discovered in maize two special forms of penicillium, the *P. glaucum* evidently being absent. They cultivated these in Raulin's fluid, and in addition to the ferment substance isolated two acids. One, named penicillic acid, killed small animals under spastic phenomena. The other, or mycophenolic acid, was apparently inert. It therefore became apparent that certain fungi only might be responsible for maize poisoning—for example, the *Penicillium puberulum* of Alsberg and Black. There is, however, plenty of evidence to suggest that all the penicillia are essentially toxic, and that this property even pertains to the entire fungus family to which the penicillia belong. This toxicity is bound up in the metabolism of the fungi, but the metabolic products may show variations under special conditions. The toxic substances are termed collectively maize phenols, and the toxic phenomena in pellagra must be due to a specific intoxication. The character of the mouldy maize which permits the formation of these toxins, and the possibility of the anaphylactic factor are mentioned by the author.

**Experimental Rickets.**—Koch completes his serial study of this subject. Spontaneous rickets in animals shows that domestication and defective care are predisposing factors. In this respect rickets is comparable with tuberculosis. Caged animals appear to acquire rickets along with the effects of muscular disease, and doubtless autointoxication also results from confinement. But while all these facts exist, the author believes that some specific germ, or germs, is the essential cause. The latter have caused a mild type of infection readily overlooked. In other cases severe acute infection was apparent. The histological changes in the bones of rickets always suggest an inflammatory process. From another angle the analogy between rickets and articular rheumatism is marked, and the author has seen the two in combination. This suggests that some form of streptococcus infection may be responsible, by attacking the growing bones and disturbing ossification. In studying the evolution of rickets in animals, there appears to be a series of relapses of some mild infectious process with successive involvement of bones. This behavior is likewise common in chronic rheumatism. Future study along the lines of the author's theory ought to solve the infection problem.

**Diagnosis and Treatment of Pleurisy.**—Königer gives a collective review of this subject with especial reference to progress. The affection he regards as almost invariably secondary. Under symptomatic diagnosis there is not much actually new to record. Two triangles, the Garland and Grocco-Rauchfuss, have been isolated with especial respect to the routine physical examination and these seem to elevate percussion above auscultation, the latter giving many equivocal results. The *x*-ray is of especial value in incipient and localized pleurisy, notably the diaphragmatic and interlobular forms. Trial puncture needs no discussion. Under etiological diagnosis the author lays great weight on the history and general examination, with especial reference to the possibility of tuberculosis. A complex case suggests the latter. The pleuritic exudate, already mentioned as a symptom, must be carefully studied for its physical, chemical, bacteriological, serological, and histological qualities. Nevertheless, it is seldom that one finds an efficient cause, like a bacterium in pure culture. Animal inoculations, once so commonly practiced with scanty results, now give something like 80 per cent of positives if we wait for weeks, which, of course, is prohibitive in practice. Even the antiformin method of studying sediments may require hours to find a few isolated tubercle bacilli. Hence for one or another reason study of exudates is not practical; with rapid methods results are usually negative. Of greater significance is the cell count of the centrifuged effusion. The technique, despite the comparatively rapid results, is complex. A great abundance of lymphocytes suggests tuberculosis in an acute febrile pleurisy, but should the condition be chronic this lymphocytosis does not possess much diagnostic value. An excess of polynuclear leucocytes in recent cases is far from excluding the presence of tuberculosis. In empyema there are several well marked differences between the ordinary purulent and tuberculous forms, one of which relates largely to the fate of the leucocytes. The cytology of pleural exudates is too extensive a subject to be summed up in a few words. This study is more or less a side issue at best because advances in our technical resources for diagnosis seem to render the nontuberculous or rheumatic case the exception. We may, of course, temporarily assume that a given case which presents no immediate evidence pointing to tuberculosis is nonspecific and treat it symptomatically. If pus is evacuated for relief, it should, of course, be examined for tubercle bacilli. The author approves of the theory that the pleura is the natural protector of the lungs from the action of disease germs; for example recovery from tuberculous pleurisy causes a general recession of all the phenomena of tuberculous origin. In regard to treatment not much is to be said. In large effusions we have numerous surgical resources; but in certain cases of localized tuberculous pleurisy local treatment can be dispensed with, general measures being sufficient.

**Variola and Vaccination.**—Professor Bäumler cites epidemics of smallpox which have recently attacked communities where child vaccination and revaccination are not customary or compulsory. The immediate result was a scramble to be vaccinated, and sufficient vaccine could not be obtained until the epidemic had acquired momentum. Such an epidemic occurred in Sydney, N. S. W., in 1913, and still more recently Belgrade was visited. All the rigor of German vaccination cannot prevent the occasional slight outbreak of the disease in mild forms which are more or less difficult of diagnosis by the general practitioner. These episodes can be traced to visitors from foreign and nearby countries. Vaccination in early childhood, at puberty, and upon entrance into the army does not guarantee immunity throughout life. The protection during these growing periods may be lost in later life,

so that persons thus vaccinated still have to be isolated and again revaccinated after exposure. The latter may have been so extensive that even in small communities it is often difficult to control enough vaccine for simultaneous vaccination. To prevent such contingencies authorities and private practitioners must be on the lookout for imported cases, mild and masked cases, etc., so that the number exposed will be as small as possible. Measles and chicken pox are most frequently simulated. In the Sydney epidemic the disease was brought from Vancouver and was at first mistaken for chickenpox. Over 1000 cases developed during the delay in vaccination. The fact that there was no mortality was most striking, in fact unprecedented. Similarly benign variola has recently been seen in African epidemics in which vaccination had never been practiced. Naturally there is nothing new here, for the term varioloid has been used for decades to characterize these mild epidemics, whether the mildness was due to the *genius epidemicus* or to partial immunity from vaccination. In 1838-9 Sydney was visited by malignant smallpox.

**Tracheal Insufflation of Oxygen in Respiratory Paralysis.**—Leschke states that Volhard, a pioneer in this field gives priority to Moritz, who performed tracheotomy upon a case of poliomyelitis and forced ordinary air into the lungs with bellows. Volhard forced oxygen into the trachea rhythmically during an operation for otogenic abscess of the brain and as regularly drew it out. He thereby kept the blood oxygenated for nine hours, when the patient died of encephalitis. Brauer used the method successfully in morphine poisoning. The well known method of Meltzer and Auer was next introduced and used in pulmonary surgery, myasthenia gravis, etc., by Elsberg. This technique had not been tested in Germany until the author's operation. He describes at length how he deferred the death of a patient with Landry's paralysis after the use of the pulmotor had been discontinued. Under oxygen insufflation patient survived 30 hours and died a comparatively painless death, escaping the usual paroxysms of strangulation. The methods of Volhard and Meltzer may each be employed, according to the severity of the case. The indications are especially Landry's paralysis, bulbar paralysis, poliomyelitis, poisonings, etc., and in suspended animation from any cause.

*April 30, 1914.*

**Genesis of Interstitial Keratitis.**—Schieck mentions some of the interesting aspects of this condition—the alleged spirochete finds, the positive Wassermann and tuberculin reactions, the possibility of a traumatic factor, the extreme resemblance to experimental anaphylactic keratitis. Despite the title of the article the author has little to say of the clinical condition which is regarded as luetic in character, but deals chiefly with the so called parenchymatous keratitis commonly regarded as of scrofulous origin and hence presumably dependent upon tubercle toxins. If these affections are anaphylactic in nature, they could be due to various causes. The subject is also closely related to sympathetic ophthalmia the anaphylactic origin of which has long been discussed. To take a concrete example—suppose a man in apparently excellent health develops a parenchymatous keratitis. The Wassermann reaction being positive, we must conclude that latent syphilis is the original pathological factor. The same lesion, however, may appear when the Wassermann reaction is negative. Spirochetes have been found in the intact cornea. In a certain number of cases of keratitis tuberculosis is in evidence, and it can also impose itself as a metasyphilitic affection. The real evidence of anaphylaxis is seen only in experimental keratitis in the rabbit. Heterologous albumin when injected within the cornea causes first a transitory reaction and some days later an actual keratitis. The opposite cornea is sensitized because when treated in the same way keratitis develops at once, and the same is seen if a general injection is given. In the double keratitis in man syphilis antigen may be imagined as having sensibilized the cornea, so that the syphilitic antibodies in the circulation cause anaphylaxis. In the tuberculous subject a von Pirquet test may also cause anaphylaxis.

**Alcoholism in German Women.**—Röper states that alcoholism in woman is rare in Germany, the proportion to men being 1 to 20 or so. But more women become insane as a result of drink than men, which perhaps argues for a psychopathic substratum. The total number of all women studied was 38, of which the upper class was represented by 12, the middle class 19, and the lower class but 7. But 10 of the women had never married. There were 8 widows and 2 divorcees. But 6 owed their condition to the seduction of their occupation (waitresses, etc.). Of the 38 women 18 showed a marked psychopathic constitution, and 26 in all showed a hereditary taint. The subjects, in other words, are born with an inferior, invalid nervous system and tendency to psychoses. The opposite state is seen in many men who abuse alcohol to an unbelievable degree, whose viscera may not be intact but whose nervous system and psyche are not involved.

---

**Disappearance of Hypophysis with Fatal Exit.**—Simmonds relates an unusual case in a pregnant woman, who developed puerperal sepsis at the age of thirty-six. After her recovery she never menstruated again, never regained her strength, became decrepit, and suffered from vertigo and loss of consciousness. She lost much flesh and was seen to age rapidly. When forty-four, diagnosis was made of senium præcox. For years she went from bad to worse, dying finally in coma. At autopsy no vestiges of the hypophysis were found. There is enough evidence to show that the organ is sometimes attacked during septic processes. Its complete disappearance may be set down to necrosis. Hence, as a result of this loss of an organ actually indispensable to life, there set in the menopause, myasthenia, vertigo, and attacks of unconsciousness, senium præcox, death in coma.—*Deutsche medizinische Wochenschrift.*

**Myatonia Congenita.**—A. F. Hertz and W. Johnson report a case of this condition in a boy aged 3½ years, who has always appeared weak since birth. He is an intelligent boy, and he is able to talk quite well. He exhibits a general want of development and an extreme degree of atony of all the muscles of his body, no particular portion being worse than any other. Marked scoliosis is present. He has never been able to walk properly. His mother thinks that he is a little stronger than he was two years ago. At present he cannot stand without help. If made to sit up, his head cannot be held erect, but falls backwards. There is marked looseness in all the joints resulting from the atonic condition of the muscles. The arms and legs can be twisted into abnormal positions without causing discomfort. This is especially noticeable as regards the fingers, which can be bent backwards until the tips rest against the back of the wrist. The heels can also be put behind the neck. No tendon-jerks could be obtained in any of the limbs. No other members of the family are similarly afflicted.—*Proceedings of the Royal Society of Medicine.*

## Insurance Medicine.

### SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

#### THE EXAMINATION OF WOMEN.

THE importance of a strict examination and of careful selection of female risks has been made clear in the previous contributions in these columns (MEDICAL RECORD, May 9 and 23) in relation to the mortality and causes of death of women.

The conjugal state exerts a strong influence in determining the mortality list. Married women, especially when the husband is beneficiary, constitute a class in which every resource known in the science of life insurance examination should be drawn upon to prevent the powerful self-selection appearing in this group as compared with spinsters or men. It becomes the duty of an examiner, especially when the applicant is a married woman and is known to him, to give attention to the desirability of the risk, as indicated by the presence or absence of speculation upon her life by the husband or self-supporting children. One of the main points is whether she has the means to pay the premiums, or whether these must be provided by others, especially the beneficiaries. The probability of speculation or adverse selection in the case of spinsters is almost negligible as these applicants are usually self-supporting women who are anxious to provide for an aged parent or some other dependent.

In studying the causes of death, a noticeably higher mortality as a result of pulmonary tuberculosis is found among insured women as compared with that among men and, further, this mortality is higher among married women than spinsters. Speculation and adverse selection accounts for a large part of the difference among women. The variance in the rate between men and women, however, is due in a considerable degree to failure on the part of examiners to make as thorough examinations and to insist on as correct, unreserved answers as they would in the case of men.

The large proportion of deaths due to pregnancy and the puerperal state indicate that great care should be adopted in examining pregnant women and that rigid selection should be exercised by the medical directors in considering these cases. Some of the companies insure pregnant women, but they should not assume such a risk unless the woman has gone through at least one normal pregnancy, lives in a favorable environment, and it has been positively ascertained that there is no element of speculation or adverse selection.

The medical examiner will not accomplish his work satisfactorily when he fears that he will incur a woman's displeasure if he persists in securing full, complete, and unreserved answers to all questions on the blank, no matter how pointed they may be. He can carry out his task, however, with equal thoroughness whether the woman is an applicant for insurance or a private patient. If he fails to retain his composure and shows signs of nervousness, feeling that he has a delicate and unpleasant commission to perform, the woman will usually notice it and become ill at ease. If, on the other hand, he goes about his work in an easy, polite, and unconcerned way, courteously but firmly insisting on the fulfillment of every requirement just as he would do were the applicant a man, the woman will seldom be embarrassed or feel annoyed. As the writer has previously pointed out in another place, good judgment in forming and putting the questions is quite necessary. For instance, it would show a lack of common sense to bluntly ask a young, refined, delicate-minded unmarried woman if she is pregnant; yet this question appears on the blank and must be answered in every case whether the woman is married or single. This information may be secured easily in a negative way by obtaining a full history of her menstruations from her and the date of the last one. The history of child-bearing may be brought out in a similar way. The examiner should be careful after information, elicited in this way, has been recorded, to have the applicant read this part of the report and state if it is correct.

A woman often fails to recognize the fact that she will become party to a legal contract as soon as she signs her statements to the examiner. The examiner is expected by the company to protect its interest and, at the same time, to direct the efforts of the woman by preventing willful or unintentional misrepresentation due to her failure to realize the strict principles involved in the forming of a contract, and also to her very natural tendency to avoid the subject of diseases peculiar to her sex.

A strict rule, adopted by most companies, forbids the presence of a third person (even the husband) while the questions are being asked by the examiner, in order that the answers may be free without any restraint or influence. During the physical examination there is no objection to the presence of a third person. An interpreter may be necessary if the applicant is a foreigner and not familiar with the English language. In this event, the examiner must be careful and select an interpreter who is not related to the applicant and who has no pecuniary interest in the transaction.

The conditions for a thorough examination and the taking of correct measurements will be materially helped by having the applicant, previous to the examination, arrange her clothing in a way that will allow a ready and unobstructed inspection of the chest and abdomen. A loose gown of some light material, instead of the thick clothing usually found, will answer the purpose. The physical examination must be as rigid and painstaking as if the applicant were a man.

The chest measurements should be taken horizontally immediately below the axilla, avoiding the mammæ. The abdominal measurement should be taken at the waist line as well as at the level of the umbilicus, care being taken not to include the crests of the ilia. If the abdomen is large below this line, the examiner should ascertain whether it is merely adipose and pendulous, or whether there is a suspicion of tumor or pregnancy.

The urine must be passed at the time of the examination, or later if more convenient, under circumstances which leave no doubt in the mind of the examiner as to whom it was voided by. The applicant may go into an adjoining room which has been inspected by the examiner or the examiner may adjourn to a neighboring room temporarily. The specimen should be warm when received by the examiner. In no case should the urine be accepted when brought to the examiner by some other person.

If these various precautions are faithfully observed, the mortality in the early policy years should remain at the normal point.

# Book Reviews.

HANDBUCH DER TUBERCULOSE, in fünf Bänden. Edited by Prof. Dr. L. BRAUER, Dr. G. SCHROEDER, and Dr. F. BLUMENFELD. Vol. I., in 2 parts, 792 pp. Price 35 marks. Leipzig: Johann Ambrosius Barth, 1914.

THE first edition of this monumental work appeared in 1904 and was mainly devoted to the therapy of chronic pulmonary tuberculosis. In this first volume of the third edition the first chapter by Prödohl, of Hamburg, is an excellent historical review of the work that has been done in tuberculosis from the time of Hippocrates to the present day, including, of course, the latest bacteriological researches. In the historical enumeration of important tuberculosis gatherings it is, however, regrettable to note the omission of the last three great international tuberculosis congresses of 1905 in Paris, of 1908 in Washington, and 1912 in Rome. Tendeloo, Professor of Pathology of the University of Leiden, gives a masterly description of the pathological changes caused by the tubercle bacillus in all the organs of the body which may be invaded. Particularly instructive are some excellent illustrations of cutaneous tuberculous ulcers. It is interesting to note Tendeloo's conclusion that when carcinoma appears concomitant with a tuberculous lesion it is not in any way favorably or unfavorably influenced by the tubercle bacillus. In another chapter, Much of Hamburg describes the three types of microorganisms capable of producing tuberculosis—typus humanus, typus bovinus, and typus gallinaceus. The author rather cautiously admits the great probability of a morphological transformation of the bovine bacillus into the human type when he says: "Jedenfalls können wir, wenn wir ganz vorsichtig sein wollen, sagen, dass eine Umwandlung des einen typus in den anderen im hohen Grade wahrscheinlich ist." The very excellent chapter on immunization by the same author must be read to be appreciated; no review could do it justice. The last paragraph treats of Friedmann's method consisting in the utilization of living tubercle bacilli. Contrary to the results obtained in the United States, Much speaks rather kindly and encouragingly of Friedmann's work. He concludes by saying the results seem rather favorable.

Professor Martius, of Rostock, writes of predisposition and individual prophylaxis and makes a very readable chapter of it, without, however, offering anything that is not known and practised by students of modern phthisiotherapy. The article by Sanitätsrath Gottstein on the epidemiology of tuberculosis is very interesting. What has been known in a general way about the influence of occupation has been again substantiated by Gottstein's carefully compiled statistics. Damman of Hanover considers in detail tuberculosis in animals and the best method to combat it. He strongly advocates State supervision. The social combat of tuberculosis as carried on in Germany is interestingly described by Kirschner of Berlin, who is one of the privy councillors of the Ministry for Public Health.

The second portion of the first volume opens with a chapter on diagnosis by Brecke, who is director of the Sanatorium Ueberruh. It is an excellent review of what is known to-day of the physical means of discovering pulmonary tuberculosis. The newer methods of sputum examination are also described. The clinical interpretation of tuberculin reactions is treated by Ritter and supplemented by some very beautifully colored photographs showing the effect of local inoculation. Lorey, the Roentgen specialist of the Eppendorf Krankenhaus describes not only the best and safest method of taking a Roentgen picture of a suspected lung, but with the aid of 45 illustrations gives a most admirable interpretation of lesions which may be seen with the aid of Roentgen rays. If the subsequent volumes of this monumental work equal the first one in value, this handbook will rank as one of the best and most complete literary products on tuberculosis thus far produced.

SCROFULOSIS. By Prof. Dr. G. CORNET, Berlin and Reichenhall. Translated from the second German edition by J. E. BULLOCK, M.D., Assistant Medical Officer, the Eversfield Chest Hospital, St. Leonard-on-Sea. Price $5.00 net. New York: William Wood & Company, 1914.

THE author of this volume has rendered a distinct service to medical science in rescuing from oblivion the old conception of scrofulosis and in reestablishing it upon a firm clinical basis. He defines this condition as a complex of symptoms almost entirely confined to childhood and early youth, including such lesions as lupus, scrofuloderma, lichen, tuberculides, eczema, impetigo, chronic blepharitis and phlyctenules, middle-ear disease, chronic catarrh of the air passages, rhinitis, pharyngitis, bronchitis, hyperplasia of the tonsils, catarrh of the alimentary canal, and certain affections of the bones and joints. The qualities which distinguish the above manifestations from non-scrofulous phenomena of the same kind are their persistency, their frequent recurrence, and their multiplicity. The author delineates the following types of scrofulosis: (1) A tuberculous form; (2) a non-tuberculous form caused mostly by the staphylococcus or the streptococcus, and (3) a combination of the first two forms. In describing the tuberculosis type of scrofulosis the author takes up the subjects of the virulence of tubercle bacilli under the following headings: Attenuated virus, bacilli of human and bovine tuberculosis, and the significance of bovine infection, including the various types of the latter. A large section is devoted to the subject of the predisposition to scrofulosis. Chapter III. deals with the genesis of scrofulosis, the modes of infection and the microbic agents being described in full. The question of heredity is dealt with in a separate chapter. The symptomatology, diagnosis, prognosis, prophylaxis, and therapeutics are all given detailed consideration. An extensive bibliography of 74 pages, and separate indices of subjects and authors conclude the volume. There can be no doubt that the author has made a contribution of permanent value to medical science. As an authority on tuberculosis he is well fitted to discuss the subject of far wider scope and more fundamental importance—namely, the subject of scrofulosis. The translator has admirably acquitted his task.

DIAGNOSIS IN THE OFFICE AND AT THE BEDSIDE. The Use of Symptoms and Physical Signs in the Diagnosis of Disease. By HOBART A. HARE, M.D., B.Sc., Professor of Therapeutics, Materia Medica, and Diagnosis in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital; one-time Clinical Professor of Diseases of Children in the University of Pennsylvania; Author of a Textbook of Practical Therapeutics and a Textbook of the Practice of Medicine. Seventh Edition, Thoroughly Revised, Illustrated with 164 Engravings and 10 Plates. Price $4.00 net. Lea & Febiger, Philadelphia, New York, 1914.

IT would appear almost superfluous to add any commendation to what has already been written in regard to this work. The plan of approaching diagnosis from the viewpoint of the presenting symptoms instead of from the viewpoint of the different diseases is one which has served an admirable didactic purpose. Thus, the symptoms are taken up separately and the different diseases in which these symptoms are present are studied. The titles of the chapters give a fair idea of the scope of this work. These titles are as follows: The face and head, the hands and arms, the feet and legs, hemiplegia, speech, the skin, the tongue, mouth, pharynx, and esophagus; the thorax and its viscera, the pulse, bloodvessels, and blood-pressure; the abdomen and the abdominal viscera, the bowels and feces, the urinary bladder and the urine, the eye, chills, fevers, and subnormal temperatures; headache and vertigo, coma or unconsciousness, convulsions or general spasms, hiccough, vomiting, regurgitation, and the character of the vomit; cough and expectoration, pain, and tendon reflexes and muscle tone. The book is fully illustrated, mostly with photographic illustrations, and contains a number of full-page plates. The index is particularly complete. There can be no doubt that this book serves a distinct purpose both to the student and to the general practitioner.

ÉTUDE CHIMIQUE DU SÉRUM ANTITUBERCULEUX DE VALLÉE. Par le Docteur BOUREILLE, ex-Interne de la Maison de Nanterre, Directeur du Preventorium Antituberculeux du Boulevard Garibaldi. Nemours: Henri Boulog, 1913.

THE writer gives schemas of temperatures and weights noted for two, three, or four years, before, during, and after treatment with Vallée's antitubercular serum. He found the remedy a powerful aid to the beneficial action of the customary therapeutics, although it may occasionally provoke anaphylactic accidents.

Outlines of Greek and Roman Medicine. By James Sands Elliott, M.D., Ch. B (Edin.) Illustrated; price $2.50 net. New York: William Wood & Company, 1914.

This little history begins with a chapter on "Early Roman Medicine," and in the second chapter turns to Greek medicine, which he divides roughly into three periods. He seems to prefer the classification of Renouard, which he designates as "accurate and convenient." This divides Greek medicine into four periods: (1) The primitive, or that of instinct, beginning with mythology and ending with the destruction of Troy, 1184 B. C. (2) The sacred, or mystic period, ending with the dispersion of the Pythagorean Society, 500 B. C. (3) The philosophical period, ending with the foundation of the Alexandrian library, 320 B. C. This period is made illustrious by Hippocrates. (4) The anatomic period, ending with the death of Galen, about 200 A. D. From the first period whatever medical history has reached us seems to be purely mythological. In the second the name of Pythagoras predominates, as does that of Hippocrates in the third. We now are treading on solid ground and are dealing with the greatest name in medicine. By great good fortune "the writings of Hippocrates have been largely preserved to us, while those of his predecessors and immediate successors have been lost." Dr. Elliott believes that Hippocrates actually dissected the human body, and that after diagnosing the presence of fluid in the chest or abdomen by ausculatation and percussion he removed it by paracentesis (p. 29).

Probably the best chapter in the book is the one relating to Galen and his influence upon the development of the medical art. After him the deluge, and the gradual merging of medicine into the universal oblivion of the dark ages.

The book is well printed and illustrated. It is well adapted for reference, but is by no means "dry." It contains practically all the knowledge we have of Greek and Roman medicine, pleasingly presented, and will afford a few hours' agreeable reading to any thoughtful physician or to an educated layman.

The Home Nurse. By Dr. E. B. Lowry, author of "Herself," "Himself," "Confidences," "Truths," etc. Price $1.00. Chicago: Forbes & Company, 1914.

This book describes in simple language and with the avoidance of technical terms the ordinary duties of the home nurse. Only those fundamentals are considered without which no one should attempt to care for the sick. There are instructive chapters on nursing in special diseases and on what to do in emergencies. As the author is an authority on nursing and a lecturer on this subject in one of our leading medical colleges the instructions given may be depended upon as conforming to the best medical knowledge and practice. It is a book which can with safety be put into the hands of the laity.

The Unexpurgated Case Against Woman's Suffrage. By Sir Almroth E. Wright, M.D., F.R.S. Price $1.00. New York: Paul B. Hoeber, 1913.

When the cause of woman's suffrage is being so energetically advocated on every side opposition from so eminent a source as the author of this book is worthy of serious consideration. He believes that the influence of woman has caused man to leave unsaid many things on this subject which should have been said; that he has been held back by the taboo on all generalizations about woman and by the fear of offending her *amour propre*. John Stuart Mills is accused of being "not scrupulously conscientious" in dealing with the woman question. No such restrictions of frailties have hampered our author, and the charge of lack of candor can never be imputed to him. He arraigns woman's motives in claiming the ballot as not from public interest or philanthropy, but because of resentment that woman should be accounted by man as intellectually inferior, and reprehension of a state of society in which more money, personal liberty, more public recognition, and happier physiological conditions fall to the share of man.

The author, after reviewing the arguments adduced in favor of woman's suffrage and showing to his own satisfaction that they are based on false premises, lines up his arguments in opposition, basing them on woman's disability in the matter of physical force, her disability in the matter of intellect, and in the matter of public morality. He considers what he terms woman's secondary sexual characteristics, namely, intellectual immorality and limitations, the inability to generalize and to see things from other than a personal viewpoint, an insurmountable obstacle to her wise use of the franchise. Woman's suffrage in his opinion would imperil both the international position and the internal equilibrium of the State. His arguments are open to at least one of the defects with which he charges woman's intellect—lack of originality. They were brought up when the advisability of higher education for women was discussed and when the question of married women holding property and controlling their own wages was agitated; in fact, whenever woman has sought a new right or privilege.

The author diagnoses the case of the militant suffragist as "militant hysteria," due to lack of a husband, a home, and children, and prescribes as a remedy (apparently in all seriousness) the sending of the patients, 3,000,000 of them, to the colonies where desirable husbands and happy homes await them. The difficulties which the universal application of this remedy to other countries as well as to England involve the writer has refrained from attacking; neither has he suggested a panacea for the married women who are identified with the suffrage cause. He has set up a fine target for the invective of the suffragists, and will undoubtedly receive at their hands no more flattering criticism than he has bestowed. At the same time there is much truth in the book that should have a sobering effect on those enthusiasts who see in "votes for women" the cure for all social ills.

Die spastischen Erkrankungen des Verdauungskanales. By Prof. Dr. Karl Walko. Price 1.50 marks. Halle a. S.: Carl Marhold, 1914.

The author has the following to say in reference to permanent spasms of the esophagus and the cardia: "These require the use of dilating sounds or apparatuses. It is advisable to treat these spastic contractures with bougies of increasing size, especially by means of the dilating balloon sound of Geisler-Gottstein or one of its modifications, possibly with simultaneous gastrotomy. For the same purpose, we may use Schreiber's dilating sound and Einhorn's metal dilator for the forced stretching of the cardia.

"By circular contraction of its muscles the stomach may simulate a stenosis in the *x*-ray picture or may intensify actual stenosis already present. Intermittent or spastic hourglass contraction, according to the view of nearly all observers (Rieder, Faulhaber, Haudek, de Quervain, Stierlin, etc.) is of great diagnostic value in cases where ulcer is clinically suspected and where from the constant circular spasms we may assume the presence of fresh or recent ulcers."

The book can be recommended in every way.

Archiv für experimentelle und klinische Phonetik (Supplement zu Passows und Schaefers Beiträge.) Herausgegeben von Prof. Dr. J. Katzenstein. Price, per volume, 24 marks. Berlin: S. Karger, 1913.

The articles to be published in this work will be reports of exact researches in the province of experimental phonetics, together with pedagogical articles and linguistic discussions. In the first volume there is an entertaining article by Dr. Catharina von Maltzen on the recognition of successively given musical intervals in the extremely high tone region, one on the measurement of breath volume in speaking and singing by Prof. R. du Bois-Reymond and Prof. Dr. J. Katzenstein, and a psychological contribution to phonetics by Dr. Wolfgang Köhler.

Die Roentgendiagnostik der Magenkrankheiten. By Dr. M. Faulhaber. Price 3 marks. Halle: Carl Marhold, 1914.

In reference to gastric ulcer the author says: "X-ray examination cannot show every ulcer of the stomach and a negative finding cannot exclude the presence of a gastric ulcer." As to the differential diagnosis between penetrating and non-penetrating callous ulcer, he says the following: "Larger deposits of barium, lying considerably outside of the stomach, having no visible connection with it, mean penetration, especially if gasbubble and division into three layers are visible and if the barium shadow remains after emptying of the stomach. Small deposits connected directly with the stomach without gasbubble that disappear promptly with the emptying of the stomach speak for a non-penetrating ulcer."

The book, now in its second edition, can be highly recommended as a help to the general practitioner in the interpretation of *x*-ray plates of diseases of the stomach.

# Society Reports.

## ASSOCIATION OF AMERICAN PHYSICIANS.

*Twenty-ninth Annual Meeting, Held at Atlantic City, May 12 and 13, 1914.*

THE PRESIDENT, DR. SIMON FLEXNER, IN THE CHAIR.

**President's Address.**—President FLEXNER said the extension of the boundaries of knowledge had been such that it had compelled medical colleges to become departments of universities. This rapid extension of knowledge coincided with the active pursuit of physiology, pathology, bacteriology, and pharmacology, either alone or in association with clinical studies for which special laboratories and institutes came to be established. Independent institutions for medical research had exercised a distinct influence on medical practice, but the foundation of these institutions was impossible until medical schools furnished an adequate supply of students whose training approximated that of the older European countries. All these conditions had acted more powerfully on clinical teaching. The professor of medicine in the university medical school had ceased long ago to be a general practitioner. The function of the clinical teacher had been newly defined within one or two decades. The Association of American Physicians had sympathized with every movement affecting the progress of medical education, and it favored this later step with the single hope, if it was in the real interest of medical progress, it might be given a chance to succeed.

**Chronic Interstitial Gastritis.**—Dr. JOSEPH SAILER of Philadelphia reported a case of chronic interstitial gastritis in a male, 45 years of age, who had been subjected to various forms of medical treatment, but none of them was of any avail. Dr. Deaver performed an exploratory operation and found the condition of the stomach entirely in accord with the clinical picture. The stomach walls were very thick. The stomach was adherent posteriorly and around the pylorus. The adhesions were released, and the stomach wall found greatly thickened. Dr. Deaver believed that gastroenterostomy would have been difficult, in addition to giving no definite relief. There were no enlarged glands along the lesser curvature, but the adhesions were dense along the greater curvature, and a definite gland mass could not be felt. There was no evidence of metastasis. The abdomen was closed and the patient made a satisfactory recovery from the exploratory operation.

Dr. DAVID RIESMAN of Philadelphia stated that with the *x*-ray we were not able to distinguish between the malignant and nonmalignant types of what was called leather-bottle stomach. This distinction could only be made by clinical observation. Recently he saw a typical case of leather-bottle stomach which was very malignant, because the patient had cachexia and ascites. Both of these conditions in this case were sufficient to determine that the condition was cancerous. The man died in a few weeks. There were no evidences of metastases in the lever, and the liver was not enlarged at any time. Another case that came to autopsy showed no metastasis from any of the viscera, but marked enlargement of the glands along the greater curvature of the stomach.

**The Nature of Peristalsis and the Action of Magnesium Sulphate.**—Dr. S. J. MELTZER of New York City advanced two assumptions. One assumption made upon the basis of experimental facts was that peristalsis was a complicated condition in which the phenomenon of inhibition played an important part, and the second was, that magnesium sulphate acted by affecting this inhibitory force.

**A Clinical Study of One Thousand Cases of Cancer of the Stomach.**—Dr. JULIUS FRIEDENWALD of Baltimore presented a clinical study of 1000 cases of gastric cancer. The cases occurred in 10,416 patients, affected with various gastrointestinal disturbances. The maximum liability to the disease occurred between the fortieth and sixtieth years. The greatest proportion occurred in males, 588 to 412 females. An hereditary history of cancer appeared in 9.4 per cent. of cases; a history of trauma in 1.9 per cent.; anemia was present in 82 per cent. Chronic endocarditis was present in 11.4 per cent.; arteriosclerosis in 69.6 per cent. A history of former indiscretions in diet was obtained in 32.1 per cent.; of alcoholism in 15.2 per cent.; syphilis in 7.9 per cent.; hyperchlorhydria in 4.9 per cent.; hypochlorhydria in 2.8 per cent.; anacidity in 89.2 per cent. Lactic acid was present in 81.9 per cent. Dysphagia existed in 6.9 per cent. of all cases. Loss of weight existed in 88.5 per cent. Anorexia was present in 89.3 per cent. Vomiting existed in 89.3 per cent. Occult blood was present in the stools in 92.5 per cent. Masses in the form of tumors were detected in 71.9 per cent. Dilatation of the stomach existed in 46.7 per cent. Perforation occurred in 2.3 per cent. Metastasis existed in 67.2 per cent. Operations were performed in 26.6 per cent.

**When and How To Use Tuberculin Preparations in Private Practice.**—Dr. S. SOLIS-COHEN of Philadelphia in his paper with this title dealt with pulmonary tuberculosis only. The disastrous results of the early use of tuberculin were owing to (1) crude dosage; (2) unsuitability of cases.

(1) Dosage. Correct principles were established by Trudeau. The opsonic index of Wright marked a further advance. Latham's method of administration by mouth, with parallel temperature curve and opsonic index guidance, demonstrated the full trustworthiness of the temperature curve alone, and simplified the procedure. The following was the author's modification of Latham's method: tuberculin residue (T. R.) triturated with milk sugar was given with skim milk, whey or beef juice. The initial dose, he said, was one one-millionth of a milligram. Both subjective and objective symptoms of reaction were watched for. The dose was repeated once or twice weekly, according to result. It was gradually increased by increments of one one-millionth of a milligram to the reaction point, and then dropped one point lower, and so continued for some weeks. Later, a further increase was attempted, and if reaction was not shown, was proceeded with in a similar gradual way. The arbitrary increment of one one-millionth of a milligram was maintained during this remittent progression until one ten-thousandth of a milligram had been reached. After that, the increment might be raised to one one-hundred-thousandth of a milligram. Thus by successive stages a maximum dose was attained at a point determined for each individual by all the factors in the case, including the rapidity of the increase, character and intensity of reaction, and maintenance of tolerance, as well as the local and general signs of improvement. The treatment was continued with intermissions, for many months, and may be resumed, if necessary, from time to time over a period of years.

(2) Selection of cases. In the majority of advanced cases, according to present knowledge, tuberculin was likely to be harmful. Experienced observers might employ it cautiously under conditions that seemed to call for its use, but others should avoid it, especially in cases showing a tendency to continuous fever, or in which there was, or had been recently, active softening. In the great bulk of early cases it was needless. Under proper treatment, medicinal as well as hygienic, recovery would take place without it. Its field of action was in the treatment of cases which (1) had not passed beyond the stage of infiltration and which (2) had shown a certain degree of improvement under proper food, fresh air, judicious rest and exercise, and other approved measures, including the right drugs, but in which (3) improvement became sluggish or ceased, or retrogression took place. The slight additional stimulus afforded by an appropriate tuberculin preparation administered at well-chosen times, and in correct dosage, would often reawaken the defensive and restorative processes of the organism and be follower by complete recovery.

Dr. ABRAHAM JACOBI of New York City had used tuberculin in doses of from one-hundred-thousandth of a milligram up to one five-thousandth of a milligram, and had never seen any unpleasant symptoms. He had given it in combination with other agents. His routine treatment in chronic cases of pulmonary tuberculosis consisted in the internal administration of guaiacol and arsenic with tuberculin, and he had observed no disagreeable symptoms which he could attribute to the tuberculin.

**Splenectomy for Pernicious Anemia.**—Drs. WARREN COLEMAN and JOHN A. HARTWELL of New York reported a typical case of pernicious anemia that grew steadily worse in spite of four months' treatment with arsenic, iron, hydrochloric acid, and four transfusions. Splenectomy was performed as a last resort. Ten weeks later, January 13, neosalvarsan was administered. The use of neosalvarsan made it impossible to

draw any conclusion as to the effects of the splenectomy except in the interval before its administration. In this interval there was no evidence of more than temporary improvement. At the present time, April 24, six months after the operation, the patient, while looking better and feeling better, is just beginning to sit up.

**Studies in Pernicious Anemia.**—Dr. HERBERT C. MOFFITT of San Francisco had been able to collect 31 cases of splenectomy for pernicious anemia from the literature, and he reported eight which were done in San Francisco, one in his own service. The results from splenectomy had been variable. In eight cases death resulted either immediately or soon after operation. A number of other cases had not been improved. In still others reported in the literature surprising improvement had taken place. In his own case, paresthesia, which was obstinate before operation, disappeared at once afterward. There were other striking changes in the blood regeneration which followed soon after operation in many cases. He had had opportunity to study the spleens after operation in eight cases, and the picture was practically the same in all. Contrary to clinical observations, the weight of the spleen was considerably greater than normal, varying from 450 to 500, and from that point down to 350 to approach the normal of 280. Most observers recorded the size of the spleen in pernicious anemia as not increased, while operative results showed the spleen was considerably larger than normal. The recent work on splenectomy should not detract attention from the ultimate causes of the disease. The author mentioned some time ago the similarity between pernicious anemia in man and pernicious anemia in animals, such as horses. Since that time he had had opportunity to observe some cases in animals and to make sections from the liver and spleen in certain cases. The microscopic appearance of the spleen and liver in these cases was that noticed in the organs removed at the operation for pernicious anemia. From a spleen removed in January an emulsion was made and injected hypodermically into a horse, with no change in the anemia. The operation of splenectomy in horses was difficult. Many arteries went into the spleen and possibly the operation could not be successfully done. He had in mind tying the arteries of horses whose spleens were affected with pernicious anemia, and it would be interesting to observe whether, as in human cases, cutting off the circulation in horses would have any effect in stopping hyperhemolysis, which is characteristic of the disease in animals as it often is in human beings.

**Studies in Experimental Arteriosclerosis.**—Dr. I. ADLER of New York City presented a preliminary report summarizing briefly the results of some experiments on dogs that he had carried on for some time. Dogs were injected, partly intravenously, partly subcutaneously, with various substances, such as adrenalin, nicotin, lead, diphtheria toxin, pure cultures of different species of bacteria, all with absolutely negative results. In a further set of experiments dogs were fed with a number of substances, under varying conditions, and it was believed that some positive results were obtained, so that the aorta in some cases showed lesions which both microscopically as well as histologically were closely analogous, if not absolutely identical with human arteriosclerosis.

**Mitral Stenosis.**—Dr. R. C. CABOT of Boston related his observations on 200 cases of mitral stenosis before and after death. His studies had impressed him with the fact that mitral stenosis fell into four clinical groups: 1. The cardiac group, in which the symptoms were apparently mechanical, such as stasis, etc. 2. The septic group, in which the symptoms were those of an acute infectious disease. 3. The embolic group, in which out of a clear sky embolism of the brain or periphery appeared. 4. That group in which there were no symptoms whatever, and the patient died of some other disease or after an operation and the pathologist found mitral stenosis after death.

**Case of Recurrent Fever in Aortic Aneurysm.**—Dr. ALEXANDER MCPHEDRAN of Toronto reported the case of a woman, aged 36, of irregular life and habits, who entered the hospital October 18, 1913, complaining of pain in the right chest for about six weeks. She had recurrent fever about every seven or eight days. The aortic arch was dilated and showed a pulsating aneurysm in the first left intercostal space. The temperature became normal and remained so in January, and her general condition improved very much. She was treated with iodides, mercury, and salvarsan.

**Patent Ductus Arteriosus with Infective Pulmonary Endarteritis.**—Drs. W. F. HAMILTON and MAUDE E. ABBOTT of Montreal reported this case and drew the following conclusions: (1) This case illustrated in a remarkable manner what hitherto had not been fully emphasized, namely, that a vegetative process was commonly associated with congenital cardiac defects. (2) These vegetations in the present case, and probably in the majority of such processes occurring in conjunction with cardiac defects, were not a simple thrombosis of mechanical origin, with secondary infection supervening, but from their onset were inflammatory in character, the result of an invasion of the vessel wall by infective organisms at the seat of maximum strain. (3) The inflammatory process present in this case manifestly did not arise as a result of an embolic infection through the vaso vasorum, but began by the invasions of the intima at a single point, the pulmonary end of the ductus, which was probably the seat of maximum strain from the two combined causes, the eddying blood stream within its lumen, and the rigid calcareous gland which lay in close juxtaposition without. (4) The present, so far as they knew, was the only recorded case in which the ductus and pulmonary artery in the neighborhod were the sole seat of the disease and in which the pulmonary orifice of the ductus had been demonstrated to be the initial seat of the lesion.

Dr. W. S. THAYER of Baltimore had had a case very closely similar to the one related in which there was an increased area of dullness in the second and third interspaces, a thrill, and a prolonged murmur beginning in sympathy and lasting over diastole with an accentuated second pulmonic sound. The diagnosis was open ductus arteriosus. As time went on the patient developed paralysis of the left recurrent laryngeal nerve. The patient was sent to a well known radiologist who took an *x*-ray and in sending the plates back wrote a letter in which he made an exact diagnosis of the condition from his standpoint, stating, "this is an instance of mitral stenosis with dilatation of the left auricle, and pressure upon the recurrent laryngeal nerve," but it did not occur to the radiologist that there were other methods of making the diagnosis.

Dr. ABRAHAM JACOBI of New York City said that he had observed a baby only a few months old who was now a boy twelve years of age. His ductus had been closed nearly three years. The speaker saw him once or twice every year and always found the same symptoms, the murmur getting less and less marked until finally it disappeared not only from the carotids but also from the pulmonary artery from below up.

**Certain Tests of Renal Function.**—Dr. W. S. THAYER of Baltimore related eighteen instances of severe advanced chronic nephritis, and concluded that where he had been able to correlate the anatomical and clinical observations they tended to fortify and to verify his previous opinion that the phthalein test was a reliable one of considerable diagnostic and prognostic value, especially in the study of chronic nephritis.

Dr. CHARLES F. WITHINGTON of Boston reported several cases of nephritis. One of the patients, a man brought into the hospital unconscious, showed unmistakable symptoms or evidence of acute nephritis. There was a history of convulsions and of his being comatose. Twenty-four hours after he was brought in the phthalein output was 70 per cent. His condition proceeded to clear up and he went out about two weeks after he was brought in, showing a surprising phthalein output, although manifesting signs of nephritis.

Dr. JOSEPH L. MILLER of Chicago stated that a man came to the hospital, not very ill, in whose case a definite diagnosis of chronic interstitial nephritis was made. He was passing 2,000 c.c. of urine a day. He could not get a trace of phthalein through in two hours. In forty-eight hours and up to the time he went into coma, he passed a large amount of urine, and at the end of that time went into coma and died. Autopsy showed a high degree of interstitial nephritis.

Dr. THAYER said there were many instances of hydropic nephritis with very few grave subjective symptoms excepting the hydrops. One found sometimes large quantities of albumin and casts in the urine, yet there was perfectly normal renal function if we estimated it by these tests, excepting the question of salt retention.

**Syphilitic Nephritis.**—Drs. ALFRED STENGEL and J. HAROLD AUSTIN of Philadelphia in a joint paper stated they had examined the urine with the polarizing microscope fifty-eight times from forty-six cases. Of these

forty-six twenty-three showed nephritis with an abundance of albumin and casts in the urine. Of these twenty-three cases six had positive Wassermanns, three had strong presumptive evidence of syphilis, but no positive Wassermanns; fourteen had not the slightest evidence of syphilis. The six cases with positive Wassermanns all showed lipoids in the urine. The rest of the forty-six cases studied were made up in part of nephritis cases of the interstitial or arteriosclerotic types, with only traces of albumin in the urine and a few hyaline and granular casts, some with syphilis and some without, any number of cases of syphilis but with no nephritis, and any number of control cases with neither syphilis nor nephritis. None of these cases showed lipoids in the urine. One of the six syphilitic cases with nephritis showing lipoids in the urine had not received any mercury. They found of further interest the fact that of their last eighty-four cases of nephritis for forty-six cases there could be recognized from the histories such accepted etiological influences as infections, lead, alcohol, excessive work, exposure, senility, etc., but that for eighteen cases no such factors could be determined. Of these eighteen cases there existed in eight either an unquestionable history of syphilis or a positive Wasermann or both, and in six more of these cases no Wassermann had been secured. In order to determine whether the common experimental degenerative nephritides of animals would be associated with lipoids in the urine three rabbits were given uranium nephritis and one dog a chromate nephritis. The four experiments were negative; no lipoids were found in the urine. Further experiments with mercurial nephritis, phosphorus and chloroform lesions and syphilitic inoculations were in progress.

**X-Ray Evidence in Early and Latent Cancer of the Stomach.**—Drs. Franklin W. White and Ralph D. Leonard of Boston said their material consisted of 114 hospital and private cases suspected of having cancer of the stomach thoroughly examined within a year by clinical and *x*-ray methods. In forty cases cancer was proved; in sixty-six it was ruled out; in eight the diagnosis remained doubtful. The group of cases was studied to determine how far the *x*-ray evidence had helped to detect early or latent cancer. Recent cases were chosen because of recent improvements in *x*-ray technique. The *x*-ray evidence in early cancer was very scanty; in latent cancer it was abundant and important. In the group of operated cases of cancer a comparison of correct diagnosis before and after *x*-ray examination showed the latter distinctly higher.

**The Pathological Evidence of the Relationship between Gastric Ulcer and Gastric Carcinoma.**—Dr. Louis B. Wilson of Rochester, Minn., stated that any existing disagreement as to the relationship between gastric ulcer and gastric carcinoma depended on (1) failure to understand the pathological data; (2) inappreciation of the bearing on the clinical data; (3) failure to appreciate the correlation existing between the two. Small gastric ulcers were usually simple and large cauliflower cancers usually showed little evidence of previous ulceration, but between these two lay a large group of ulcerated lesions of the stomach, some of which were ulcers only and others of which resembled ulcers in all respects, except that in addition they also showed cancer. So far as the pathologist was concerned he could not positively distinguish, in many such specimens, between simple ulcer and ulcer plus cancer, except with a microscope. When in such a specimen showing cancerous areas no cancer cells were found in the base of the ulcer one was warranted in assuming that the ulcerative lesion preceded the cancer. A review now in progress of all the tissue removed from the stomach and duodenum in the Mayo clinic since 1905 showed that approximately 60 per cent. of the specimens which showed cancer gave more or less pathological evidence of the precedence of ulcer in the same area. Of the specimens of gastric tumors examined pathologically and diagnosed either cancer or cancer on ulcer there was agreement between the clinical diagnosis and the pathological diagnosis in more than 80 per cent. of the cases.

**The Inspiratory Exaggeration of the Dicrotic Wave in Pericarditis.**—Dr. Albert E. Taussig of St. Louis, Mo., stated that ordinarily, the dicrotic wave in the radial sphygmogram did not vary in size with the phase of respiration. In pericarditis, however, it became more or less exaggerated, sometimes greatly so, during inspiration. In all the cases studied from this point of view, the phenomenon was seen. Anatomical considerations rendered its occurrence readily explicable. It might have diagnostic significance.

**Intrauterine Amputation.**—Dr. George Dock of St. Louis, Mo., reported a case bearing on the pathology of so-called congenital amputation with *x*-rays and photographs.

**The Etiology of Some of the Infective Tropical Granulomata.**—Dr. Richard P. Strong of Boston stated that among the infective granulomata which occurred more commonly in certain tropical countries, which were perhaps of unusual interest from an etiological point of view, were verruga peruvinia, ulcerating granuloma of the pudenda, and frambesia. The relation of these forms to one another was considered. Verruga peruvinia and oroya fever had been considered to be merely different stages of the same disease, oroya fever having been regarded as the initial stage of the granulomatous verruga stage. The two diseases, however, were quite distinct and had a very different etiology. Verruga peruvinia was due to a virus which might be transmitted to some of the lower animals, while oroya fever owed its origin to a parasite of the red blood corpuscles. The two diseases also had a very different pathology. The etiology of ulcerating granuloma did not seem to be definitely determined. In view of the recent work in the transmission of the virus of verruga to some of the lower animals, it was recommended that more extensive experiments be carried out with the idea of transmitting ulcerating granuloma to monkeys.

**A Differential Study of Coccidioidal Disease and Blastomycosis.**—Drs. P. K. Brown and W. T. Cummins of San Francisco stated that cats and white rats were found to be markedly insusceptible to infection. Rabbits and guinea pigs appeared to be somewhat more susceptible to coccidioidal than blastomyecetic infection. Coccidioidal involvement was noted in two rabbits, while the cerebrospinal tissues remained unaffected in all animals in advanced disease. Passage through animals exalted the virulence of the organisms. Highly acid and alkaline agar offered but little inhibition to the growth of the organisms. There was profuse aerobic growth in, but no fermentation of, eighteen sugars. Fifty dyes were studied for their inhibiting effect upon the growth of the organisms. Crystal violet was found to be the most inhibitive and in concentration forty times greater than the minimum inhibitory dose, was not toxic for guinea pigs and white rats. They discussed the differentiation of the two diseases clinically, pathologically, and bacteriologically and by animal experimentation.

**The Influence of Benzol Inhalations on Experimental Pulmonary Tuberculosis in Rabbits.**—Dr. William Charles White of Pittsburgh stated that benzol C.H. was the best solvent for the fat portion of the tubercle bacillus. It extracted a greater percentage of fat than any other single solvent would take from the bacillary substance. Because benzol could be easily vaporized and utilized as an anesthetic, it was thought possible in this way to dissolve living tubercle bacilli after their entrance into the pulmonary capillary system by way of the ear vein and before the formation of the tubercle. It was hoped in this way to obtain a solution of all the living portions of the tubercle bacillus within the body and the possible development of a retardation of the process produced by a fatal dose of tubercle bacilli and the establishment of an immunity to a further dose of the organism. Contrary to the desire expressed in the theory, he found that in every instance whether the infecting tubercle bacilli were of low virulence or of high virulence, the resulting infection in rabbits was very much more severe in those treated by inhalation of benzol than in those infected with the same weight of infecting organism. The symptoms produced in rabbits by the inhalation of benzol were similar to those described by Torald Sollmann for the inhalation of gasoline vapors. Animals might be given benzol inhalations, 5 c.c. every second day for periods up to three and even four weeks without resulting in death. The resulting leucopenia varied very much, the lowest white cell count was 3,800 per cm. The red cell anemia was very variable, the lowest in our series being 3,600,000 per cm. The majority retained a normal red cell count. The blood smears and counts exhibited changes similar to those described for the injections of benzol by Selling and others. In all thirty-three animals were used; twelve controls and twenty-one treated. The pathological findings in many of these animals were very striking. In 30 per cent. of the treated animals, after receiving 5 c.c. inhalations of benzol every second day for three weeks, and

then being allowed to live two to three weeks longer, extreme enlargement of the spleen was found. In one instance the spleen measured 13 x 3.5 x 3 cms., and the circumference of its largest part was 9.5 cms. There was a large hemorrhage in the substance of this pleen. There was in all twenty-one treated animals but a single case of purpura with hemorrhages into the mucous membrane of the stomach and bowel. There were marked fatty changes both in the liver and the kidneys of the treated animals.

**Some Relations of the Brain and of the Olfactory Apparatus to the Processes of Immunity.**—Dr. HENRY SEWELL of Denver, Colo., drew the following conclusions from his experimental work on this subject: (1) Guinea pigs sensitized to horse serum may be desensitized by residence in a horse stable. (2) It was probable that this reaction might be rapidly achieved through the olfactory sense or more slowly by absorption through the respiratory membrane. (3) The period of anti-anaphylaxis was of less than two days' duration. (4) The converse of this, sensitization of normal guinea pigs in stable air he had not been able to achieve. (5) Removal of part of the brain of a sensitized guinea pig produced much more severe shock than the same amount of injury in a normal animal. (6) This shock was apt to be followed by a period of anti-anaphylaxis of short duration. (7) Section of the olfactory nerves within the cranial cavity preceding the brain operation by a day or more abolished the tendency to shock. (8) Such nerve section in the normal animal also seemed to reduce the shock arising from definite brain injury. Depression of the olfactory sense through cocaine and the resemblance of symptoms from poisoning with this drug to those of anaphylaxis were discussed. The body as a whole might be sensitized through the peripheral application of horse serum after a definite latent period which did not seem to be affected by previous general sensitization.

**The Normal Amount of Diastatic Ferment in the Urine and Feces and Its Variation in Diseases of the Pancreas.**—Dr. THOMAS R. BROWN of Baltimore stated that from his study of the diastase-content of urine and feces in normal and in certain pathological conditions, the following conclusions could be drawn: (1) In healthy individuals the diastase-content of the urine falls within quite definite limits. Markedly small amounts of this ferment in the urine, in the absence of renal changes, were suggestive, although not diagnostic, of pancreatic disease, but the real value of these normal limits would probably be in furnishing criteria in testing the renal function by the diastase output of the urine. (2) The stool, if rigorously exact methods are carried out as to food (milk), purgative employed, preservation of specimen, estimation of ferment, etc., also furnished a content within definite limits. He could not insist too strongly upon the procedure being exactly the same in all cases. The effect of waiting too long after the stool had been obtained before making the examination, the influence of variations in temperature in the place where it was kept, and of different laxatives and different foods, was so great as to render the results obtained by methods in which insistence upon such a rigorous technique had not been made of much less value. (3) Extensive carcinoma of the pancreas showed no diastase in the tube of least dilution in his method, and this absence of ferment should prove of help in the diagnosis of this condition. (4) In chronic pancreatitis diastase was present in the stool, but in markedly diminished amounts. (5) In achylia gastrica the diastase-content of the stool was practically normal in all the cases examined. This, in the first place, suggested that in the absence of hydrochloric acid some other method of pancreas invasion was called into play; and, in the second place, that the diarrhea met with in certain of these cases of achylia gastrica—the so-called gastrogenous diarrheas—was not of pancreatic origin. (6) If all the controllable factors were standardized, the results obtained by the study of the diastase-content of the stool should be of real value in the diagnosis of pancreatic disease and in the study of functional disturbances of this gland.

**Aconite as a Vasodilator.**—Dr. WILLIAM HANNA THOMSON of New York City stated that after many years of experience in the use of aconite in chronic interstitial nephritis, he regarded it as the most efficacious vasodilator which we possessed, when given systematically in full doses. Aconite thus administered reduced, at once, the blood pressure, produced a full and compressible pulse, and greatly increased the percentage of the elimination of urea in interstitial nephritis. The most important action of aconite, when administered in interstitial nephritis, was to increase the elimination of urea. The beneficial effects of aconite were particularly pronounced in mental derangements of the nature of melancholia with high blood pressure.

**The Subcutaneous Administration of Oxygen as a Therapeutic Measure.**—Dr. JOHN MCCRAE of Philadelphia stated that he had used oxygen in this way for the last two or three months and believed it was the rational method of administering it, and properly placed, it was useful. He had had occasion to employ it in a surgical case which had a severe operation. The patient loked as though he might die in a short time. His respiration was 60; he had extreme edema of the lungs, extreme pallor, profuse perspiration, and signs of impending death. With repeated injections of oxygen the man recovered. He had used oxygen in thirty cases and believed it should be a part of the armamentarium of the surgical operating room.

**Infectious and Toxic Forms of Transverse Myelitis.**—Dr. B. SACHS of New York City reported five cases of complete transverse myelitis. Of this number, four recovered completely, and one proved fatal. The first of these cases he reported two years ago with the idea that the transverse myelitis was due to the poliomyelitic virus, that statement being based on the fact that the case appeared during the epidemic of poliomyelitis in New York City, and in many respects it was similar to poliomyelitis. There was some peculiar form of infectious transverse myelitis which in four out of five cases led to recovery. The condition was more common than heretofore supposed and should receive further consideration.

**Epidemic of Streptococcus Sore Throat.**—Dr. JOSEPH A. CAPPS and Dr. J. D. DAVIS of Chicago described in a joint communication an epidemic of streptococcus sore throat in Jacksonville, Ill., which was traced to the milk of cows affected with streptococcic mastitis.

Dr. GEO. M. KOBER of Washington, D. C., pointed out that he made his first collection of milk-borne epidemics in 1894, and at that time was impressed with the studies made in England by Kline, Crookshank, and others in regard to so-called epidemics of scarlet fever which they attributed at that time to an inflammatory condition of the teat or udder of the animal. In analyzing the situation he concluded and ventured to express the opinion in 1895 that these were not true cases of scarlet fever, but typical instances of either staphylococcic or streptococcic infections, because he had seen a great many instances where an eruption similar to that observed in cases of scarlet fever was due to streptococcus infection.

With our present knowledge of milk-borne diseases, nothing short of pasteurization of milk would confer immunity from these infections.

Dr. R. C. CABOT of Boston asked what sort of an eruption it was.

Dr. CAPPS replied that it was erythematous. Four of the cases were described and diagnosed by very good clinicians as erysipelas.

**Pathogenesis of Poliomyelitis in the Light of Recent Research.**—Dr. SIMON FLEXNER of New York City stated that recent experimental studies on poliomyelitis confirmed the view that in man infection occurred through the upper respiratory tract, and that the virus passed to the central nervous organs by way of the cerebrospinal fluid, and not by way of the blood.

**Officers.**—The following officers were elected for the ensuing year: *President*, Dr. S. J. Meltzer, New York; *Vice-President*, Dr. Henry Sewell, Denver, Col.; *Secretary*, Dr. Geo. M. Kober, Washington, D. C., reelected; *Recorder*, Dr. Thomas McCrae, Philadelphia, reelected; *Treasurer*, Dr. J. P. Crozer Griffith, Philadelphia, reelected.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held April 2, 1914.*

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

THE program was arranged by the Section on Dermatology.

**Modern Diagnostic Methods in Syphilis.**—Dr. JOHN A. FORDYCE read this paper and said that the present diagnostic methods of syphilis were those applied to the demonstration of the *Treponema pallidum* in a suspected lesion, the reaction of the blood to the Wassermann

test, the findings in the spinal fluid, and the luetin reaction. In estimating these diagnostic methods in the various stages of syphilis the importance of careful clinical training in recognizing the different stages of the disease must not be forgotten. Clinical observation and laboratory methods supplemented each other. He emphasized the necessity of careful clinical training as the great majority of practitioners either were not prepared to carry out the necessary laboratory examination or were situated away from centers affording such facilities. He called attention to the multiform character of the primary lesion and urged that every means be employed to make an early accurate diagnosis in order to abort the infection by intensive treatment while it is still local. Owing to its simplicity and rapidity the dark field illumination was the method of choice for demonstrating the spirochetæ pallida. They are usually fairly numerous where antiseptics have not been previously applied and in cutaneous chancre offered little difficulty in the recognition of the organism, but in the mouth greater difficulty was encountered in differentiating them from the spirocheta dentium. Where spirochetæ are not demonstrable and the clinical diagnosis is doubtful repeated Wassermann examinations should be made as in the great majority of cases the reaction was positive after the fourth week. Dr. Fordyce said that the original Wassermann was conceded to be superior to all modifications which had been devised, the only departure from the original method permissible being in the matter of antigens as it had been demonstrated that the use of alcoholic extracts of guinea-pig, human, and beef hearts fortified with cholesterin gave more delicate and more uniform results. This was particularly well illustrated in tertiary cases where the percentage of negative reactions with manifest symptoms had been markedly reduced. The diagnostic value of the Wassermann reaction in the primary stage was overshadowed by the demonstration of the spirochetæ in the lesion. In his experience the earliest reaction had appeared at the end of two weeks; the majority not until the fourth. He had under observation a large number of patients treated within two weeks after the appearance of the chancre with positive microscopic findings and a negative Wassermann in whom the affection had been aborted. Here the Wassermann was more important as a guide to the effect of treatment. In some patients at the end of two weeks a developing reaction might be observed. This might continue for two or more weeks, at the end of which time inhibition would be complete. During this stage of development sometimes a strong reaction might be provoked by an injection of salvarsan. He cited several cases to illustrate the foregoing points. In the secondary stage of syphilis with the outbreak of cutaneous and mucous membrane manifestations the reaction was positive in 100 per cent. of cases. This was a very important symptom as it was a deciding one between the secondary eruption of syphilis and other skin affections which simulated it and were sometimes puzzling even to the trained dermatologist. In the latent period of syphilis the only symptom was the positive Wassermann. Many of these cases showed strongly positive reactions during active treatment and it might be that we had fast or permanent fixation which we were unable to influence by repeated courses of treatment. Where a large amount of treatment had been administered it was well to let the patient rest for several months as it frequently happened that after intensive treatment the reaction gradually grew weaker for a period of months. In cases where with adequate treatment the reaction remained ±, or indeterminte, for a period of six months or longer it was advisable to give a provocative salvarsan injection. Should the reaction become stronger there was an indication for continuance of treatment. If it remained unchanged one might be justified in disregarding it. In tertiary cases with manifest lesions Dr. Fordyce found that about 95 per cent. gave positive reactions. The Wassermann reaction in tertiary syphilis was of great importance in differentiating it from other conditions, as tumors. This corroborative evidence was conclusive when the lesions were situated in the skin, but when the mucous membrane or viscera were involved the problem was more complex for the patient may have a carcinoma independent of his syphilitic lesions or it might be engrafted on a leucoplakia of the tongue or cheeks, several cases of which were cited. Dr. Fordyce also touched upon other forms of cutaneous disease which sometimes simulated gumma very closely as tuberculosis, sporotrichosis, blastomycosis, and persistent bromide and iodide eruptions. The reactivation of a negative Wassermann by an injection of salvarsan, as suggested by Gennerich and Milian, was now such a well known biological phenomenon that it had found a place in the routine of diagnosis and treatment of syphilis. A number of cases illustrative of the value, not only from a diagnostic standpoint, but in determining the cure of a patient were narrated. Referring to Noguchi's cutaneous reaction, Dr. Fordyce said it had perhaps found a place in latent and tertiary syphilis, but from his own experience the results with leutin were not sufficiently uniform to warrant its use at present except as supplementary to the Wassermann test. Dr. Fordyce said that great strides had been made in the diagnosis and treatment of syphilis since lumbar puncture was being more universally applied. It was not possible at the present time to give a characteristic serological picture for cerebrospinal lues, tabes, and paresis. Bearing in mind that there were transitional or borderland forms it was necessary to supplement the Wassermann findings with careful and minute clinical examinations. In tabes he had found the reaction of the blood positive in 66 2-3 per cent. of the cases. In the spinal fluid Nonne's Phase I and pleocytosis were usually marked in about 100 per cent. of well developed cases with active manifestations. The Wassermann reaction was positive with larger amounts of fluid to 1 c.c. and with 0.2 c.c. or less in about 20 per cent. In the early forms of the root type the serological picture might be practically negative. Whether these cases would give positive findings later on only further observation and time could tell. In the degenerative forms where all activity had subsided the results were negative. In taboparesis and paresis the serum reaction was positive in about 100 per cent. of the cases. In the fluid a positive Phase I and a variable lymphocytosis with a positive Wassermann reaction in larger amounts to 1 c.c. in 100 per cent. and with 0.2 c.c. or less in about 95 per cent. In cerebrospinal lues the reaction in the blood was positive in from 70 to 80 per cent. of the cases. Phase I was usually positive, pleocytosis was variable, complement fixation was positive in larger amounts, a smaller percentage fixing with 0.2. In cerebrospinal arteritis the blood might or might not give a positive reaction and the findings in the fluid might all be negative excepting the globulin reaction unless there was an accompanying meningitis.

**Modern Treatment of Syphilis.**—Dr. JEROME KINGSBURY presented this paper in which he stated that the present day treatment of syphilis might for convenience of presentation be considered under two heads: first, the methods employed for the removal of lesions; and, secondly, those now in vogue to obtain a permanent negative Wassermann reaction. The first was obviously the most important since we included as lesions not only syphilomata in the widest sense of the term, but also the secondary degenerative processes due indirectly to the spirochete. In discussing the various luetic manifestations, their relative importance, both clinical and sociological, should be fully appreciated. With this end in view, ignoring chronological sequence, the lesions of syphilis might be roughly divided into three groups. In the first were included the actively contagious lesions of the disease; in the second lesions that were of grave import to the patient, and in the third the relatively benign lesions. The lesions of the second and third group might be looked upon from a *clinical* standpoint as noncontagious, notwithstanding the fact that in nearly all of them living spirochetæ might be demonstrated. In considering the actively contagious lesions of syphilis the question of immediate prophylaxis was of prime importance. The practicing physician dealt with subjects with actual contagious lesions and it was his duty not only to sterilize these lesions in the shortest possible time, but also to control the patient during the period of possible contagious relapses. Speaking broadly, exposed lesions abounding in spirochetæ are peculiar to the early period of the disease. At this time the infected individual was of the greatest danger to the community, and intensive treatment was imperatively indicated. The most powerful symptomatic remedy at this time was unquestionably salvarsan. It was far superior to any other remedy in the degree of rapidity of healing of exposed lesions, with special reference to the chancer mucous patches and other moist lesions. Used in the early stages of the disease it shortened the contagious period by days and some-

times even by weeks. Naturally to secure rapid results only the intravenous method should be used. The method now used in preparing the solution of salvarsan was practically the same as that originally recommended by Ehrlich. At the present time, however, instead of 300 c.c. we use but from 150 to 180 c.c. of water. The technique of injection was largely a matter of choice. Some operators preferred to have the solution run into the vein by gravity, others inject it from a syringe. The simplest apparatus was generally the best. In very obese patients the salvarsan might be given intramuscularly or in some instances by enteroclysis. It was generally better, however, under local anesthesia, to dissect to a vein in the arm. The preparation and administration of neosalvarsan was so much simpler than that of salvarsan that many physicians preferred to use it rather than the older remedy. It was dose for dose, somewhat less potent than salvarsan. Five doses of neosalvarsan would seem to be required against four of salvarsan. The simplest method of administering neosalvarsan was devised by Aavant and first used in this country by Brayton. Concentrated solutions of neosalvarsan were injected into the vein from a 10 c.c. hand syringe. The needle might be attached to the syringe when inserted and its proper adjustment in the vein was shown by the flow of blood into the cylinder of the syringe, mixing with the solution. It was not necessary for the patient to assume a reclining position and often the tourniquet might be dispensed with. With infants and small children the neosalvarsan should be administered in appropriate doses by means of intramuscular injections, preferably in the buttocks. In syphilitic lesions that were of considerable gravity to the patient, lesions which if unchecked led to mutilation, invalidism and death, among which might be cited, gummatous infiltration and caries of the bones of the nose, frontal sinus, or hard palate, with at times great loss of substance, or impairment of function, intensive treatment was indicated. Salvarsan should be administered, but always in conjunction with mercury and often with iodine of potassium. In leucoplakia, which frequently underwent carcinomatous degeneration, salvarsan was occasionally useful. In gummatous infiltration of the tongue, however, better results were obtained with mercury and iodine of potassium than with salvarsan. In visceral syphilis mercury and salvarsan should be administered, but always in conjunction with iodine of potassium. In syphilitic astitis and arterosclerosis salvarsan had proved rather disappointing. It was in these specific diseases of the cardiovascular system that our best results were obtained with iodine of potassium. In paresis and tabies the injection into the subarachnoid space of neosalvarsan dissolved in the patient's own serum, while more or less experimental at present, offered at least in the early cases some prospect of cure. In cerebral syphilis, while the best symptomatic results were obtained with iodide of potassium, it was advisable to also administer mercury and salvarsan. In selected cases the iodide of potassium might be administered intravenously. The relatively benign lesions of syphilis were the late cutaneous manifestations of the disease. These lesions, except in the rarest instances, are non-contagious, and as they were practically never associated with lesions of the viscera or nervous system the importance of their removal was chiefly to relieve the patient of the annoyance of the disfigurement they caused, the principal ones being the cutaneous gummata, the nodular, circinate and serpiginous lesions and the familiar and rebellious syphilides of the palmar and plantar surfaces. Intensive treatment was always desirable in any stage of syphilis, but insofar as the removal of late cutaneous lesions was concerned, we might often accomplish this with oral medication and the efficacy of the old mixed treatment of a symptomatic remedy was well recognized. There were forms, however, of the palmar and plantar syphilides that would not respond to either mercury or iodide of potassium when administered by mouth and it was necessary to employ injections of either salvarsan or mercury. In some respects salvarsan is the most satisfactory and should be administered intravenously. Mercury, however, if given properly and in sufficient dosage would always remove these lesions. Calomel might be given intramuscularly or one of the soluble salts intravenously. From the foregoing it might appear that the treatment of syphilis was still regarded as a symptomatic one. As a matter of fact, however, the removal of lesions was merely the preliminary step and should always be supplemented by efforts to obtain a permanent negative Wassermann reaction. Our modern anti-luetic therapy was a very definite one—the complete destruction of the spirochete in all of their stages of development—notwithstanding the fact that a laboratory symptom was now substituted for a clinical one. The continuance of treatment in a patient presenting no lesions had for its object the prevention of later clinical manifestations of the disease. To attain this it was necessary for one to obtain a Wassermann reaction that would remain permanently negative, for the treatment of syphilis could not be considered eminently successful unless the patient was secured against relapse. In a case of early syphilis a series of six salvarsan injections should be given at intervals of a week or ten days. If neosalvarsan was employed the interval between injections might be shorter, but it was advisable to increase the number of injections to eight or nine. A series of salvarsan injections should always be followed by a course of mercury. Inunctions furnished a rapid method of introducing this remedy into the system, but most authorities preferred to administer mercury by intramuscular injections. Of the non-soluble salts calomel is the most active and intensive, but the salicylate of mercury was more generally used for routine injections. Injections of from two or three grains should be given weekly. A series of twenty injections of mercury should be followed by another series of salvarsan injections. Then more mercury, followed by another series of salvarsan injections. In theory and for the purpose of laboratory studies of the serum it was desirable to have an interval of a month or two between the serial injections. It was often unwise, however, to suspend treatment, especially during the first year. Vigorous treatment should be continued regardless of a negative Wassermann, and a break in the treatment frequently interfered with the active co-operation of the patient. It was time enough for intermittent treatment and serum tests during the second year of the disease. With intensive treatment in cases of early syphilis negative Wassermann reactions were readily obtained, and at present it seemed probable that in the majority of cases this very satisfactory serological condition would persist. In dealing with late cases presenting a strong positive Wassermann reaction the results of treatment were variable and often unsatisfactory. Salvarsan was frequently unable to influence this laboratory symptom. In cases where a strong positive reaction persists after a series of six or eight injections of salvarsan it was doubtful if the reaction could be influenced by a continuance of this remedy and these patients might be regarded as Wassermann-fast to salvarsan. It was in cases of this type that intensive mercurial treatment was indicated.

Dr. Abner Post of Boston said that the modern methods of diagnosis had put the study of syphilis upon a much higher plane than before. They had established the diagnosis in numberless cases that were without them obscure and doubtful. The discovery of spirochetæ in a suspected sore established the diagnosis—but the discovery of spirochetae had been followed by a condition which was to be regretted. It had led to the belief on the part of many, especially of those who had come into practice since the great discovery, that it was impossible to make a diagnosis of primary syphilis without their demonstration. Now it was perfectly possible to recognize a very large proportion of primary sores by their clinical attributes. Given a known exposure, an incubation longer than was needed for the appearance of any of the pus producing organisms, an innocent little erosion, which gradually became elevated upon a painless circumscribed and non-inflammatory growth beneath it, and which was accompanied by lymphatic glands in its immediate vicinity, which gradually and painlessly enlarged and you might be sure of a syphilitic primary lesion, and it was necessary to know such clinical aspects to recognize primary sores in unusual and unexpected localities in order that one might search for the spirochetae which should clinch the diagnosis for even the most sceptical. Again, the use of mercurial and other antiseptics rendered it not infrequently impossible to find spirochetes until the antiseptic had been suspended for a time, and clinical knowledge was extremely useful in such cases. Too much could not be said in favor of the dark stage, but one could hardly expect doctors who settled in the smaller towns to be forever on the lookout for spirochetae, and still with the modern facility of travel syphilis was being spread everywhere. The more the gross aspects of

syphilis were taught the less likely was he to be caught by some accidental outbreak, the less likely to inoculate himself from some unsuspected source. The dark stage and the stained specimen ought to be so used in teaching as to clinch the recognition of the clinical characteristics. The Wassermann reaction was one of the great discoveries of recent years. It was a very great blessing to all who were interested in the study of syphilis. It has certainly helped in the study of syphilis of the internal organs, but there was a certain small percentage of known syphilis which was not recognized or given a positive reaction by the Wassermann. Even the claim of the most advanced was that the particular antigen gave a positive reaction in a larger number of cases than any other. It must be confessed that his personal interest was largely fixed upon that small percentage of cases unrecognized by the serological test. With these cases in mind even the Wassermann test showed the absolute necessity for careful clinical study.

Under the circumstances it was a little difficult to believe that we had reached as yet an absolutely reliable serological test. The speaker emphasized the diagnostic possibilities that lay in the Roentgen rays. He believed we should yet come to search the skeleton of congenital syphilitics for evidence of syphilis exactly as we now looked over the skin and the lymphatics. They were accustomed to look at the bones which were tender or the seat of pain, but lesions were sometimes found in syphilitic children which were not suspected. They knew the deformities of the cranium and nasal bones. Graves of St. Louis had drawn attention to what he believed to be a characteristic deformity of the scapulae. It seemed only logical to look further for other evidence of imperfect growth or periosteal change. The same might be said of bone changes in cases of acquired syphilis of long standing. Changes in the bony system began just as early as those in the nervous system. The internists were also making good use of *x*-rays. The lungs, the stomach, the heart, were all now carefully studied by its aid. There is one other method of diagnosis which was so far only a hope, and that was the inoculation of rabbits. There was little in the present situation to encourage even a hope, but it was not an impossibility. It was but a short time that the use of animals in the study of syphilis had been possible at all; what manner of diagnostic use could be made of them remained to be seen.

The constant calls for aid in diagnosis that were made upon those who interested themselves especially with syphilis by men devoted to other branches were most encouraging.

They all know the value of "606." The doctor who refused to use it in early disease just as soon as he could make his diagnosis omitted the best means of absolutely cutting short the disease.

It had been his practice to use the drug before a diagnosis was possible, as, for instance, in the case of a young woman who had been exposed in such a manner that escape from the disease seemed impossible. But it should be recognized that the drug was a powerful and dangerous one, and when a man whose intimate friend had suffered from severe nervo-recidives preferred to take the chances of other treatment he could not feel like urging "606" very strongly. He also believed in the value of mercurials. They had been warned at first against the use of "606" in cardiac cases. That was before the number of cases of cardiac disease of syphilitic origin was recognized, and repeated small doses had helped to restore many such cases to active life, though by no means all subjected to such treatment. But there were some cases in which mercury deserved the preference, and "606" must be considered the adjunct. That was true in many cases of congenital syphilis, not the babies alone but later cases, the children with interstitial keratitis. The younger the child the better the mercurial acted. Some of them needed "606" in addition, but not all. The condemnation which was so freely bestowed upon the internal administration of mercurials was regrettable. It was not always the most effective way, but it had its value. If he were a military surgeon with his patients under control he doubted if he should use it, but with patients who traveled back and forth over the face of the earth it was a good way to continue treatment. It has an effective and good way of treating children. Personally, with a dispensary class of patients he preferred it to injection or inunction. There was an important fact to be remembered. It was only through differences of opinion that any progress was made. A world in which all doctors agreed would be a very slow and uninteresting one.

Dr. B. LAPOWSKI said that the solution of the question of the treatment of syphilis lay in experimental and laboratory studies, scrutinized by clinical observation. The new discoveries in the domain of syphilis gave a new impetus to the knowledge of syphilis. The whole world was bent at present on trying to find, by the light of the new discoveries, a firmer and sounder basis for future treatment than any which they had at present, and they owed a great gratitude and acknowledgement to Dr. Fordyce for his splendid work in this field, for his endeavors to bring before them the modern basis of treatment and diagnosis of syphilis. The search, the discovery and the establishment of such a basis should be of great benefit and of vital importance for the *future* generation of syphilitics. But the development of this basis was laden with danger for the *present* sufferers of primary and secondary syphilis, who supplied them with the material for their investigations. But by controlling and weighing the laboratory findings, by treasuring up clinical facts, they would make the actual, present application of the new methods more solid and seaworthy. It was in this spirit that he offered his few remarks.

The fundamental benefit of an early diagnosis, by the demonstration of the presence of the spirochetæ, before the seroreaction was positive, lay in the possibility of interfering with their remedies in a very early period, according to the maxim: "Frapper vite, frapper bien." But in his recommendations in this point the speaker was not modern enough, as a diagnosis was not necessary in order to start treatment. In order to act upon the maxim, start as soon as possible. The tendency was to treat all cases in which the slightest suspicion of specific infection was entertained at once, without waiting either for the demonstration of spirochete or positive seroreaction, relying upon the outcome of the seroreactions, which was to be regularly undertaken, to establish the lacking diagnosis, a positive seroreaction showing that there was an active virus, that was, that the patient had contracted syphilis, a negative seroreaction proving that the patient was free from the virus. And it is immaterial to the patient how he was freed from the virus, be it by early parasiticide action of the timely administered remedy, or owing to the fact of his never having had the virus. (Neisser.) The advice to examine the spinal liquid was of importance to establish a new symptom in the course of the development of syphilis, in order to treat more actively, to prevent the possibility of future involvement of the nervous system. This was of small importance for those physicians who always treated syphilis in a very active way (Cal. injections and inunctions) by the chronic intermittent method, who acted upon the same principle, only without having that symptom to support their principle. As to the treatment of syphilis, the modern method agreed in one main point, namely, the treatment should be very intensive, especially during the early period of syphilis, whether starting with salvarsan and continuing with active preparations of mercury (calomel. oleum cinereum, inunctions) or starting with mercury and continuing with salvarsan, considering salvarsan as secondary, additional, useful only in certain stages and conditions of the disease. Lately Dr. Mentberger collected 274 cases of death after salvarsan—41 in nonspecifics, 9 after subcutaneous injections, 21 after intramuscular and 196 after intravenous—and among those cases, up to 1914, there were only four cases from the American literature. The deaths occurred mostly in the secondary stages of syphilis, two in primary cases. If they collect all other cases, especially counting the cases of deaths in this country, including all cases of death, whether syphilitics or not, more than 400 can be counted. While during the whole century of administering mercury, only 70 cases of death occurred, and in many of these cases death could have been avoided (as embolism) by judicious care on the part of the physician. That salvarsan was a useful remedy was unquestionable, but the method of its intravenous application was of great danger, no matter how cautiously and carefully the physician applied the remedy. There was always a great risk which cannot be avoided.

Dr. WALTER J. HEIMANN said that to attempt to add anything to the very complete expositions of the diagnosis and treatment of syphilis heard this evening would be futile. One question, however, was raised

in the discussion which, it seemed to him, merited further consideration, namely, the deaths and cases of poisoning due to the use of salvarsan. The gentleman who preceded him sounded an alarming note in his remarks on this matter. He personally had witnessed a fatality, which he could explain on no other basis that that of the toxicity of the drug. He mentioned that Gaucher had compiled a series of two hundred cases from the literature of death from salvarsan. The speaker himself had been able to find as many more, bringing the total up to about four hundred on the continent of Europe. At the same time only four cases had been reported in the United States and Canada. This disparity was ascribed to the fact that such fatalities have been suppressed in the literature of the new world. Assuming, for the sake of argument, that there might have been a hundred more deaths in America, they still had a comparatively small total throughout the civilized world, considering the million or two injections already given. According to the statistics presented by the previous speaker, only seventy deaths could be ascribed to mercury in the entire literature of syphilis, which seemed to prove that the use of salvarsan should be abandoned. On closer study of the facts, however, he believed that the blame for these deaths could be traced to other causes. In the first place in a review of the types of cases treated were found many patients suffering with aortic aneurism, aortic insufficiency, specific renal arteriosclerosis, tabes, paresis, and other serious luetic lesions of the central nervous system. Such cases were prone to sudden death very often without any ascertainable reason. Why, then, should the salvarsan be held responsible, *per se*, for these deaths, if they occurred as a coincidence after an injection. In the second place, without in the least wishing to challenge the ability or standing of the authorities who reported these cases, another point of view might be presented which might throw light upon this unfortunate question. The bulk of all these injections was given in the large medical centers of the world, very few deaths having been reported, excepting from the better known French and Austrian clinics. From what the speaker had seen of the Hôpital St. Louis in Paris and the Allgemeines Krankenhaus in Vienna, so far as the departments of dermatology were concerned, he was struck by their filthiness so forcibly that it was impossible for him to conceive of surgical asepsis in such an environment. He believed that this would account for many of the deaths reported. In the larger German and Swiss clinics, which were scrupulously clean and properly equipped, according to our modern lights, there had been very few, if any deaths. It must be further borne in mind that in treating the later manifestations of syphilis with so potent a drug one might often suddenly overthrow the nicely adjusted metabolic balance to which the patient has gradually accommodated himself. Thus, they might in certain instances cause fatalities. This, however, was less a fault of the drug than of those who did not yet know all that was to be known about its use. This type of therapy was still comparatively new and they had not yet entirely exhausted their list of indications and contra-indications. In the meantime, it seems to him that the use of salvarsan was anything but dangerous, particularly when one considered the risks of inadequately treated syphilis, both to the individual and to the community.

## THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held April* 28, 1914.

THE PRESIDENT, DR. T. PASSMORE BERENS, IN THE CHAIR.

**Surgical Replacement of the Prolapsed Kidney.**—Dr. DOUGAL BISSELL presented this paper which he illustrated by lantern slides. He said that in discussing the surgical problem of permanent replacement of the prolapsed kidney, the approach to the organ demanded their first attention. The posterior or lumbar route was now generally selected, but the technique of approach varied, and had not yet been standardized. In the technique which he advocated the initial incision began over the twelfth rib, about one and one-half to two inches from the spine, a little above and to the inner side of the angle formed by the last rib and the erector spinæ, or at a point immediately above the last digitation of the serratus posticus inferior. It extended downwards on a line parallel with the general direction of attachment of the latissimus dorsi to the erector spinæ and the lumbar fasca, and terminating about one-half an inch from the crest of the ilium, and 10 cm. (4 inches) from the spine. The next incision was made along the line of attachment of the aponeurosis of the latissimus dorsi to the erector spinæ. The lumbar fascia was completely exposed when the lumbar portion of the latissimus dorsi was thus transferred to the outer margin of the wound. The lumbar fascis was then incised at its upper portion on a line parallel to and immediately below the twelfth rib and the incision extended as necessity demanded. The lower area of the transversalis portion of the intraabdominal fascia was thus exposed. By means of lantern slides Dr. Bissell showed the technique employed and spoke of the advantages of this technique as follows: (1) The approach to the kidney necessitated the least injury to the tissues encountered. It was the most direct route and facilitated deep manipulation. (2) The sustaining sutures encircled both poles, and insured immobility until firm union had taken place. Their high placement in the tissues of the back insured a practically normal position of the organ. (3) The kidney area exposed for attachment was the most extensive surface available, and so situated as to permit the kidney being anchored in normal, anatomical relationship. (4) In closing the wound only a minimum amount of the simplest suture material was required, and the replacement of the tissues was absolutely anatomical. Dr. LEWIS STEPHEN PILCHER said that twenty-four years ago, in 1890, when Dr. O. B. Douglas was President of the Medical Society of the County of New York, and who was present at this meeting seated at Dr. Berens's right hand, he took part in a discussion of the subject of nephropexy which took place in the American Medical Association. At that time it was a new subject. Gradually there occurred to their minds the possibility of relief by fixing a movable kidney and this possibility went through the profession. As a result of that discussion there were fixed in his mind certain principles both of technique and diagnosis which had guided him ever since. He was glad to find that the experience and study of Dr. Bissell had reached the same point that he had himself so long occupied. Wherever one found a loosened kidney, attack it. There had been a furor of fixation of the kidney among surgeons, at least a part of the time, since 1890. As a result there had been many disappointments and gradually the pendulum had swung back as though there had been danger of abandoning this most valuable surgical procedure. It was well that attention should be called to this today and with force. At present the surgical mind was occupied with the subject of ptosis and in a larger field than the kidney itself. They now realized that ptosis of the kidney in many instances was only a part of a generalized ptosis. Was it not true that when they were face to face with a movable kidney that they were uncertain whether other parts should not be attacked rather than the kidney itself. He has persuaded that in many instances fixation of the kidney might be assumed the important part in the relief of the patient. Colonic ptosis and gastroptosis occupied their minds to the exclusion of everything else. The relation between the colon and the kidney was very intimate. He was inclined to think that as time went on the pendulum would swing again. He believed there was a place for nephropexy in rational surgery.

Dr. ARNOLD STURMDORF said that to judge and appreciate Dr. Bissel's contribution to the surgical correction of nephroptosis, two fundamental conceptions that had crystallized from a maze of controversy must be accepted. First, we must recognize the existence of a pathological nephroptosis as a clinical entity. Whether such a nephroptosis was part of a general enteroptosis or not, the fact remained that the prolapse of the kidney might be the activating factor in the whole symptom-complex and thus determine our therapeutic aim. Secondly, that a correct surgical procedure was capable of reestablishing and maintaining the distorted kidney topography and relieving the patient. It was known that the functional disturbances resulting from general enteroptosis were manifested largely in the right abdominal cavity. The anatomical relations of the right kidney to the duodenum and hepatic flexure make it very evident that any topographic distortion of such relation must of necessity present a symptom-complex involving all or any of these correlated organs. Furthermore, recent pyelographic studies have shown the

destructive influence on the kidney parenchyma of even slight and intermittent kinks in the ureter, so that the necessity for a correct reposition and retention of a prolapsed kidney could not longer be questioned. Most, if not all, of our previous operative measures for the correction of this condition were based upon a faulty conception of normal kidney support. They had searched for ligaments where there were none and ignored the displacing factors. He could not enter here into the dynamics of intra-abdominal pressure and would briefly state that the kidneys lay in shallow troughs on either side of the spinal column known as the renal or paravertebral fossæ, their convex posterior surfaces fitting into these shallow concavities as one saucer may rest in another—in which position they are maintained principally by the centrifugal force of intra-abdominal pressure.

If the kidneys were transfixed through the back of a vertically suspended cadaver, then the abdomen opened and the transfixing needles removed, the kidneys descended several inches. These facts were unrecognized or ignored in all previous operations and in addition, it was taught that it was the mobility and not the position of the kidney that caused the trouble. In kidney ptosis, the skeletal habitus showed the paravertebral fossæ as too shallow and consequently we must overcome this abnormality by substituting adhesion for cohesion of the kidney, but such adhesion must fix the kidney at the normal level, in its normal relations without angulating the ureter. Dr. Bissel's operation marks an epoch in the evolution of nephropexy, inasmuch as it is based upon correct principles and aims at an accurate restoration of normal topography; its advantages which were emphasized were that it did not depend upon an independable flap of capsular tissue for suspension; does not denude the anterior surface of the kidney and that it elevates the kidney to its normal level where it is safe from all expulsive influences. In proper cases it was permanently curative in its results.

**A New Operative Treatment for Selected Cases of Spastic Paralysis.**—Dr. WILLIAM SHARPE, together with Dr. FARRELL wished to offer a new operative treatment for selected cases of spastic paralysis in children, and the paper was merely a report of the operative treatment of 43 cases of spastic paralysis showing intracranial pressure by an ophthalmological examination. These 43 operated cases were the ones selected as being suitable for the operation from the examination of 127 cases of spastic paralysis, i.e., one in every three cases examined. Their results had been so gratifying that they felt justified in presenting the progress of the cases treated by them up to the present time. He emphasized the following facts: First, that they were not operating upon the mentally deficient, the constitutionally inferior and idiots in the hope of restoring them to a normal mentality. Second, that they were not operating upon microcephalic children in the belief that the brain would develop and become normal by enlarging their cranial capacity, a belief long ago exploded. Third, that they were not operating upon cases of spastic paralysis due to a lack of development and malformation of the cortex of the brain and the pyramidal tracts, cases forming at least one-half of the total number of spastic paralysis, the so-called Little's Disease, in which a cranial operation would do no good and from the very pathology of the condition a cranial operation could be of no benefit to the patient. On the other hand, they were operating upon those cases of spastic paralysis giving a history of difficult labor with or without instruments, and upon opthalmoscopic examination; the definite signs of increased intracranial pressure were to be seen upon the fundus of the eye. The most satisfactory and desirable cases for operation were the ones with no impairment of the mentality, but these cases were rare when there was intracranial pressure present; much more commonly did they find a more normal mentality in these cases of lack of development and malformation of the pyramidal tracts, unless very extensive. The condition of spastic paralysis resulted most frequently from a lesion of the brain occurring before birth, during birth, or shortly after birth. It was characterized by more or less complete paralysis of the part affected, and was associated with a stiffness or spasticity depending upon the extent of the involvement of the pyramidal tract; this hypertonicity produced muscular contractures and deformities, usually flexor in type, with a corresponding overstretching of the opposing muscular groups, usually the extensors. One of the most common lesions of the brain producing spastic paralysis was that of intracranial hemorrhage of the newborn. It was of venous origin most frequently. According to the extent and pressure of a hemorrhagic clot upon the cortical surface did they find clinically the signs of such interference of the pyramidal tract; if over the upper portion of both motor areas, then both legs were affected, and a spastic diplegia resulted. Intracranial lesions due to the various forms of hemorrhage comprise about 70 per cent. of the cases of spastic paralysis in children; whereas, lack of development and malformation of the cortex and pyramidal tracts, and that group of spastic cases due to a meningo-encephalitis complicating measles and scarlet fever constituted most of the remaining 30 per cent. of the cases. The treatment of spastic paralysis had been most discouraging and unsatisfactory. During the past few years, the treatment had been directed towards an improvement of the results of the central intracranial lesions upon the extremities, and it had been a most discouraging field of work. The operations which had been used in the past and were being used to improve the condition of spastic paralysis were only of temporary benefit. It occurred to him why not do a decompression operation in those selected cases of spastic paralysis having a possible hemorrhage on the brain and showing any signs of intracranial pressure; and so he began having the eyes of spastic children examined carefully with the ophthalmoscope for signs of intracranial pressure. He had operated upon 43 cases, most of them being of the extreme type, and the results had been gratifying. Of these 43 cases, 17 were diplegics, both arms and legs being affected, 11 were paraplegic, only the legs being involved, while the remaining 15 cases were hemiplegic. Epilepsy in its various forms was present in 16 of the 43 cases. Five of their operated cases had died; each of these was under two years of age, of the extreme diplegic type, emaciated and therefore very poor operative risks. The improvement in their selected cases for operation was very marked and they believed that cranial decompression was indicated in those cases of spastic paralysis showing intracranial pressure by the ophthalmoscopic examination. This operation was not a formidable one for one trained in cranial surgery. The anesthetic should be administered by an expert. Dr. Sharpe showed some moving pictures taken of the patients before operation and at regular intervals after operation, in order that the impairment of posture and gait might be accurately recorded.

Dr. CHARLES S. HUNT said that to err in anesthesia was a most serious matter, for it might be said that the patient under the influence of anesthetic was on the borderline of life and death, and one had no more right to jeopardize that life than to take life. Yet, day in and day out, that chance was taken as was well known by our lax laws and methods controlling anesthesia. Anesthetic deaths were too numerous today for the advancement we had made in this branch of medicine and most of these fatalities were due to errors of judgment in selecting a suitable method and agent for that special case. One hesitated to present anything not used in the everyday routine of anesthesia for fear of further confusion. It seemed that each man had a method all his own and the only one that should be used. The use of oxygen with ether and chloroform was not new, and attention was called to it again that its true worth might be recognized. After a year's work with the heated ether vapor with oxygen in brain and spinal surgery, the writer felt justified in stating that they had had much more satisfactory results to the patient, the surgeon and the anesthetist than from any other method that he had tried. They had used the heated oxygenated ether vapor in the series of cases shown and had obtained much more satisfactory results than by vaporizing the ether by the foot pump. Any method that takes the chill from the ether vapor in transit to the patient's lungs causes less irritation to the respiratory mucous membrane than vapor not so treated, as was shown by less secretion, cough, and respiratory troubles. The combined use of oxygen and heated vapor lessened the possibility of any severe respiratory shock and permitted one to obtain ether tension in the blood and tissues with a far less toxic and irritating agent which did less permanent damage to lungs and kidneys than a cold straight ether vapor. The speaker had used the heated oxygenated ether vapor in patients with kidney lesions, with bronchitis and fever, and in two cases with a history of pulmonary tuberculosis in which it was not possible to use nitrous oxide and oxygen on account of

the nature of the operation. Oxygen had made nitrous oxide a much safer anesthetic than in its pure state of mixed with air. It was far more important with chloroform and ether, the former taking up 40 per cent. of oxygen from the blood, ether less. From clinical observations he assumed that the oxygen content of the blood was very little disturbed where oxygen was used to vaporize ether. In most of our vapor appliances the ether bottle was not large enough to meet all the requirements. This had led him to use a sixteen ounce bottle, using a half a pound of ether instead of a quarter of a pound in a six or eight ounce bottle. With the large bottle there was more ether surface, hence more vapor. Heated oxygen ether vapor had advantages in obstetrics both for the infant and the mother. The apparatus used was so simple that the writer said he hesitated to present it, but its efficacy was its redeeming feature. He had a case which contained the sixteen ounce ether bottle, a large chloroform bottle and the heater. The case was hung on a 200-gallon oxygan tank and connected. A long rubber tubing permitted the anesthetist to be away from the operative field. The face and head being covered with sterile sheets, the guides for the anesthetist were the respiration, pulse and capillary circulation under the finger nails. If the patient was not doing well the face and eyes could be observed with very little disturbance. The author thought he might be criticized for not working with a definite percentage of vapor and for giving up automatic devices, but said that the one thing he had learned was to allow the patient to be the guide as to the percentage and the amount used. There was one other point he wished to make and that was with regard to the position of the head in brain surgery. If the Richardson mastoid block was one used the old sand bags would be discarded.

Dr. RUSSELL HIBBS said that he had followed Dr. Sharpe's work and he was sure with his experience in spastic paralysis many would be relieved of their distressing condition. The cases that he had followed had improved very much and just how much was due to the operation and how much to the after care he could not say.

## Books Received.

*The* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

BIOCHEMIC DRUG ASSAY METHODS, with Special Reference to the Pharmacodynamic Standardization of Drugs. By PAUL S. PITTENGER, Ph.G., Ph.C., Phar.D. Edited by F. E. Stewart, M.D., Ph.G. Cloth; price, $1.50 net; illustrated; 158 pages. P. Blakiston's Son & Company, Philadelphia.

CONSIDÉRATIONS BIOLOGIQUES SUR LE CANCER. Par FELIX LE DANTEC. Paper; price, 1 franc; 53 pages. A. Poinat, Paris.

DIE GONORRHOE DES WEIBES. Für Die Praxis Dargestellt. By Prof. Dr. F. FROMME. Paper; 56 pages; price, 2 Mks. S. Karger, Berlin.

THE FUNDAMENTAL BASIS OF NUTRITION. By GRAHAM LUSK. Cloth; price 50c. net; 62 pages. Yale University Press, New Haven, Conn

## Therapeutic Hints.

**Iodine in the Treatment of Plague.**—A correspondent in an Indian paper calls attention to a simple method of treatment of bubonic plague, which treatment is said to be quite efficacious. The patient is given a dose of castor oil and then from five to seven drops of tincture of iodine in a little water. The buboes are painted with tincture of iodine. A milk diet is given. The following morning there are administered two drops of tincture of iodine in a little water. Quinine is given if fever is present. This method of treatment was employed in nine cases of plague, all of which recovered. At the time during which these cases were under treatment there was an outbreak of a virulent type of plague in the town in which these cases occurred and 500 deaths were recorded. Practically the same method of treatment had previously been employed in 51 cases of plague with 50 recoveries.

**The Prevention of Bichloride of Mercury Poisoning.**—W. E. Fitch suggests that the bichloride of mercury tablets that are sold to the laity should contain, in addition to 7 3/10 grains of corrosive sublimate and 7 7/10 grains of ammonium chloride, 1¼ grains of tartar emetic. It is claimed that the last drug will produce vomiting before the bichloride of mercury is absorbed and before it exerts its irritant action.—*Pediatrics*, June, 1914.

**Calcium Chloride in Erysipelas.**—S. Kawakami reports that he has obtained good results in the treatment of erysipelas by means of the injection of a 1 per cent. solution of calcium chloride. The author's experience comprised forty cases. There were injected from 20 to 50 cubic centimeters of the solution, the usual dose being from 20 to 30 cubic centimeters. The size of the dose was regulated according to the patient's strength and the severity of the disease. After the injection the patient generally felt warm and in rare instances experienced a transient palpitation of the heart. At times there were sweating, fever, thirst, general weakness, etc., but in a few hours the patient generally felt comfortable. A rare complication was diarrhea. The local signs markedly improved, the course of the disease was shortened and a speedy recovery ensued.—*Sei-i-Kwai Medical Journal.*

**The Treatment of Chorea.**—René Bénard notes that the medicinal treatment of this condition is most varied. Marfan has advocated the use of salicylate of sodium in such large doses as from 3 to 7 grams. The two most important drugs in chorea are antipyrine and arsenic. Comby gives the former in doses of 0.50 gram or more. His formulas are as follows:

℞ Antipyrine, 10 grams.
Simple syrup, 190 c.c.
Spirit of peppermint, 1 gram

or

℞ Antipyrine, 10 grams.
Extract of licorice,
Glycerin, aa, 15 grams.
Distilled water q.s. ad 150 c.c.

The dose of either of the above is one tablespoonful, which contains in the former 0.80 gram and in the latter 1 gram of antipyrine.

If the attack of chorea does not respond to the use of antipyrine, one may then resort to arsenic.—*Bulletin Général de Thérapeutique.*

### A WORD OF CAUTION CONCERNING PALPATION UNDER THE FLUORESCENT SCREEN.

BY JAMES T. CASE, M.D.,

BATTLE CREEK, MICHIGAN.

ROENTGENOLOGIST BATTLE CREEK (MICHIGAN) SANITARIUM AND ST. LUKE'S HOSPITAL, CHICAGO.

THE importance of an *x*-ray examination in the diagnostics of internal medicine, so well recognized and practised in Europe for a decade or more, is now also receiving merited appreciation in this country. Those fully acquainted with the details of technique of European roentgenologists realize that *x*-ray work, as practised on the continent, especially in relation to internal medicine, is essentially fluoroscopic. The making of plates and prints is a matter of very minor consequence in the average continental roentgen examining department. In America, on the contrary, *x*-ray examinations have, since the first, been roentgenographic rather than roentgenoscopic. It is true that pioneer work in fluoroscopy was done in this country. Pioneer fluoroscopy of the chest was practised by Dr. Francis H. Williams of Boston. But the sad experiences of many early pioneers in fluoroscopic work gave justly a decided setback to the development of the screen method of *x*-ray examinations until such time as proper protection could be afforded the roentgen examiner.

It seems that day has arrived. Properly protected instruments for fluoroscopic examinations are now available. It is probably impossible to produce a practical instrument which will *absolutely* protect the operator from the influence of

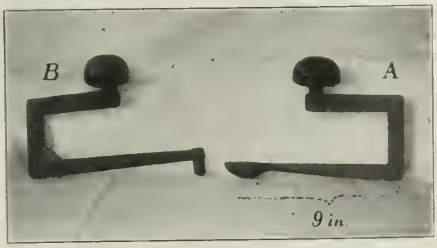

FIG. 1.—A, Holzknecht's "palpatorium" or "distinctor"; B, author's modification of the Holzknecht palpatorium.

the *x*-ray, but it seems that *practical* and sufficient protection is now available.

The purpose of this paper is not to discuss the relative value of roentgenography and roentgenoscopy. In the study of fractures and in the recognition and localization of calculi and foreign bodies, roentgenography is not only the more reliable, but it also affords the necessary permanent records of the case. In the study of disease of the thorax, the plate records are desirable and often necessary for interpretation and comparison with the other clinical findings. In the study of the

FIG. 2.—Shows the method of applying the distinctor to the fluorescent screen. The screen is held vertical in order to illustrate the position better.

alimentary tract, however, fluoroscopy is the method of choice. The roentgenogram furnishes a representation of the static conditions present, the shape (at the moment) and the position, but, of far greater importance in the majority of cases, roentgenoscopy furnishes needed data concerning mobility, motility, and other questions relating to function which by roentgenograms alone either can not be shown at all or only with difficulty and at considerable expense. After a large experience in roentgenographic and roentgenoscopic examination of the alimentary tract, the writer can truly say that, with the exception of gallstone and duodenal ulcer cases, in comparatively few instances have the roentgenograms added any material fact of importance to the roentgenoscopic findings.

One of the most important advantages of the fluoroscopic method is the possibility of guided palpation under fluorescent screen. This may be accomplished by the hand or by some mechanical "palpatorium" not opaque to the *x*-ray. Palpation with the bare hand cannot be too strongly condemned. A few of the more foolhardy are content with only the protection afforded by a leather glove. More nearly approaching satisfactory protection to the palpating hand is the use of a heavily leaded

rubber glove. Even this, however, does not afford complete protection as can be easily demonstrated by making a röntgenogram of the gloved hand with an ordinary tube such as is used for fluoroscopic work. Of course, the ray which reaches the examiner's

Fig. 3.—Shows the palpator in use. The arrow points to the examiner's right hand, which is upon the handle of the palpator.

hand is filtered through the aluminum or leather filter which should always be interposed between the tube and the patient, the leather, aluminum or other material of which the table top is composed, the body of the patient and the material of the glove. It may be contended with some reason that this is sufficient protection, but for complete safety, one should palpate with a spoon or some similar device.

Among the chief purposes of palpation are the determination of mobility, relation of various shadows, and the identification of points of pain on pressure in relation to the bismuth shadows. For

Fig. 4.—Bismuth-filled colon twenty-four hours following the bismuth meal. Notice that the two legs of the splenic loop lie very closely together, and, in view of the history, it is desirable to know whether or not there are adhesions about the bowel which may have an influence in causing constipation. See Figure 5.

this means a mechanical palpator may be employed. Fig. 1 shows the wooden "palpatorium" or distinctor first suggested by Holzknecht. This wooden spoon with various modifications the writer has employed ever since its description by Holzknecht and he considers it an indispensable part of his instrumentarium. This instrument has such shape that the bowl of the spoon can be placed beneath the screen while the handle is on the upper side, where the holding hand may be further protected

Fig. 5.—Same case as Figure 4, except that the Holzknecht spoon is applied separating the left half of the transverse colon from the descending in order to demonstrate the mobility of the parts. The arrows point to the area of decreased density due to pressure of the spoon. This illustrates the value of compression, as in search for urinary stone, etc.

by the lead glass which backs the fluorescent screen. A glance at the accompanying cuts will demonstrate

Fig. 6.—Roentgenogram of the right lower quadrant of the abdomen showing the cecum, ascending colon, and part of the transverse. The crest of the ilium is also easily outlined. The arrows point to the clear area made by pressure of the palpator, with the appendix showing in the middle of the clear area

in a moment the advantages of a palpator of this sort. Whether or not neighboring loops of bowel can be easily separated, the mobility of the cecum, the appendix, the transverse colon, the pylorus, the descending colon, are all points which may be studied by the aid of the palpatorium just as well as by manual palpation.

The writer has constructed a modification of the Holzknecht distinctor which is frequently preferable to the Holzknecht spoon. This consists of a wooden finger-like projection which replaces the bowl of the spoon. A brass tack or other bit of metal is driven into the tip of the "finger" so that its exact location may be easily seen. This modification of the palpatorium is of service especially for the identification of points of pain on pressure.

Only those who have experienced the satisfaction of palpating the bismuth-filled stomach or bowel under the fluorescent screen can fully appreciate visualized abdominal palpation under fluoroscopic guidance, but adequate protection must be insured before such palpation can be practised. Unless the greatest caution is observed to insure proper protection in roentgenoscopic work, great suffering and even loss of life may result from the wave of enthusiasm for fluoroscopic *x*-ray work which is now sweeping over this country.

No one should infer from the above remarks that ordinary roentgenographic work is free from danger to the roentgenologist. It is a comparatively simple matter, when the problem is intelligently attacked, to secure protection against two to five milliamperes of current, which is as much as anyone ever uses for fluoroscopic work. But in roentgenographic work, where forty or fifty or even more milliamperes of current are employed, protection must be proportionately more secure.

## TRIGGER FINGER, ITS CAUSE AND MECHANISM.

By ADONIRAM B. JUDSON, M.D.,

NEW YORK.

A PROFESSIONAL man, 76 years old, had an attack of arthritis in the fingers of both hands in June, 1913, with resulting trigger finger in the proximal phalangeal joint of the middle finger of the right hand, with swelling and deformity and stiffness of the joints of the middle and ring fingers. These results are still present. Motion past the right angle in either flexion or extension develops a painful snap, or jerk. This may be described as a momentary hesitation followed by a sudden acceleration. The jerk is more severe after the joint has been undisturbed for some time, and especially on waking in the morning. After it has been repeated a number of times for experiment or observation it is painless and comparatively slight. It is never entirely absent. When the hand is quiet there is no pain except what is felt in chronic arthritis on pressure or when motion is forced beyond the point of comfort. Many of the uses of the hand are interfered with. A pencil cannot be sharpened in the usual way by flexion and extension of the fingers. It also impedes writing and sewing. A woman thus affected said that a needle in her fingers seemed as large as a pencil. Other manual movements are at times brought to a sudden stop in a surprising, inconvenient, and more or less painful way. The momentary pain is sometimes very severe.

Cases of this kind have been occasionally reported and they have given rise to an extensive literature devoted largely to cause and mechanism. This leads to rather delicate ground. A recent writer withholds assent from certain theories declared by him to be "weird," and then proceeds to advocate one still more elusive and mysterious. Foreign writers also have developed decided differences of opinion. One declares that the presence of a node on a tendon cannot account for the peculiar action because no nodes are to be found, which leads another to remark that his predecessor did not know how to examine. It is necessary therefore to move carefully along this path. It may be stated incidentally that the sensation of a node moving with a tendon may be felt by pressing not only on the head of the third metacarpal bone but also on the lower end of the radius in the wrist.

The peculiar action of a trigger finger resembles that seen when a pocket knife is opened or shut. Movement is smooth till a square shoulder at the near end of the blade presents an obstacle which retards motion till a certain point is reached when motion is accelerated with a jerk. A counterpart of this obstacle may perhaps be found in a node on an articular surface where it would cause the halting, corduroy-road action of a trigger finger. In

the construction of a knife, however, an important feature is present which is absent from the anatomy of the hand, and that is the strong steel spring concealed in the handle of the knife. It produces positive pressure between the surfaces composing the metallic joint. If the spring were absent, or if its place were taken by a strip of some inert substance like cork there would be no jerk, and shutting and opening the knife would be perfectly smooth. While there is nothing very closely resembling a steel spring in the hand or forearm, still we may find a muscular action a force which draws the surfaces together and creates a pressure comparable with that produced by the steel spring.

The fact that the digital joints are the only ones subject to this affection gives rise to the well-founded presumption that they have mechanical features found nowhere else. This is true. The digital joints are supreme. The rest of the upper extremity may be considered as preparing the way for the superlative functions of the hand. The mobile shoulder blade, the circumduction of the shoulder joint, the provision for pronation and supination found in the forearm, the circumduction of the carpus, and the revolution of the first into opposition to the other digits, all these prepara-

tory devices and processes culminate in the thumb and fingers which guide the pen and the scalpel. The matriculation ticket of an old-time medical teacher bore the picture of a human eye at the end of an index finger, tactus eruditus. These potent terminal members control the painter's brush, the sculptor's chisel, the notes and keys of the musician, and the tools of the skillful workman and ingenious inventor. They are slowly leading their fortunate owner into civilization.

The fingers require not only delicacy and swiftness but also strength. Small in bulk and weight, and far removed from the point of resistance in the inertia of the trunk, they still are endowed with great strength. Their power comes from important groups of muscular fibers assembled in the mass of the forearm. The long tendons of one set, the flexor sublimis, are inserted in the bases of the second phalanges. They make pressure on the articulating surfaces, especially those of the nearest joint, the affected one in the case here reported, pressure augmented by the pull coming from the other group, the flexor profundus, whose tendons pierce those of the sublimis to be inserted in the distal phalanges. These long tendons are bound to the phalanges by fibrous sheaths and as they lie close to the bones and parallel with them a large part of their force is expended in pressing the articular surfaces together, the residue being given to moving the joint.

Motion is doubtless impeded by intraarticular irregularities in other parts of the body where joint surfaces are held in contact by the static resistance of circumarticular ligaments and to some degree by the dynamic influence of muscular contraction. No joints, however, but those of the digits are subject to the exceptionally great pressure of powerful muscles acting through tendons lying parallel to, and in close contact with, long bones. The strength of these muscles is shown by the unyielding grip exhibited by the hand in an emergency. It is clear that when digital muscles are in action they concentrate on small articular surfaces pressure as positive and distinct as that made by the steel spring of the pocket knife.

After witnessing the dissection of a normal hand, by the kindness of Dr. Gallaudet, it appeared to me that the node seen in the accompanying photograph of the affected hand, on the radial side of the base of the second phalanx of the middle finger, might extend into the joint where it would project as an obstacle on the palmar edge of the articular surface at the base of the phalanx. At this point it would be in apposition, when the joint is at a right angle, with the rounded lateral articulating condyle on the radial side of the head of the proximal phalanx. It is evident that when these two eminences, one abnormal and the other normal, pass each other, as they do when the joint traverses the right angle, they must, when pressed together by muscular contraction, experience a momentary hesitation followed by an acceleration of speed such as is seen in trigger finger. That there may be cases which do not have their origin in arthritis is suggested by the personal experiences and research of my friends, Drs. Weir and Abbe.

It is surmised that as the flexors are stronger than the extensors the jerk of trigger finger would be more severe in flexion than in extension. This is found to be the case as a rule. And further, it is found that the jerk is lessened or absent when passive is substituted for active motion. These and other experiments are interesting and sustain my proposition to a certain extent, but they are wanting in scientific accuracy, and their results are not constant. Aside from these experimental observations, the presence of unusual pressure between the joint surfaces when voluntary motion is made by the fingers, and the probable presence of a node on one of the surfaces give sufficient warrant to the following proposition: In trigger finger an obstacle of arthritic origin on one of the articulating surfaces is surmounted with momentary hesitation followed by a jerk or sudden acceleration of speed, as the joint moves under the exceptional pressure which voluntary action interposes between the articular surfaces of the digital joints.

*X*-ray views have been taken in this case, but they fail to show any notable change in the bone. Ordinary inspection, however, shows swelling and deformity, with a projection, seen in the figure, on the radial side of the base of the second phalanx of the middle finger. The joint is $\frac{1}{8}$ inch wider at this point than its fellow of the other hand. Dissection would probably reveal surface irregularity. It is to be hoped, however, that an autopsy will not be proposed in the immediate future as the joint herein described is part of the still good right hand of the author.

There has been no local treatment except by a gutter splint of sheet aluminum applied with a single strip of adhesive plaster to keep the joint extended at night. At the end of the year the jerk is less marked, but pain and stiffness continue and involve the metacarpophalangeal joint. Persistent catharsis has been maintained with oleum ricini, and as a result perhaps no other joint of the body has been attacked by the infection which is held to be the cause of chronic multiple arthritis, an affection intractable and not as yet well understood.

## PRURITUS ANI.

BY JEROME M. LYNCH, M.D.,

NEW YORK.

PROFESSOR OF RECTAL AND INTESTINAL SURGERY, NEW YORK POLYCLINIC.

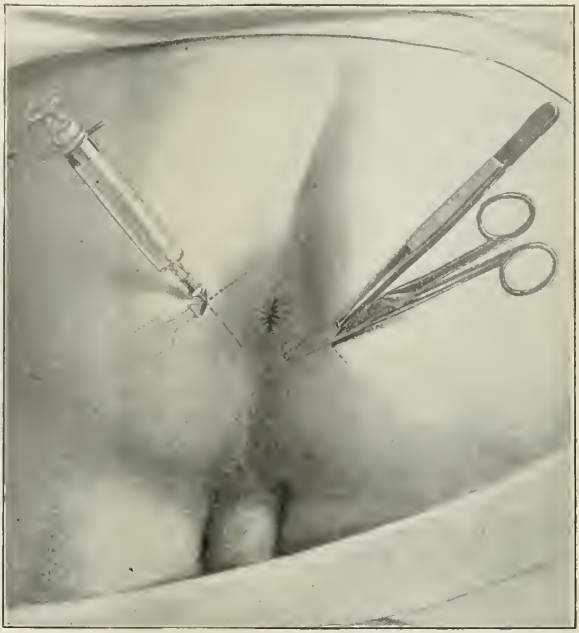
PRURITIS ANI is a distressing and abominable malady. Its etiology is obscure. We will not now go into the many theories that have been advanced as to the cause, but confine ourselves to the surgical aspects of the condition. While almost every physician who has had occasion to treat these cases has many cures to his credit, there are some cases so intractable that all efforts fail.

Among the alleviations suggested are removing all the skin around the anus with a curette; the use of a red-hot cautery; the injection of alcohol; injections of a warm or cold saline solution, and various other methods, with varying results. That the patient is willing to undergo such extreme measures indicates his misery. One can hardly propose anything too strenuous to a patient suffering from pruritus ani, any hope of relief being eagerly embraced.

As to surgery, in these cases it is certainly not in order for every case of itching, but when all approved medical tactics have failed surgery must be adopted, and the satisfactory procedure will be one that can be easily performed, is free from danger, and accomplishes complete relief. Several such

operations have been devised, notably Ball's and Krouse's.

*Ball's Procedure.* "The skin having been cleansed as completely as possible, a curved incision is made on each side of the affected area, enclosing the entire ellipse with the exception of a narrow neck in front and behind. These incisions are carried down to the sphincter muscle, and the flaps raised by careful dissection with scissors from the surface of the muscle, round its anal margin, and up the anal canal to above the mucocutaneous junction, the dissection extending round the entire circumference; all connections with the subjacent tissues are divided. The pedicles in front and behind are now undercut to a point well beyond the area of irritation, and the outer concave edges of the incision also undercut to a distance of at least a quarter of an inch free of the involved skin all round. Care must be taken to stop all bleeding, and the flaps should not be replaced until it is completely arrested, as the formation of a hematoma in the wound might compromise the vitality of the flaps. The flaps are finally replaced and retained by sutures, a few intervals being left between them for drainage. The immediate result of this operation is to render the entire ellipse included between the incision, the pedicles, and the outer edges, as far as they have been undercut, superficially anesthetic and the itching is at once relieved. The first case operated on, in this manner, occurred five years ago. Except for slight superficial vesication upon one side of the flap, healing was rapid. Cutaneous sensation returned some months after the operation, but by that time the skin had become so altered that the pruritus did not return, and the patient has not had a moment's trouble with itching since. His case had been an extremely severe one, of sixteen years' duration, and his life was so miserable that he threatened suicide if he could not be relieved.



Lynch's Operation for Pruritus Ani. (From "Diseases of the Rectum and Colon," By. J. M. Lynch; Lea & Febiger, Philadelphia.)

"I have now operated fourteen times by this method; in all of them the relief was immediate; in no case did the vitality of the flaps suffer, and in none of them has there been any return of pruritus in the area dealt with, even after the return of normal sensation. Two cases came back asking for treatment of small spots of irritation over the tip of the coccyx which had escaped the previous operation; both were dealt with by raising and replacing a small flap of skin which included the affected spot. On one occasion I have dealt similarly with a localized patch of pruritus with marked trophic changes in the front of the vulva with equally satisfactory results. Since the first note of this operation for pruritus ani was published (*British Medical Journal*, Jan. 21, 1905), I have received information from several surgeons who have adopted it with uniformly satisfactory results."

Krouse's operation differs from Ball's in that instead of making two elliptical incisions he makes six linear incisions radiating from the anus and following the course of a circle, whose center is the anal canal. One incision is anterior, one is posterior, and two are lateral. The skin between these folds is dissected up so that the sensory nerves are temporarily severed. The advantage he claims for his operation over Ball's is that the blood supply of the flap is not impaired in his operation, whereas in Ball's there might be difficulty of this kind. Krouse states that in some twenty operations he has never had the slightest sloughing or anything that would suggest nutritional disturbance of the flap. Primary union has occurred in all cases.

The writer believes the methods detailed below as devised by himself have all the advantages and none of the disadvantages of other procedures. The entire operation is performed under local anesthesia, and in no way inconveniences the patient or enforces confinement. It is not beset with possible complications, as are the other procedures; there is a minimum amount of scar formation, and the direction of the scar makes stricture impossible, while the blood supply of the operated area is so little disturbed that the danger of sloughing is nil. The patient is placed upon his left side, with knees and thighs flexed. A point is chosen about one and a quarter inches from the anus. At this point a 1 per cent. solution of novocain or a 1/5 of 1 per cent. solution of cocaine is injected. An area extending to the posterior midline is anesthetized. At the point above mentioned a small curved incision is made, about one-half inch long, and extending just through the skin. Through this incision a blunt-pointed dissecting scissors, curved on the flat, is introduced, as shown in the illustration. With this instrument a blunt subcutaneous dissection is now carried out, working to the anus mesially, and to the raphé anteriorly and posteriorly. When completed there is an area of skin, extending from the anterior raphé to the posterior commissure and involving all the skin within a radius of one and a half inches from the anus, which has been deprived of its sensory nerves. Any bleeding may be controlled by pressure. When the bleeding has stopped a small piece of rubber tissue is introduced into the incision and permitted to remain twelve to twenty-four hours. Sometimes, in addition, a horsehair stitch is taken through the incision; but this is not usually necessary. As a rule, at the end of forty-eight hours the wound is entirely healed. Either at the same sitting or at some subsequent time the same

procedure is followed on the other side. The results of this operation have always been satisfactory. Though there may be a recurrence, this is not likely to take place for two or three years, and two or three years of relief to a patient is a great boon. The itching, of course, ceases immediately, and perianal sensation being lost, the irritation soon lessens. With proper treatment all local conditions should promptly clear up.

We have now employed this operation in over thirty cases during the last four or five years, and in no instance have any complications arisen, excepting one case, where there was slight hematoma, and in that case we failed to put in a drainage for the first twenty-four hours. However, after the hematoma was evacuated the patient made an uneventful recovery.

The advantages of this operation are:

That it can be done under cocaine.

That there is no risk.

That it can be performed in the office.

That it does not incapacitate the patient from business.

That it gives immediate relief.

## NEEDLE PROTRUDING THROUGH WALL OF STOMACH.*

By OLIVER C. SMITH, M.D.,
HARTFORD, CONN.
VISITING SURGEON TO HARTFORD HOSPITAL.

THE following case of needle protruding through the stomach wall is interesting from the fact that the foreign body was probably carried in the stomach, producing symptoms for over two months; it is one of extreme rarity, as only one such recorded case has been found after a careful search of the literature.

The patient, a married woman, aged 37 years, of neurasthenic tendency, was operated upon three years previously for calculous nephritis and the right kidney was removed. Following her operation she regained her weight, and from a condition of invalidism became quite well. Early in August she experienced sharp, transitory pains at the epigastrium, both at meal time and in the intervals. She gradually became afraid to eat, lost weight, and early in September vomited small quantities of bloody mucopurulent fluid. The patient

Skiagram showing a needle protruding through the wall of the stomach.

had no recollection of having swallowed any foreign body or poisonous material, nor was she in the habit of holding pins or needles in her mouth.

*Presented before the Surgical Section of the Hartford Medical Society, Nov. 24, 1913.

A bismuth skiagram taken by Dr. Arthur C. Heublein revealed a normal stomach in size and contour, but showed clearly a foreign body, pin or needle, protruding 1½ cm. through the anterior stomach wall at a point 3½ cm. proximal to the pylorus on the lesser curvature. A second skiagram was taken two days later just prior to operation confirming the findings of the first.

Operation at the Hartford Hospital, October 2d, under gas-oxygen-ether anesthesia. The stomach was exposed and the pointed end of the needle, dark but not corroded, was found protruding through the wall of the stomach in the peritoneal cavity at a point corresponding to the appearance in the skiagram. The needle was drawn out of the wall of the stomach by forceps, breaking immediately after its removal, the portion of the needle lying within the cavity of the stomach being extensively corroded. The small opening in the stomach wall was closed with two purse-string sutures and the wall of the abdomen was closed without drainage. The stomach regained its normal function within a few days, and the patient rapidly regained her lost weight.

The only similar case which the author has been able to find is recorded by Dr. Alexander Nicoll in the *Lancet*, Vol. 1, page 772, 1908. In the course of the article entitled "Remarkable Case of Persistent Ingestion of Needles" he describes an operation in which a needle was found protruding through the wall of the stomach as in the case here reported. The accompanying illustration is a skiagram showing the needle protruding through the gastric wall.

## SUBSEQUENT REPORT OF PATIENTS WHO RECEIVED INJECTIONS OF FRIEDMANN VACCINE OVER A YEAR AGO.*

By GEORGE MANNHEIMER, M.D.,
NEW YORK.

OWING to the scarcity of reliable reports I thought that those still interested in the subject might gain some information as to the value of the Friedmann vaccine from an account of even a limited number of well observed cases. Eighteen patients were injected under my supervision early in March, 1913, *i.e.* fourteen months ago. A preliminary report on these patients was made in the MEDICAL RECORD of June 7, 1913. I summarized the result at that time as follows:

"In not a single one of these eighteen cases was there definite improvement to date, attributable to the vaccine. In some the disease progressed, evidently unchecked. In no instance did the temperature return to normal. Five of the eighteen developed abscesses, four of them small, and one large. Excepting this case, I could not say that any distinct injury has been done by the vaccine. I cannot determine whether the vaccine hastened the progress of the disease where it has occurred."

There was one error in that summary. Instead of "five" of the eighteen developed abscesses, I should have said "6." To-day I have to add a seventh one, who developed an abscess from his fourth injection, whereas all the others had it at the site of the first. Otherwise there is not much to modify in that summing up. But I will briefly sketch each case, relate the subsequent course, and add my comment.

CASE I.—Married woman 41 years of age; in good general condition. Chronic pulmonary tuberculosis of 15 years standing, advanced but stationary. Had but one injection; examined ten times since. No change either way. Tendency to tachycardia and a rise in blood pressure above 170 are disquieting features.

*Read before the National Association for the Prevention and Study of Tuberculosis, Washington, May 8, 1914.

Case II.—Man of 35 years; in excellent general condition; chronic pulmonary tuberculosis since 13 years; moderately advanced. Had at one time vasomotor rhinitis and asthmatic bronchitis. Emphysematous habitus. Had but one injection; developed a small abscess which broke two months after the injection, and ceased discharging three months later. Had a "cold" in October, 1913, and with it a hemoptysis of about one ounce. Two more feverish colds during the winter, but attended almost steadily to his small cigar store, and is today as well as last year. The injection did not influence him in any way.

Case III.—Married woman of 38; in good general condition; chronic pulmonary tuberculosis of 9 years standing, advanced. Had one injection which gave rise to an unusually large abscess. This I thought at the time might be caused by the previous frequent administrations of tuberculin or by the puncture of a vein, or by an overdose. In the light of recent reports from Germany I suggest to-day as another more likely cause of this unusually large abscess that the vaccine was contaminated by pus germs. This patient's local and general condition have materially deteriorated during the year—according to the report of her family physician, Dr. G. M. Wells, of Indianapolis. The patient believes that she was made worse by that one injection, and her physician is inclined to concur in this opinion. I can only accept the discomfort caused by the large abscess, and the disappointment caused by the failure of the treatment as damaging factors.

Case IV.—Girl, 22 years of age; chronic bilateral pulmonary tuberculosis of 9 years' duration, advanced. Had small abscess from the first and only injection, and was worse two months later. Has not been heard from, but is known to be alive and at work as before injection.

Case V.—Man of 41, chronic pulmonary tuberculosis of 5 years' standing, unilateral; good general condition. Five weeks after injection had first hemoptysis of his life; weight slightly decreased. Could not be traced since April 15, 1913. The patient no doubt ascribed his hemoptysis to the injection. We cannot blame him for his belief, but we who know the natural history of the disease cannot accept this post hoc, ergo propter hoc-reasoning.

Case VI.—Man of 38; youngest of ten children; poorly developed thorax; chronic pulmonary tuberculosis of 3 years' duration; active at the time of injection. Beginning infiltration of epiglottis; trace of albumin and casts in the urine. Came from Mississippi to New York for this treatment, received it, traveled to Tennessee, got married, and returned with his bride. Then was kept in bed and well cared for. The time between May 16 and July 30 he spent at a Southern sanatorium. A small periprocitic abscess, caseous pneumonia, and rapid softening of one lung, ulceration of epiglottis and interarytenoid space with severe dysphagia, obstinate diarrhea marked the swift progress of the disease and brought on the fatal termination July 30, 1913. No autopsy. The vaccine, if it did not hasten, was absolutely powerless to check the spread of the disease.

Case VII.—Man of 28; bad family history and build. Many hemoptyses, one lasting 10 days, 3½ weeks after first injection. May 11 took a second injection from another physician. May 14 expressed himself as subjectively relieved, but had lost 7 pounds, and showed no improvement in lung condition. Could not be traced since.

Case VIII.—Man, 31 years of age; formerly excessive smoker; sick about 3½ years; chronic pulmonary tuberculosis of moderate extent but with much dyspnea and tachycardia. Received four injections in all—a good measure according to the inventor. He developed laryngeal tuberculosis, and died January 21, 1914, under signs of profound toxemia—according to Dr. C. L. Wheaton, of Chicago, who will report this case in detail. No autopsy. The vaccine, if it did not hasten, was absolutely powerless to check the onward march of the disease.

Case IX.—Traveling man of 27; chronic pulmonary tuberculosis since 1909. Periprocitic abscess on right side since 1912, opening and closing repeatedly. Received four injections. Felt and looked well, when examined last on March 16, 1914, but had not gained in weight. Left lung shows signs of an arrested process; retracting dullnes, bronchial breathing and bronchophony over upper parts of upper lobe; behind, broncho vesicular breathing well into the apex of the lower lobe; no rales. To the right of the anus is an infiltrate with an old and a tiny new fistulous opening discharging thin pus. A fresh small infiltrate exists on the left side opposite. This patient spent two months last summer in his country home in Minnesota, then went back to business, but lived a sensible life. He was told by the injecting physician that he was cured, and would receive the fourth injection only to "make sure." We cannot pronounce him cured even at this early date. At best the lung process is temporarily arrested. But has the vaccine done it? If it did, say by arousing the defensive forces of the body, why did it permit the implantation of the tubercle bacillus in a new area? The value of the vaccine in this case is open to grave doubt.

Case X.—Man, teacher, 28 years of age; very moderately advanced chronic pulmonary tuberculosis with marked intestinal disturbance. Received one injection from Friedmann in March, 1913, and when the latter wantonly disappointed him, a second injection from another source in May. Returned to his home in Wisconsin, grew progressively worse, and died the end of November, apparently from intestinal tuberculosis—an unexpectedly rapid course. No autopsy.

Case XI.—Physician, 47 years of age, had tuberculosis of left apex in 1907, which completely healed under climatic and tuberculin treatment, so that he could take up his practice again in 1908. Early in 1912 feverish cold and since then more cough and some loss of weight. February, 1913, small hemoptysis, occasional pleuritic pain. Wanted the injection to prevent relapses. He apparently felt uneasy about his chest. After injection chest pain and cough less; gain of 2 pounds. About six weeks later caught cold again; coughed and expectorated more, and did not look as well as before. Even a vacation did not benefit him. In August he suddenly developed a left-sided pneumothorax with effusion and very severe constitutional involvement. After many weeks in bed he went to a health resort where he is now improving nicely. This colleague of ours was so disgusted with Friedmann after the latter had shown himself in his true colors, that he would not think of taking another injection. The first one did not fortify him at all against the fresh outbreak which was preparing at the time. The same criticism applies to

Case XII.—Lawyer, 28 years of age, incipient tuberculosis of both apices for over a year. He improved remarkably under hygienic-dietetic treatment at home in New York City. Was allowed to go to business middle of January, 1913. End of February caught cold; had cough expectoration, pain in right chest, fever and sweats—all of which disappeared within three days. March 2: slight oppression in chest and occasional night sweats, sputum scanty, no bacilli. Injected, March 8. On March 11 again the short, sharp pain in right lower chest. March 18 reports himself feeling stronger. March 25 pain in right lower chest and distinct pleuritic friction over right lower lobe posteriorly; 147¾ pounds, the highest weight since beginning of illness. April 21 reports by letter: laid up in bed since end of March with what his physician called bronchopneumonia, with severe hemorrhages, fever, and appearance of bacilli. Not examined by me since March 25. Apparently did not want the second injection. Here also the disease was about to spread at the time of the injection, and the vaccine was absoluety powerless to prevent that spread. I heard indirectly that this patient spent some time in a health resort, and is now again attending to business.

Case XIII.—Man of 31, known to have tuberculosis of kidney and bladder since 1905; difficult to diagnose at first. Many operations. July, 1908, left kidney removed. But old symptoms of burning, frequent micturition, pus, shreds and tubercle bacilli in the urine returned and kept up in varying intensity. At work. Cystoscope shows region of left ureter ulcerated. January 8, 1913, left ureter removed. Injected March 8. No improvement; infiltrate broke down and discharged a little pus. On May 14, 1913, suddenly stricken with severe headache, chill, fever, thirst, vomiting, and retention of urine; later on developed convulsions, loss of consciousness, blindness, paralysis of arms; later on severe epigastralgia, polydipsia, polyuria, strabismus, and stiff neck. This illness lasted three months, and was diagnosed by physicians in a small New Jersey town as uremia and meningitis. I had occasion to examine him again on March 23, 1914, and found emaciation, weakness, beginning infiltration of left apex, enlargement of right kidney and liver, urine turbid, flocculent, containing pus but no

tubercle bacilli; double optic atrophy; paraplegia disappeared. He describes his decline to the vaccine, but there is no evidence of this. We know that patients with one kidney are very prone to develop uremia, if that single kidney is subjected to strain or becomes diseased. This patient had manifestations of renal insufficiency before the injection. When eating much meat he would get shortness of breath, chilliness, trembling, palpitations, dizziness and rapid bounding pulse—or attacks of urticaria. It is hard to say how much the remaining kidney is affected by tuberculosis.

Case XIV.—Hospital orderly, 24 years of age; tuberculosis of kidney and bladder since 1909; left kidney removed then. Still burning, pollakiuria, and mycturia in varying intensity. He also developed a small abscess in the third month after injection. No improvement; tubercle bacilli still in urine; condition today unchanged.

Case XV.—Boy of 5 years. Tuberculosis of cervical lymph nodes since 4 years; one chain extirpated. Had moderately large abscess at site of injection. Lymph nodes unchanged to this day.

Case XVI.—Boy of 10 years; since 1911 tuberculous coxitis with dislocation. Walks very well with a small Lorenz plaster-spica, without which the femur will not stay in place. Received but one injection. The orthopedic surgeon who had him under his care would not consider a second injection when he heard Friedmann advise the removal of the spica, so as not to interfere with the local circulation of the antibodies. The boy's condition to-day is not satisfactory, there is more bone destruction and the general condition is unimproved.

Case XVII.—Man of 25. Chronic pulmonary tuberculosis since 8 years; since November, 1912, beginning tuberculosis of right knee joint. The one injection had no effect. This was disappointing because in fresh bone lesions prompt improvement was looked for. To-day the young man is worse, the lung and knee affection having progressed.

Case XVIII.—Boy of 17. Tuberculosis of right ankle ten years ago, operated and healed. Since 8 years tuberculosis of right knee. First injection, March 8; second, May 26; 3d, November 12; 4th, December 24th, 1913, the last three without my knowledge and consent. The fourth gave rise to a moderately large abscess. Result: the knee is more swollen, more painful and tender and more disabled. There is slight loss of weight; but worst of all—since middle of April there exists a painless cartilaginous swelling of the left epididymis and left seminal vesicle, undoubtedly tuberculous. This boy had frequently been advised to have a resection performed. Now even a thoroughly successful operation on the knee would not cure him of his tuberculosis. This new complication makes the prognosis decidedly serious. In this case the vaccine was administered in full dose, but proved, to say the least, utterly worthless.

*Conclusions.*—Of eighteen patients treated in March, 1913, under my supervision fifteen could be followed up, and of that number three are dead. The number of injections in these three cases were one, two, and four, respectively. Of the remaining twelve patients, ten received one and two four injections. Five of the ten patients who received one injection developed abscesses at the site of the injection and were therefore unsuitable for further injections for an indefinite period, according to the inventor. The other five patients were not reinjected, either because they did not see the improvement they had been led to expect or because they had become worse and had lost confidence in Friedmann. As to their present condition, five of them are now unchanged and five are worse than a year ago.

One patient, who had four injections, feels well and presents signs of an arrested lung process, but he has not gained in weight and has developed a new tuberculous process in another part of the body. The second patient with four injections has tuberculosis of the kneejoint and is now decidedly worse than before; he has in addition developed genital tuberculosis. The infiltrate of the fourth injection broke down and discharged pus.

Where abscesses resulted at the site of the first injection, the vaccine apparently produced no additional harmful effect. The disease remained uninfluenced. Friedmann neglected to prevent abscessformation, although he claimed to know how. To be very charitable, one might judge from one single case that decided natural healing tendencies, aided by common-sense treatment, will not be hindered by the remedy. When in a quiescent case the first subjective and objective symptoms of a new outbreak appear and one naturally wishes to check it, the remedy is absolutely worthless for that purpose. It cannot prevent the tendency to spread, if a case is so disposed. We have on purely clinical grounds a right to be suspicious of its alleged harmlessness. The method of its administration has been anything but careful and intelligent. For these reasons, and on account of the absence of curative and preventive powers in this series, it cannot be recommended.

41 West Fifty-first Street.

## SHOULD THE SANITARY CONTROL OF PROSTITUTION BE ABANDONED?

By JULIUS ROSENSTIRN, M.D.,

SAN FRANCISCO, CAL.

CHIEF-OF-STAFF AND ATTENDING SURGEON, MOUNT ZION HOSPITAL; CHAIRMAN ADVISORY COMMITTEE MUNICIPAL CLINIC OF SAN FRANCISCO.

In the second volume of the Rockefeller Series, issued by the Bureau of Social Hygiene,[1] Abraham Flexner gives an excellent exposition of the various methods for the handling and regulation of prostitution by the principal governments of Europe. Although to the student of this sociological problem these details are not new, his is the first comprehensive compilation of the modern status of laws and measures regulating the social malady among the higher civilized European countries.

In thus describing the prevailing conditions it was but natural that a critical discussion should accompany their relation, and Mr. Flexner has freely indulged in this privilege. He has condemned all existing efforts for the control of prostitution, regulatory and sanitary as well, and proclaims himself an abolitionist pure and simple, explaining that his interpretation of that term signifies an advocate for the abolition of all regulatory ordinances and all sanitary control of prostitution.

From a review of the existing systems in countries exercising regulation he professes not to discover any marked effect upon either the extent of prostitution or the spread of disease, and feels that official police supervision leads to abuses and oppressions far outweighing the resulting problematical benefit. He equally condemns segregation in separated streets or city districts, houses of prostitution, police regulations, and, last but not least, sanitary control, and advocates a system where no special discrimination should be exercised against prostitutes as such, but that they should be held liable only for those acts which offend against the ordinary criminal code, including offensive street solicitation.

The removal of the prostitute as a separate item from the criminal code has, for the first time in this country, been one of the main features inaugurated by the Municipal Clinic of this city (San Francisco) since its opening in March, 1911, and one which I strongly advocated in a paper which I read before the International Congress of Hygiene and Demography in Washington, D. C., September,

1912.[2] There is consequently no argument on this point between Mr. Flexner and me.

Some of the restrictions yet enforced in countries professing abolition might even be removed in pursuance of the spirit of equality before the law. Prostitutes there are still compelled to live alone and not allowed to club together though there is no exploitation by a third party. These countries do not make any distinction between the reprehensive brothel and a mere living together of two or more prostitutes in a common domicile, which should be permitted. They suppress both and thereby fall short of the professed equal treatment. However, as earnestly as I advocate for the red light votary a position of equality with everybody before the criminal and civil laws, just as earnestly do I demand a special regulation for her in the code of sanitary laws.

In order to arrive at this final conclusion we must review, from Mr. Flexner's book, a number of statements and facts to understand their ultimate significance and value. That venereal diseases, together with tuberculosis, form the devastating scourges of mankind, has been proven by many incontrovertible statistics of hospital morbidity and mortality throughout the world. A recent moderate estimate[3] credits New York City with about 1,000,000 venereally diseased individuals, more than 1 to every 5 persons, men, women, and children.

This condition prevails with the exception of some rural districts throughout this entire country. Our American army reports point to the highly discreditable prevalence of venereal diseases in its ranks, showing by far the highest percentage of morbidity among all the armies of civilized nations.

Mr. Flexner does not attach very much value to army statistics, but others will differ with him. They will justly dwell on the excellence of this material for reliable comparison. In every country these men are of the same age, remain under similar conditions of life as to work, nourishment, and physical status, and the question will be asked, to what is due the low percentage of venereal disease in the armies of countries like Germany, France, Austria, where sanitary control is exercised, if not to this same sanitary control? England, without it, has in its insular army a ratio of venereal diseases far exceeding that of any of the other civilized nations of Europe, while her Indian contingent, after ten years of sanitary control in garrison districts, shows a comparatively low percentage with an absolute decrease of 66 per cent. of morbidity since the introduction of these measures.[4]

A sanitary control of prostitutes is objected to by Mr. Flexner for these main reasons: (1) All regulative measures have proved ineffective; (2) As a regulation it constitutes an infraction of liberty and singles out women; (3) It creates an illusion of safety and leads to greater indulgence; (4) It reaches only a part of the prostitutes; (5) It has, where established, not succeeded in diminishing the spread of venereal diseases.

Let us consider these various objections:

It is a universally recognized fact that all truly repressive measures against prostitution have utterly failed, the efforts of vice commissions notwithstanding; nor shall we waste any time or space in disputing that the methods hitherto practised in European countries are, with one or two exceptions, antiquated and utterly worthless for producing any desired result. What is wrong? Are the methods at fault, or the basic principle of sanitary control?

Prostitutes throughout continental Europe have been under the special supervision of the police authorities. They are classified as criminals and special police rules and ordinances have been enforced for the regulation of their life and conduct, not exacted from any class of criminals out of jail. They are permitted to reside only in certain definite parts of a city, they may leave their houses only during certain hours of the day or night; they are barred from showing themselves on many of the public streets and from some of the public theaters, and from certain parts of those they are allowed to attend. Even their style of dress is subject to regulation. Only Austria, during the last two years, and the Scandinavian countries have followed modern views and are liberated from the worship of these relics of medieval barbarism.

Is it not a natural consequence of such treatment, inflicted upon the inscribed prostitutes, that those who can possibly avoid submitting to its Draconian regulations, should try to do so, and prefer to take the chances of escaping detection and swell the ranks of clandestine prostitution? No wonder that such a system only reaches a comparatively small percentage of the women!

The methods of sanitary control in these countries are equally insufficient and reprehensible. The intervals between individual examinations are far too great, extending over periods of from one to several weeks. Microscopical examinations of secretions are made only once in two weeks or a month; in some places no microscopical examinations are made at all. How are successful results to be achieved with such work? House examinations by the official physician, and acceptance of the certificates of private physicians open the door to fraud and deception, and when an unfortunate victim of disease is discovered she is subjected to the indignity and hardship of lock hospitals, or to the terrors of the dungeon-like St. Lazare Hospital.

I do not doubt in the least that there are members of American Vice-Commissions, and fanatical reformers who, in their blind efforts for the sudden extermination of prostitution, would welcome the transplantation of such barbarous proceedings to American soil, regardless of their injustice and the cruel suffering they entail.

Fortunately this acute hysteria of a wild reform movement has passed its zenith, and saner views are gradually spreading, based upon a conviction of the primary responsibility of society itself for such deplorable conditions and a realization of the futility of violent and relentless severity in the fight for their repression, with reliance placed rather on educational uplifting and the amelioration of deficiencies in the social structure. But if we rebel against these unjust and cruel measures, should we go so far as to reject an up-to-date sanitary control for the people's protection from the insidious spread of a pernicious group of diseases calculated to undermine the health of the nation?

It is admitted beyond the shadow of a doubt by even the adversaries of sanitary control, that these venereal diseases have already spread to an alarming extent throughout the entire country, and that nothing effectual has been done to stem the rising tide. The main source of this general infection is to be found, to the exclusion of nearly all others, in prostitution, open and clandestine.

It is generally and freely conceded that all measures to suppress prostitution have failed to make

any appreciable impression upon its extent. Granting even that educational and sociological progress may finally succeed in practically exterminating the social malady, this most desirable goal will be attained only after a lapse of one or more centuries.

During that time prostitution is to remain with us, and for many and many long decades in a probable unabated prevalence. What are we going to do about it? Are we not going to try and cleanse the main source of infection and refrain from persecuting prostitutes, when, freed from a special police regulation, they are controlled by health authorities only?

This proceeding was adopted in this city (San Francisco) with the opening of the Municipal Clinic in March, 1911, and was carried through with such slight modifications as its novelty made advisable.

Two reports of its sanitary and general success have been given,[2] and whoever examines these reports with an unbiased judgment cannot doubt that the solution of the sanitary problem was there taken in hand successfully. The women were treated with all the consideration accorded to private patients; the individual examinations were made at intervals of four days, and conducted with the aid of the most approved scientific methods. The result was a decrease in morbidity of 66 per cent., a gradual appreciation of the benefits derived from this system by the women themselves, and a desire to obtain the certificate of examination even by women not of the regular rank and file.

There is no claim that all, or even the greater part, of the clandestine prostitutes were reached. But among the regular clientèle of the Clinic, the conviction spread that this new health provision accomplished really as much good for the women as for the general public, and all passive resistance to the required examinations was overcome.

It is but an empty pretext advanced by opponents to sanitary control, that such an enforced sanitary regulation infringes upon the rights of personal liberty. Flexner does not join them, he says, as long as good results are obtained, the liberty of the individual should not stand in the way of such a beneficial regulation. In the light of defense against the inoculation with dangerous disease from a certain class of individuals, has not the public the right to self-protection by submitting such individuals to enforced regulations which will lessen or remove threatening danger of such gravity?

The Supreme Courts of the State of New York have taken this view, and decided that no infraction of personal liberty was committed by the enforcement of a law demanding regular sanitary examinations of prostitutes.[3] Is there any reason to doubt the great benefit gained in reducing the specific morbidity of these women 66 per cent. and preventing diseased ones from spreading the infection among each individual clientèle of from one to several times ten visitors per night?

All doubts expressed by various writers, and reiterated by Flexner, as to the reliability of determining freedom from venereal disease should be discarded. The modern clinical and laboratory methods of examination show whether an individual is cured or has entered a latent stage of the disease.[4] The rapid development of physical, chemical, and biological diagnostic and therapeutic methods justifies us in expecting even much greater progress in the near future. There should be no encouragement of retrogression. If there are real and essential faults to be found with certain features of our sanitary control let us correct them and thereby improve and advance the system, not abandon it in favor of a chaotic state of uncontrolled universal venereal contamination.

The Scandinavian countries have been held up by Flexner as examples of what can and should be done by the adoption of so-called abolition. Does the system applied there really and truly deserve the name "abolition" as defined by Flexner, namely, the abandonment of all sanitary control of prostitution?

The laws in these countries ordain that all physicians are required to report daily, with or without names, their patients suffering from venereal diseases. These patients are to be furnished with copies of the laws referring to the contagion and spread of venereal diseases, and must affix their signatures to a document stating that they have been thus warned. The physician also obtains information as to the source of his patient's infection and communicates this information to the Health Office. The person so accused is requested to call at that office, and informed there of the nature of the charge, not disclosing the accuser's name.

All so-called voluntary compliances with these requests of the authorities, and the much boasted guardianship of individual liberty, are rendered illusionary by the express-stipulation of the law that in case a person refuses to obey the order to call at the Health Department, the aid of the police is to be invoked to enforce such order, and if upon examination a person is found to be ill, treatment may be compelled to the extent of forcibly detaining the infected person in a public hospital. The law furthermore punishes persons by imprisonment for a term not exceeding three years, who, knowing themselves to be victims of venereal disease, communicate it to others through sexual intercourse. If we ask which is the class of individuals most likely not to avail themselves of the offered free treatment, ambulant or hospital, the answer would naturally be the prostitutes, as the treatment and simultaneous close observation deprive them of their livelihood. To them, in the first place, the choice of ambulatory treatment would hardly be granted, as only such privilege is accorded to reliable persons; others are immediately interned in hospitals after the examination has confirmed venereal infection. Is there really any material difference between this circumlocutory manner of sanitary control of prostitutes and a direct one through the Bureau of Health? It may be advanced that this method of denouncing the real or supposed sources of infection helps to bring a greater contingent of prostitutes, namely, a greater part of the clandestines, within the power of the authorities. Let us even concede for argument's sake, that the number of clandestine prostitutes brought under restraint may be increased, but what new obnoxious features have we then to accept with this exchange of systems?

The source of infection is denounced primarily by the infected patient to his physician, and by the latter communicated to the health authorities. Irrespective of the unavoidable errors to which such guesswork of laymen is evidently subjected, what frightful prospects are opened by this procedure to the most vicious and slanderous calumny, more apt than anything else to wreck a career and ruin a life!

That this is no imaginary danger can be easily proved by simply comparing in the Copenhagen police reports the number of denounced women with that found diseased upon examination.

| Year | Women Examined Upon Accusation | Women Found Ill Upon Examination |
|---|---|---|
| 1907 | 388 | 172 |
| 1908 | 548 | 195 |
| 1909 | 703 | 226 |
| 1910 | 797 | 155 |
| 1911 | 740 | 160 |
| | 3176 | 908 |

In these five years 3176 women were examined by order of the Copenhagen police, and merely 908, or 28 per cent., were found to be infected. Thus in five years, in a city not much larger than Cincinnati, 2268 women were wrongly accused of having been the source of a venereal infection; they were forced by the police to submit to an examination by the police surgeons, and were found to be free from disease. It is needless to point out the disastrous mistakes, most terrible in their consequences, such a system is liable to cause, and still less necessary to assert that no American community would tolerate even its tentative proposal.

The avoidance of official graft is said to be one of the advantageous characteristics of such a system. This seems to me an equally futile assertion. While it is true that our police officials do not enjoy such unrestricted public confidence as to credit them with an altruism sufficiently pronounced to control prostitutes without an eye to personal profit, I might easily contend that our police corps are painted far blacker than they deserve and that as a body they compare not unfavorably with those of other countries. However, the modern sanitary system of control practised here, and in a measure introduced also in Vienna and Budapest, transfers the supervision and active handling from the police to the health authorities. There is no greater difficulty here than anywhere else in getting honest men, if they are wanted, for an honest purpose.

It is the meanness of purpose which, more than anything else, besmirches and corrupts its workers. What are we coming to with spies for prohibitionists, spies for the Sabbatarians, spies for the discovery of indecent literature, spies for the madly rampant vice crusaders? These gumshoe experts must bring evidence, true or manufactured, or lose their jobs. The outcry of the New York *Sun* on May 8, 1913, and the letter of Rev. W. S. Rainsford, published by that paper a few days later, branding these hirelings of a frenzied Puritanism as notoriously corrupt, undependable, and dishonest, and giving proofs from an extensive experience of their ignorance, their lawlessness, their questionable devices for collecting evidence, and their general trustlessnsss, did not surprise anyone who, with a passing knowledge of these affairs, knows how to read between the lines. It only serves to demonstrate that men, hired to spy on individuals suspected of having committed acts disapproved of by their employers, will usually report commitments of such acts regardless of the truth.

In legitimate and lawful pursuits, private or public, men of the higher civilized countries are not fundamentally different in their regard for truth or honesty the world over. The police and health officials in Copenhagen and Christiania, detailed to attend to the control of venereal diseases, did not work any better or more honestly than those of San Francisco, Vienna, or Budapest, and the sanitary improvements of these latter cities were accomplished without dragging thousands of innocent women before the police under the false charge of being carriers of venereal infection.

If that system in the Scandinavian lands represents abolition, I venture to say the American people will have none of it, and the question arises again, what will we do to stem the fearful tide of venereal diseases constantly pouring in upon a defenseless people?

Will it be advisable to take recourse to repression and join those who, in their vain and shallow self-sufficiency, formulate laws that sanctify their own more or less distorted notions, and make of the moral laws department of our legal structure an attractive target for well-merited shafts of contemptuous ridicule?

All these efforts to change the morals of mankind by legislative acts are doomed to failure so long as public opinion does not overwhelmingly support them. They do worse than fail to correct the evil conditions aimed at, they invariably increase their prevalence, and, failing to enforce the law, subject it to ridicule and contempt. The people of the "dry" States are consuming more liquor to-day than they ever did, and are forced to resort to all kinds of debasing subterfuges to gratify a taste stimulated by the obstacles of an unreasonable repression. The general verdict of army officers condemns the closing of the canteen as a most objectionable measure in its effect upon the sobriety of the men. Will the repressive laws written by the sexual prohibitionists accomplish more?

Flexner seems to think so when, in the last chapter of his book,[1] he writes of repression, "I do not mean that repression will have accomplished little. On the contrary important good is achieved at the moment and still more in the long run." It is impossible for me to agree to this.

In discussing Flexner's assertion we can eliminate Europe, for, with the exception of England perhaps, no such anti-vice laws or commissions exist in any European country; prostitution is under regulating ordinances. Even the English laws are a dead letter. The laws against brothels and the despicable white slavers are directed against the exploitation of the women victims, not against prostitution itself. America alone offers a fertile soil for an exuberant crop of anti-vice laws and vice commissions.

In our large cities vice commissions have sprung up like mushrooms, which, with virtuous self-sufficiency and the unswerving severity of the Inquisition and the Vehmgericht of old, exercise the moral custodianship of their respective communities, haul the refractory *filles de joie* into the courts, thence into the workhouse, whence they emanate again into the street to resume the vicious circle. From State capitols and from pulpits a new crusade is proclaimed and armies of active virulent stone-throwers seem to have forgotten the beautiful parable of the far-seeing Master.

With its very birth, that singular New York Adultery Act must have freed the great Empire State from all such breaches of the law, for since its enactment in 1907, hardly half a dozen people have been brought to trial and convicted.

That remarkably sweeping Mann anti-white slave law tends more to prosecute the prostitute and the indiscreet philanderer, than the miserable white slavers who so prominently figure in the naming of the act, and who are so rarely caught and convicted. There ought to be only one place

in the present state of society for the numerically much overrated white slaver to occupy—*the gallows*—but this law allows no distinction between the welcome male roommate and escort of a traveling demimondaine, and her seducer and exploiter for commercial purposes. By means of crossing a State's boundary line, adding a distance of perhaps a few yards only, the traveling companion of a lady of easy virtue is transformed from a delinquent joy-rider to a white slaver, with the assured prospect of a temporary address at the penitentiary. This law is not a relic of medieval barbarism; it passed both houses of Congress in the year 1911, and was duly signed by the then President of the United States and is being enforced now, to-day, in the year of our Lord, 1914.

Such are the outgrowths of a system of repression that has swept over the greater area of the United Sates and has not yet finished its course. It has created for this country a rather isolated position in inflicting the severest and most disgracing penalties for offenders against certain parts of a moral code the following of which might best be left to the private judgment of the parties most concerned. This attitude of the people of the United States has been regarded by other civilized nations with astonishment, not wholly unmixed wih ridicule.

I cannot but regret that a man of unquestionably high intellectuality and good analytical judgment should give even mild praise to misdirected efforts of such a nature. It is to be feared that upon the authority this well written book carries with it, efforts of another kind to check prostitution may suffer, such as child protection and education, energetic social uplift and betterment, and a more generous and even distribution of the wholesome joys and pleasures of life. These efforts which touch the root of the social malady rather than its leaves and blossoms, might be neglected for a useless and cruel surface destructiveness of an ever renascent growth. In the wake of such tendencies struts the false belief in the effectiveness of this destructive extermination, and a consequent neglect of sanitary protection from the social malady.

Public and clandestine prostitution furnishes the breeding place of nearly all the infections with venereal diseases. Here we must concentrate all our efforts to check their spread. Regular biweekly examinations of the prostitutes must be made with issuance of certificates by the Health officials; free clinics must be established for the treatment of venereal diseases for men and women, and hospital admissions granted to such cases as require hospital supervision for any reason, such as poverty or danger to others or themselves. Let all cases of venereal disease be reported by number to the health authorities, but such reports to be made by physicians only, and based upon their own knowledge, in order to avoid conditions brought about by the Scandinavian spy system.

Some ways should be found to advocate the general use, in these circles, of precautionary prophylactic measures. Attention of both, men and women, should be directed to the protective qualities against gonorrhea, of an injection with silver salt solution immediately after, and against syphilis, the application of calomel salve immediately before cohabitation.

In all these measures the greatest possible discretion and tact should be observed in order to shield unfortunate persons afflicted with venereal diseases from the unjust prejudices and condemnation of the general public. But in our endeavor to be just and impartial in treating the male and female venereal sufferer alike let us not give way to a false and cowardly sentimentality disastrous in its consequences. Prostitution is a factor to be confronted with open vizor. It will be with us in undiminished prevalence for many and many decades to come. How soon the above outlined educational and social measures will materially influence its eradication nobody knows. During all this time, perhaps for many future centuries, the breeding of disease will continue to emanate from this center of pollution.

Prostitution, the indiscriminate, promiscuous subjection to sexual intercourse for money, *palam sine delectu pecunia accepta*, is being practised as a profession, and as a profession full of great dangers to public health. It therefore demands the enforcement of special sanitary regulations for the protection of those who are engaged in its exercise and for the protection of the general public. And let there be no outcry that such special sanitary regulations for prostitutes bring undue and deep humiliation to that class of women. *No humiliation of any sanitary regulation could equal the disgrace of the profession which requires it.*

*Society is profoundly accountable for the existence of prostitution and this terrible responsibility conveys upon it the imperotive duty of adopting means to minimize the evils of the social malady and protect itself from the resulting injuries.*

I do not wish to consider here the great measure of street or district segregation, as it is not a purely sanitary measure and the opinions upon the advisability of adopting it in its strictest sense are, even among the regulationists, by no means uniform. Other factors of moral and criminalistic nature determine the answer to this question; local conditions also take a part. The entire matter seems to be still in the balance at present and must be left to future experience for final decision. In quite a different light, however, must we consider the sanitary measure of a regularly recurring examination of the prostitutes.

The prostitutes are the main disease carriers, for infected men have only a slight share in its distribution; the man's capacity for the ordinary way of spreading venereal disease being limited to a few cases a week, while the ordinary prostitute accommodates her 25 to 30 visitors in 24 hours. As a rule the man is incapacitated through pain and refrains from having intercouse during the acute and infective stages of the disease, while the woman goes on plying her trade. And here we have the main objects of our task. To stop the infected prostitute from plying her trade as soon as her infection is discovered, preventing her from reentering the active ranks until cured or rendered innocuous; and the extension of this supervision over the largest possible number of public and clandestine prostitutes should be the first and most important step in the sanitary control of prostitution and in the people's protection from its sanitary injuries.

We have tried to accomplish that here in San Francisco with the establishment and work of the Municipal Clinic[2] under health department control only. The women of the red light district, who visited the clinic for their bi-weekly examination, and its certification, were treated with the same

consideration and courtesy that are due to private patients. This proceeding, which never even suggests a criminality of the institution's clients, but regards them in the light of ordinary human beings in need of sanitary supervision and advice, gained the fullest cooperation from all grades of the city's prostitutes.

The reduction in their morbidity was remarkable, 66 per cent. in two years, and though no reliable statistics of the general decrease of venereal disease throughout the city are at my disposal, their essential reduction among the great contingent of prostitutes, I consider as its incontrovertible proof, and as the foremost important accomplishment of this special sanitation.

The objection, so frequently voiced by opposing repressionists and apparently also shared by Mr. Flexner, that the issuance of a certificate of examination will be regarded as a guarantee of safety by the laity, and induce many men to throw aside their former fear of infection and visit these women, is not supported by the experience of medical men.

No physician who has had any dealings with men afflicted with venereal disease would pay much heed to this part of the argument. If there really are many men whose fear of venereal infection is greater than the strong voice of sex desire, tempting through all the years of adolescence and manhood, it has not been the good fortune of the physician to meet them in any convincing number. The first question of the patient recovering from a case of venereal infection is "When may I resume sexual intercourse?" Boys and men alike are all pressing their medical counsellor for permission to resume sexual relations where they have been left off. No hesitancy about another trial of the joys of Klingsor's pleasure-grounds. If the experience of illness and suffering does not act as a preventative, surely the mere fear in the inexperienced, of a possible infection, will hinder only a very few men. Facing the uncountable many who would be shielded by sanitary control, stand possibly an insignificant few lured by their belief in the safety of indulgence.

A recession of the sanitary control of prostitution means therefore an equal recession of protection from the spread of venereal disease. The spirit of progress points not to an abandonment, but to ceaseless vigilance and constant improvement in the systems of sanitary control, employment of the most advanced, complete, and reliable means of examination, and a humanely generous and reasonably sympathetic treatment of the women concerned. This must be accompanied by the establishment of a system of general child protection, early educational methods, including sex hygiene, and social betterment in the handling of the great problem of prostitution, instead of the prevailing course of criminal persecution.

In order that such a change may be accomplished, saner views as to the legislation for criminal prosecution of all cases of sex immorality should enter the minds of our lawgivers, and existing irrational laws should be modified or repealed. Men of the learning and high authoritative standing of Mr. Abraham Flexner can contribute in their special publications more than many others, toward stemming this flood of ridiculously hysterical vice campaigns, with their subsequent disinterments of barbarous medieval systems of prosecution of prostitutes. It would be difficult to devise a more efficient plan for the general dissemination of venereal diseases than just such persistent persecution, which renders it impossible for any department of health to exercise a wholesome check on this continuation of the world-wide spread of infection by its only rational remedy, *a thorough and modern sanitary control of prostitution.*

## CLINICAL ESTIMATION OF THE CHOLESTERINEMIC INDEX.

BY CECIL KENT AUSTIN, M.D.,

PARIS, FRANCE.

IMPROVEMENT in research methods and apparatus is slowly but surely forcing on the practitioner the obligation of considering his patients from entirely new points of view, so that the day of the self-sufficing physician has now closed never to dawn again, and in his place has arisen the man who is merely one link in a chain, the others being the specialists and laboratory workers of all kinds. It, in fact, now becomes difficult to realize the position of the medical man in remote and scarcely populated regions; just to take one example, think of how serious a handicap it would be not to be able to have free recourse to *x*-ray examination!

In the last few years specially important progress has been made in the chemical, as opposed to the histological and biological, examination of the blood—"the fluid tissue of the body." After mere globular numeration and leucocytic differentiation came the study of the mode and rate of coagulation and the practical use of serum-injections in therapeutics; this was followed by the estimation of the blood urea-percentage and its outcome, Ambard's constant—of such utility in renal disorders, to which was soon added the blood percentage of uric acid. But whereas the practical value of the urea test is now generally admitted this is far from being the case with uric acid; not only does the latter require the withdrawal of quite an amount of blood from the patient's arm, but the accuracy of the figures obtained by the method is seriously thrown into doubt by some chemists. In fact, this unfortunate uric acid seems to have been born under an evil star. I need not say to an audience of physicians with how great a degree of favor uric acid and its supposed pathological importance has now for decades past been received by the public at large; they look on it as a question definitely settled, with which they are entirely familiar. And yet, although it has now been abroad in the land for nearly a century, medical authorities seem less agreed than ever

about its nosological status. As an instance of how tottering its position is in some quarters, both as regards its pathological significance and the results obtained by its classical treatment, I may cite the case of Professor Lemoine, of Lille, who feels that he is authorized by the experience acquired since Bright's time in throwing altogether overboard the uric acid causation of arteriosclerosis, in wiping the slate clean of the whole affair, and in beginning afresh! This he has done in connection with cholesterin, the latest substance to be estimated in the blood, and the subject of the present paper; and he has now for several years past, and in a number of publications, endeavored to show that arteriosclerosis and atheroma are due to excess of cholesterin circulating in the blood.

It had long been evident to different clear-sighted men that important data must necessarily result from a thorough study of the cholesterin question, but they were always deterred from taking the matter up by the lack of any suitable method of ascertaining its percentage in the blood. This problem was, however, finally solved by a chemist here, Dr. Grigaut, the collaborator of Professor Chauffard, who at last succeeded in devising two methods that have given satisfaction, one a laboratory one for chemists only, the other, colorimetric, sufficiently practical for routine, clinical work. Armed with these methods, Chauffard and his assistants have gone into this question pretty thoroughly, and from their researches have emerged a certain number of facts that are of interest both from the point of view of general pathology and of ordinary practical medicine. This question has unfortunately so far hardly reached the general medical public, owing, undoubtedly, in great part to the fact that most of the publications of Chauffard and Grigaut have appeared in literature that does not fall under the eye of the practitioners even over here—the Comptes-rendus of the Biological Society, the volume published in honor of Professor Lépine's scientific jubilee, and Grigaut's thesis, 1913—so that it may prove to be not without utility to the brethren at home, who naturally would have still lesser occasion to see these publications, to give a brief résumé of the chief points of the question.

Cholesterin, which is a non-phosphoric liquid body somewhat similar to fat, is a normal constituent of the blood, in which its serum percentage varies from 1.20 to 1.80 per 1,000 c.c. Anything from one gram downwards can then be looked on as a hypo-condition, and from two grams upwards as hypercholesterinemia. The percentage of this substance has been sought with a patience and perseverance that can only elicit our admiration in a wide range of conditions of both health and disease, and the conclusion arrived at has been that its main rôle is that of a neutralizer of infectious agents and toxins. Its origin is in part from certain articles of food, and in part endogenous; Chauffard leans toward the opinion that the suprarenal capsules and corpus luteum play a preponderating part in its production in the body itself. It forms a normal element of many of the tissues of the body, and in particular of the nervous system, while sometimes large deposits of it, cholesterin tophi, are to be met with in pathological conditions, the chief of these being gallstones, which are often pure cholesterin, atheroma of the larger arteries, the lesions of xanthelasma, and the arcus senilis of the cornea and fatty retinitis. If xanthelasma, then, depends on a chronic excess of cholesterin circulating in the blood, it becomes easy to understand for what reason the removal of such spots by operation gives such unsatisfactory results.

It is during the acute stage of the infectious disorders that the cholesterin index falls to its lowest point. The curve of this index follows in such cases a course very similar to that of the temperature, only upside-down. When the temperature in enteric is at its highest and the patient at his worst, the cholesterin index is at its lowest; it approaches the normal again and even coincides with it when convalescence is reached; but it then rises well above the average and remains there for a certain period, and this fact is of great importance, in consideration of the frequency with which an attack of typhoid fever serves as starting point for the development of biliary calculi. The same thing takes place during the acute febrile episodes that occur during chronic tuberculosis; the cholesterin index descends at each such intercurrent manifestation, and is in inverse proportion to its severity.

The index rises and remains above the normal chiefly in certain chronic conditions, and during and immediately after pregnancy, which is again of great clinical interest, on account of the close relation existing between the formation of gallstones and the bearing of children; we have thus marked hypercholesterinemia connected both with typhoid fever and parturition, the two best-known starting points of hepatic lithiasis. Cholesterin is also present in excess in chronic renal trouble and in established biliary lithiasis.

Such being then the salient points already established in connection with cholesterin, the practical deductions become evident at a glance—that our endeavor should be to increase the supply of cholesterin that is at the system's disposal in certain cases, and to diminish it in others—the latter category of cases being apparently, at least until further notice, far more important than the former.

Whether any practical results are to be expected from the therapeutic administration of cholesterin during the acute stage of infectious disorders, and in particular of enteric fever and pulmonary tuberculosis, has still to be demonstrated; but it would seem that encouraging results have already been obtained in some of the graver forms of anemia, such as the pernicious variety.

But the treatment of hypercholesterinemia is evidently destined to take a most important part in therapeutics in the future, if the views put forward in all seriousness by Chauffard and Lemoine prove to be well grounded. Chauffard in his recent work on biliary lithiasis* lays emphasis, on the one hand, on the unsatisfactory results that are obtained from the treatment of this condition when it is once firmly established, and, on the other, holds out hopes that in this circumstance, as in all others in medicine, prevention will prove the patients' salvation. In other words, he expects that with patients who by family history or personal antecedents seem heading for biliary lithiasis and all its concomitant mishaps, examination of the cholesterin index and careful treatment of the hyper-condition, if demonstrated, may save the subject from the ultimate perils of this very serious disorder.

And what can we say should Lemoine's theory prove true? The arteriosclerotic state is so common and so grave, and ruins such myriads of vas-

*Chauffard, A.: "Leçons sur la Lithiase Biliare," Masson & Co., Paris, 1914.

cular systems, and, through their agencies, of kidneys and brains, that *anything* that would enable us to see a little light in this question would prove nothing short of a universal boon to mankind. Personally I look upon the uric acid theory, as regards both causation and therapeutics, as definitely bankrupt, and with it its attendant Pleiades, iodides, alkalis and lithia, with their manifold successors. Unfortunately, Lemoine appears so far to be alone in his opinion, although, nothing daunted by this solitude, he perseveres in his work and sends forth paper upon paper on the question. Time alone can decide in the matter, but it is certainly to be hoped that someone will appear before long with a satisfactory exposition of the pathogenesis of this condition.

From a therapeutic point of view cholesterin can be increased or diminished in the blood by direct administration in the form of an extract of bile, or through food. The organic extract of the corpus luteum can also be tried. The articles of food that contain cholesterin in the highest proportion are egg yolks, fish roe, butter and cream.

20 Rue Chalgrin.

## THE MANAGEMENT OF CARDIORENAL DISEASE.*

By CHARLES EDWARD NAMMACK, M.D., LL.D.,

NEW YORK.

VISITING PHYSICIAN TO BELLEVUE AND TO ST. VINCENT'S HOSPITALS, AND PROFESSOR OF CLINICAL MEDICINE IN CORNELL UNIVERSITY MEDICAL COLLEGE IN NEW YORK CITY.

LESIONS about the valves of the heart cannot be repaired, but certain compensatory processes can be set in motion by which the effects of these lesions can be balanced and so-called compensation be established or maintained. It is unnecessary in this paper to discuss the effects of single or individual lesions because the later manifestations of all are similar, resulting in cardiac enlargement, muscular and arterial degeneration with changes in the blood pressure, and ultimately back pressure effects in different organs. Practically, we treat our cardiac cases with reference to whether compensation is established, or compensation is broken. However interesting the recognition of murmurs in the heart may be, from a diagnostic standpoint, our therapeutic indications are pointed out by the work power of the heart and not by its adventitious sounds. It is one of the preservative provisions of Nature that whenever the heart is called upon to do extra work from any cause (nervous, valvular, or connected with increase of blood pressure in kidney disease), a healthy heart muscle can increase in strength in proportion to the work it is called upon to do, *provided that this at first lies within the original capabilities of the muscle.*[1]

In well compensated valvular lesions of the heart the routine use of heart tonics should be avoided, and muscle nutrition should be preserved by avoiding strain and by judiciously strengthening the muscle by dietetic, climatic and hydrotherapeutic means, preferably without the use of drugs. An exception to this rule sometimes occurs in cases of aortic regurgitation, where disagreeable symptoms may be produced, referred to the brain, the respiratory apparatus, the heart, and the stomach, and these may require special symptomatic treatment.[2] These symptoms depend upon ischemia of the brain, due to the sudden regurgitation of blood during each diastole, and are best met with opium, unless renal insufficiency coexists, when opium is contraindicated and recourse must be had to bromides for the palpitation, and quinine for the cerebral anemia. Cold to the epigastrium and precordium will help to relieve.

Aside from this incident, compensated valvular lesions require attention to diet rather than to drugs. Diet of a full caloric equivalent should be taken, but large meals should never be allowed, because a full stomach embarrasses the right heart. For similar reasons fermenting foods should be avoided, alcohol taken sparingly, if at all, and tobacco absolutely forbidden. Seaver of Yale has calculated that one cigar diminishes muscular power 25 per cent. in an hour.[3] Albumens and fats, fresh or stewed fruits, and green vegetables should be taken and carbohydrates reduced to a minimum. Reducing the liquid intake relieves the heart of much labor, prevents stomach distention, and by concentrating the blood increases the hemoglobin content. The theoretical explanations of the value of restricted fluid intake in cardiac disease are not convincing, but practical experience abundantly proves its value. It is frequently important to compare the fluid intake and output so as to determine when water retention is taking place, as this indicates failure of the heart to pump the water to the emunctories of the body.

Of equal importance with regulation of diet are rest and exercise in all valvular lesions of the heart. Unless patients can adopt the plan of eating small meals at regular intervals, rest for an hour after a full meal should be enjoined, as at this time nearly two-thirds of all the blood collects in the abdominal veins. Graduated exercise, however, may be indulged in later, always cautioning the patient to stop if dyspnea or præcordial distress develops. Exercise may be of the active, passive, or resistive type, and must be as carefully chosen for each individual as any other measure of treatment. Patients should be out of doors as much as possible, and the climate that permits this should be chosen when the patient's financial circumstances will permit. Four elements enter into the consideration of climatic treatment of heart disease, viz.: Altitude, mean temperature, temperature variations and humidity. Cardiac patients do not do well at high altitudes, and when compensation is disturbed should be kept at sea level. Extremes of heat and cold should be avoided and places like Southern California, when the mean annual range is small, should be selected. Humidity must also be considered, as any checking of the radiation of bodily heat throws a tax upon the cardiovascular apparatus. Baths should be neither too hot nor too cold. Hot baths produce a relaxation of capillaries,which always taxes the vasomoter center and the heart, while cold bathing causes a severe initial shock with contraction of the peripheral arterioles. Sea baths are, therefore, likely to be injurious. Lukewarm baths, 10 or 15 minutes immersion in water at 90 to 95 degrees, are useful, and the water may be medicated with four or five pounds of salt, or with carbonic acid gas, either of which is supposed to cause some relaxation of the peripheral capillaries and reduce the work of the heart. This combination of diet, climate and hydrotherapy will, in most cases, suffice for the management of compensated heart lesions without the employment of drugs.

When compensation is failing or broken, the same

*Read before the Society of the Alumni of St. Vincent's Hospital, April 8, 1914.

measures of treatment in the main, will be indicated, but with the conjoint administration of such drugs as may help to restore the disturbed balance of the heart. Thus, absolute rest in bed is the most important element, with the patient in the erect or semi-erect position, and this rest should be continued for a long time. The diet should consist mainly of a mixture of cream, lime water and milk, with the addition of a little fresh fruit, an egg, or a little meat, to avoid flooding the circulatory apparatus with fluid. Cold to the precordial region may be a valuable help. After these measures have been instituted, the indication for the use of heart tonics must be considered. A heart tonic is a medicine which aids the heart in prolonging its diastole and in enforcing its systole to the maximum. Of these, digitalis holds the first rank, but, like all powerful weapons, its use and its abuse must be thoroughly understood. Its tolerance by the patient, and his susceptibility to its action, must be carefully tested, at the outset, by small doses carefully watched. My own preference is for the infusion, freshly prepared from the best English leaves and given ice cold, to the exclusion of the "pure principles" of digitalis which are now so numerous and which are notoriously uncertain in their action. In gastric irritability, however, I often use digitalin hypodermically. Digitalis is contraindicated when the heart muscle is degenerated, as in myocarditis, fatty heart, and in the extensive degeneration of the left ventricle, which accompanies decompensated aortic regurgitation. These cases will not respond to digitalis, and, in fact, degeneration of heart muscle may be assumed in cases where the physiological action of digitalis cannot be produced by the administration of a reliable preparation of that drug given for three days. A condition of the arterial walls, such as extensive atheroma or fragility, may also contraindicate digitalis, lest by raising the arterial pressure it may lead to rupture. In these cases, strophanthus may take its place, or a combination of digitalis, and the nitrites may be found useful. Strophanthus strengthens the action of the heart muscle and slows the pulse, and does not raise arterial pressure to the same degree as does digitalis. In Bellevue Hospital, we often use strophanthin, either hypodermically or intravenously, in bad cases of decompensation. Other substitutes for digitalis, when this drug is inapplicable, are convallaria, adonis vernalis, caffeine, theobromine, and strychnine. But none of these should be used when the arterial tension is high, as each of them increases the arterial pressure.

In extreme cases of cardiac failure, there is no time for the slow action of heart tonics, and emergency measures must be adopted. Camphor, ether, and ammonia are the best, supplemented by brandy, champagne, and coffee. Camphor is best administered hypodermically in 10 per cent. solution in ether, or in 25 per cent. solution in sterile oil. Ether by the mouth may be given in the form of "Hoffman's anodyne." The aromatic spirits of ammonia is a rapidly diffusible stimulant for emergency use. Adrenalin hypodermically if the systolic pressure is low.

When failing compensation has reached an advanced degree, the effects of back pressure become manifest in various organs, as a result of venous stasis or passive congestion. These effects are shown in the brain, the lungs, the liver, the kidneys, and the gastrointestinal tract, and while the measures directed towards improving the general heart action are still indicated, certain modifications or additions may become necessary on account of the urgency of added symptoms. Confining this paper to the back pressure effects in the kidneys, passive hyperemia of these organs calls for careful regulation of the diet. It is important to differentiate merely stasis in the kidney from a real nephritis. The presence of a valvular lesion, and of back pressure effects in other organs, will usually decide. Milk diet is useful here, but the total quantity of milk in twenty-four hours should not exceed one quart and as this furnishes but 900 calories, sugar of milk, a little meat, fats, cereals, fresh fruits, and vegetables should be added to preserve nutrition.

In considering the subject of nephritis we find the anatomical or pathological classifications of that condition to be most confusing. From the clinical and therapeutic standpoints it is best to recognize three conditions, viz., (1) acute nephritis; (2) chronic diffuse nephritis—either following an acute attack or developing insidiously from the beginning, and (3) "vascular" nephritis or cardiorenal disease. In both forms (2) and (3) cardiovascular signs develop sooner or later and it is difficult to determine whether the changes about the heart and arteries are primary or secondary, or whether the same causative factor affects simultaneously the cardiovascular apparatus and the kidneys. The last idea includes the newer conception of what is generally understood as "Bright's disease." The determining feature is high arterial tension, with resulting cardiovascular changes and nutritional disorders, particularly in those parts that are supplied by end-arteries, viz., the kidneys, the retina, and the brain. The cases should therefore be treated as heart cases rather than kidney cases, and along the lines previously stated in this article for compensated valvular disease. What the exact toxemia is that induces this condition is as yet obscure, but a disordered gastrointestinal tract and liver, or some obscure perversion of metabolism, may be the source of the poison. A deranged bowel function floods the liver channels with toxic albuminoids and alkaloids; the liver cells are unable to cope with this tide, and the intestinal toxins filter through into the circulation beyond, where the kidney cells cannot deal with them efficiently, owing to their incomplete elaboration by the hepatic cells. Escaping thence into the general circulation they cause autointoxication and cardiovascular as well as renal changes follow.

This view of the vicious circle established is graphically put forward by Alfred C. Croftan[2] and appeals to me with more force than any of the perverted metabolism theories which I have had opportunity to read and ability to understand. Accepting it as a working basis, causal treatment of cardiorenal disease should concern itself first with the prevention of intestinal putrefacation. While the production of complete intestinal antisepsis may be a chimera, certain drugs may be useful, either chemically by direct contact, or physiologically by stimulating the natural defenses of the organism to greater activity. Cholagogue drugs are marked examples of the latter, because they increase the flow of bile, and bile is the best intestinal antiseptic. Nonpoisonous metallic salts, like sulphocarbolate of zinc, and bismuth preparations, may act chemically.

The diet selected must fulfill three conditions:

(1) It must be sufficient to maintain nutritive equilibrium; (2) It must be non-irritating to the kidneys; (3) It must not throw too much work on the digestive and circulatory organs. The more chronic the nephritis, the greater is the necessity that patients should receive daily the full caloric value in their diet. An exclusive milk diet is dangerous for many reasons. In the first place, there is a deficit of iron in milk, for adult life. Secondly, milk forms large quantities of nitrogenous end-products, chiefly urea, which throw an excessive task upon damaged kidneys. Thirdly, milk enough to maintain caloric nutritive equilibrium would amount to about three quarts a day, an amount of fluid by far too great to be forced through the cardiovascular apparatus. Fourthly, milk is very rich in phosphates, and unless these are changed into insoluble calcium phosphates by the addition of lime water, much unnecessary elimination work is thrown upon the kidneys. Finally, disgust and loss of appetite with gastric dilatation may be caused by exclusive milk feeding. Despite these drawbacks, the sensible administration of milk is a necessity in every case. The deficiency in iron can be met by the addition of an iron preparation. Excess of phosphates can be neutralized by lime water. The daily quantity can be limited to three pints, or less, given in divided doses, at frequent intervals, and with the addition of one fifth cream. And albuminous, fatty, and starchy foods can be given in addition, judiciously. Albumen may be given in the form of meat, eggs or vegetable albumens. Clinical experience and analytical study confirm the common belief that light meats are better than dark and red meats, because cooking causes white meats to lose more of the dangerous extractive than is the case with red meats.[4] Eggs were formerly forbidden in nephritis, but, because of their high nutritive values, 80 calories each, I allow patients from two to four fresh eggs every day. Vegetables growing above ground, although not of the same nutritive value as underground vegetables, are preferable, unless they contain irritating oils or other pungent principles, like radishes, asparagus, or garlic. Salads are useful, especially with abundant oil dressing, but without mustard, spices, or condiments. Starchy foods are useful and permit the addition of much fat in the forms of butter and cream. Among beverages, alcohol should be absolutely forbidden, beer is best omitted, and tea and coffee are theoretically contraindicated. Cocoa may well take the place of tea and coffee.

However discordant may be the views of laboratory workers regarding the effect of withdrawal of salt from the diet, the clinical fact remains that such withdrawal will cause the diminution of edema resulting from renal disturbances causing inadequate elimination of sodium chloride. When dropsy is the result of other causes, as poor circulation from weakened heart action, or from primary insufficient excretion of water by the kidneys, the salt-free diet is of no avail.[5] When dropsy is associated with arteriosclerosis complicating renal disturbance, the Karell cure, of partial starvation and decreased consumption of liquids, has reestablished diuresis, diminished arterial pressure, and caused subjective relief of cardiac oppression in many of our Bellevue patients.

The drug treatment of cardiorenal disease is of minor importance, for we know no drug that will influence a chronic nephritis. Remedies are used to prevent constipation, to secure as much intestinal antisepsis as is possible, to influence the heart action and the arterial pressure, and to relieve dropsy and internal edemas. These remedies have all been alluded to in earlier parts of this paper. Drugs should be used sparingly in any case of chronic nephritis, and reserved for emergencies that require energetic treatment. Hydrotherapeutic means are much safer and more efficient for influencing the heart's action and the blood pressure. High blood pressure depends upon three elements—the amount of the blood, the force of contraction of the heart, and the degree of peripheral resistance. Changes in the peripheral resistance can be brought about both by cold and by hot applications, but heat should be the method of choice in these cases, as the fall of pressure following heat is much more permanent and its production less dangerous than that produced by cold. The simplest way of applying heat is by lying still for ten minutes twice a day in a bath tub of water at 100° F. The addition of salt or carbonic acid assists in relaxing the peripheral capillaries. During the bath, cold may be applied to the head to diminish the danger of collateral hyperemia of the brain. Dry heat, by the electric light or hot air bath, produces a decrease in the total volume of blood through sweating, and this concentration of the toxic bodies in the circulating fluid may be dangerous. Sweating by moist heat is therefore preferred, and has been proven to be without danger of blood concentration. Hydriatic measures also allay the nervous irritability which so often accompanies cardiorenal disease. Hot water also exercises a profound influence on the general metabolism.

In selecting a climate for chronic nephritics, preference should be given to one in which the daily temperature fluctuations are very small, the altitude low, and the atmosphere dry. Southern California, Arizona, and New Mexico furnish the ideal locations in this country; Algeria, the Riviera, and Egypt abroad.

The surgical treatment of Bright's disease, warmly advocated by the lamented Edebohls, has not gained the confidence of American surgeons. Bright's disease is a systemic disorder, and the kidney lesion but one of its manifestations. Splitting of the kidney capsule can no more be expected to cure Bright's disease than could washing out the intestine be expected to cure typhoid fever. The modern methods of study of kidney disorders, by functional testing, have resolved chronic nephritis into three well-marked types, vascular, tubular, and uremic. From 40 to 50 per cent. of cases, however, will show mixed forms of these types. Yet in every instance an attempt should be made at their differentiation, as the treatment of each is different from that of the others, the mixed forms requiring treatment according to the dominant type. An excellent schematic classification, adapted and enlarged from a schema given at von Noorden's Clinic, has recently been put forward by Herbert Edwin Barigut.[6] No abstract can do justice to this excellent paper. It shows clearly that some things beyond the recognition of albumin and casts are necessary for exact diagnosis and rational therapy. In fact, more or less extensive destruction of renal tissue may exist without albuminuria or casts being detected[7] and be recognizable only by functional tests, as has recently been emphasized by McCaskey. McCaskey points out the necessity for

recognizing the precise type of renal impermeability present in a given case, *i.e.* whether for urea, chlorides or water. He gives some interesting tables of elimination of urea after the ingestion of preformed urea. The phenolsulphonephthalein test for kidney efficiency is of value for prognosis, rather than for diagnosis. It is used as a routine measure in our wards in Bellevue Hospital, but does not help to decide the particular type of nephritis present, although of great value as an indication of impending danger. In contemplated surgical operations on either kidney, it may be of great value in determining unilateral or bilateral kidney inefficiency. Ambard's "uremic constant," or the estimation by mathematics of the functional value of the kidneys, requires a little more teamwork on the part of a working physician and a laboratory chemist than is usually available for general practice.[8] But inasmuch as in the secretion of urine several distinct processes take part, as filtration, osmosis, selective cellular activity and absorption, it follows that functional kidney tests are at best unreliable, save for indicating renal insufficiency.[9]

## THE CAUSE AND VACCINE TREATMENT OF CHRONIC RHEUMATISM.

BY HORACE GREELEY, M.D.

BROOKLYN, N. Y.

ACTUAL experimentation proves, what was long surmised, that the introduction into an animal of a parasitic organism whose virulence is nearly balanced with the host's power of resistance frequently results in the establishment of chronic foci of infection in locations not reached by the blood plasma and leucocytes in full concentration. Such is notably the case in rabbits made chronic carriers of typhoid bacilli, who, after intravenous inoculation, frequently harbor organisms in their gall-bladder for prolonged periods; and in the same animal, inoculated with various races of the human parasitic cocci, as a result of which various degrees of arthritis develop—this last experimentally proved, as long as fifteen years ago by Dor, V. Dungern, Schneider, and Poynton and Paine.

In man the spontaneous development of similar conditions has long been well known (such as chronic gall-bladder infection by the typhoid bacillus, or more commonly by its near relative of the colon, chronic ear discharges following the exanthemata, and so frequently due to the continued presence of a diphtheroid bacillus) the organisms evidently locating while the favorable conditions of a period of reduced blood resistance prevail. But once established behind bulwarks of partially necrosed tissue they are enabled, through multiplication of aggressive powers by weight of their actual numbers, aided, often, by a process similar to the acclimatization of plants, to make slow headway against at least those body cells lying on the extreme outskirts of the circulatory system and next at hand, where individual cell nutrition is at the lowest and the protection afforded by the blood enzymes is least.

Pathologically the lesions of the chronic rheumatic joint disease are found to begin where the circulation is at a minimum, especially around the terminal blood vessels in the ends of the bones and beneath the cartilages—places well calculated to afford snug retreat for such streptococci as fall or grow into the circulation from a focus on or in the mucous membranes. Perhaps such localities are peculiarly favorable as the dense and unyielding surroundings in adults, not visited normally by much blood, do not readily permit the phenomena of inflammation, which are now known to determine the most rapid destruction of infecting bacteria. The great rarity of the disease in its chronic form among the young whose joints during the growing period are much more vascular is in conformity with this, but the predilection of the acute inflammatory form for youth at first thought might seem to contradict some of these inferences. Here, however, we are evidently dealing with a gross infection, suddenly flaring up in one with greatly lowered resistance, such as occurs when rabbits, whose general resistance has been lowered by preliminary dosage with colon bacillus vaccine, are experimentally intravenously inoculated with cultures of streptococci which, from their quantity and the free hand given them by the lowered blood power, are enabled to lodge and establish themselves at once in comparatively large vessels, generally developing a condition similar to human acute articular rheumatism. A like dose in an uninjured animal usually shows itself by blocking the smaller vessels of the synovial membranes and causing a subacute inflammation in and around the joints. Of course, to explain the acute form, we might also presume the presence of a small number of more virulent organisms acting upon a person with abnormally low resistance, or any adjustment of the forces of parasite and host that will give marked advantage to the former, and the result will be the same—an acute disease, but not the chronic form, which, as I have said, is due to slow and feeble development of stray organisms from the mucous membranes in areas of poor vascularity in persons with slightly lowered resistance. Further, that the acute form should strike the young is but in conformity with what is observed with other acute infectious processes, since, given an omnipresent infecting agent, such as the streptococcus, no one can be long in the world before encountering it with, under the circumstances described of special susceptibility, the given result, an acute disease.

Here I should remind the reader that I am considering acute inflammatory rheumatism, chronic articular rheumatism, apd arthritis deformans as but different manifestations of one cause modified by individual susceptibility, both constitutional and local, and duration of disease. Any peculiarity of the particular streptococcus infecting a given case, having been most probably developed under the influences acting upon it as a parasite upon that case, may be included in said idiosyncrasy.

We have several chronic bacterial parasites whose biology is so related to the economy of our body cell life that they, except under unusual circumstances, never pass much beyond the saprophytic stage. They exert little influence upon the body cells, and, as a direct consequence, the body cells exert little upon them. Such a mutual toleration seems to exist in the case of the streptococcus which grows on our mucous membranes, but which occasionally finds circumstances so favorable, as in a prepneumonic lung, in a puerperal uterus, or in a blocked or injured gland, as to so multiply its powers of offense, by slight structural variation or enormous overgrowth, as to cause the acute processes of such maladies as pneumonia, puerperal fever, erysipelis, etc. But usually this organism is content to enwreath the surface epithelial cells of our mucous membranes, occasionally growing into the stomata between them, and into the ramifications of the glands discharging thereon. As age progresses, and more and more damage has been wrought to our armour, our avenues of communication become clogged, and the readiness diminishes with which we bring our defensive and offensive powers to bear, now at this and now at that threatened point. We find then a relatively greater offensive power to be possessed by our parasites, which, unlike our body cells, being individually independent, never suffer from the defaults of others. Consequently, when an individual or two drop or grow into the circulation they are often wafted about, inhibited while in the blood stream, until they lodge in some nook or cranny where, if conditions permit, they develop. Such conditions are presented in and around the joints of the susceptible. Not to be too special or to make rheumatism more than a particular manifestation of a general streptococcus infection, I remind the reader that it has been demonstrated that ulcers of the mucous membranes, including stomach and intestines, can be and have been caused in animals by intravenous introduction of these organisms, so that there must be many other favorable localities besides the joints. Klotz, in the *Journal of Pathology and Bacteriology* for October, 1913, reported the case of a boy of 6 years who, after a six months' illness with rheumatic symptoms, died and came to autopsy. Aortic and mitral valves showed the usual vegetations of endocarditis, and the aorta a saccular aneurysm of recent origin, and for quite some distance in its ascending limb there was a marked infiltration around the vasa vasorum. All lesions gave a pure culture of streptococci; so that disease of the large vessels, even the varicosity of some veins, may be due to this organism. It may be reasonably suspected of causing at least some cases of chronic nephritis.

But returning to our sheep—the slight growth permitted to such an organism amid its surroundings beneath the cartilages or within, perhaps, the ligaments of the joint, often may produce no symptoms. These appear just in proportion as the tissues react—a slight or no reaction is alone consistent with the maintenance *in situ* of the bacterium which would otherwise be soon destroyed. (Acute inflammatory rheumatism never merges into the chronic form, although in rare instances it may be followed by it.) As the result of such slight growth some thickening of the joint tissues to-day with some more added tomorrow, evidenced by pains more or less evanescent, in time develops enough deformity of the parts to make the usual motions frequently productive of actual mechanical injury—which does much to cause the suffering of the chronic form. Of course, one can imagine that even a microscopical area of slight infiltration beneath the cartilage, if connected with the sensory nerves, might cause pain, but, as I believe, such nerves are here few and far between, most of the suffering probably comes from involvement of the synovial membranes and periarticular tissues. When chronic articular rheumatism passes into the condition with arthritic deformity, then the usual initial lesion beneath the articular cartilages has progressed so far that, with the aid of the mechanical injury wrought to the inflamed areas when they are ground between the ends of the bones, there is often no cartilage left and the bared bones grind upon one another with every motion, which, however, is finally greatly limited by the thickening and distortion of the other joint elements.

One may deduce from the foregoing that during life the bacteriological search for the organism in and around an involved joint might easily be a failure and, when I add that there are many cases on record in which, at autopsy, cardiac vegetations gave a pure culture of streptococci and yet the heart blood was absolutely sterile, one will recognize that in our hunt we may be very warm, as the children say, but yet miss our quarry.

I reported in the April number of the *Long Island Medical Journal* a series of 16 cases treated with autogenous vaccines in ten of which I had made careful blood search for the causative micrococcus, taking unusually large quantities of blood during an acute exacerbation of the disease, but in only one half of these was I successful. In the ordinary case I have never thought that the probabilities of a catch justified exploring in and around the joint with an aspirating needle but, if there be a fresh effusion, a culture of the organism may usually be got therefrom. There are, of course, recorded in the literature numerous cases in which such finds have been made, as well as many autopsies at which cultures of streptoccocci were obtained from diseased joints. And, in fact, there exists no case of chronic arthritis in which positive bacteriological findings cannot be made by such examination of the joints post mortem. A series* of 88 bacteriological examinations of the joints, at as many autopsies of persons dying from miscellaneous causes, was recently reported, and in all except some 13 cases (5 with a rheumatic history) the findings were negative, thus corroborating the indications of the positive findings made in actual cases of rheumatism.

Furthermore, in these days of complement-fixation methods, specific focal reaction should convince, and, if one grows from a given patient a culture of either a pharyngeal or a urinary streptococcus, a proper-sized dose of vaccine from the same, especially when given during the existence of joint sensitiveness, will, by a marked increase of joint congestion and pain, demonstrate cause and effect. Of course, since not over 90 per cent of all arthritic inflammations are due to the streptococcus, some cases will arise in which such diagnostic manifestations will not appear, when it will be up to the investigating bacteriologist to make good and find the real criminal. Care should, however, be exercised in the first place to secure all available bacteriological evidence of the causative organism's

*Beatie and Yates: *Journal of Pathology and Bacteriology*. Vol. XVI, 404.

identity, else one may be led to discredit methods of great reliability and specific worth, and the patient be lost to a life of chronic invalidism.

There is as much variation in the manner of growth and in the cultural manifestations of streptococci grown from different individuals, and even from different parts of the same individual, as there is among specimens of a given plant grown in different climes, and on different soils in the same clime. For instance, one scraped from the surface of the tonsil may show in smears as a long-chain-producing organism, and may develop in culture as the same or as a diplococcus or staphylococcus. It also usually fails to cause hemolysis on bloodagar, while another from the depth of the same tonsil, found as a diplococcus, will often hemolyse, and develop long chains upon suitable media. Organisms isolated from the nodes so frequently found in the neck and shoulder muscles of cases having muscular involvement, and those taken from the heart valves in cases of endocardial complications, are usually possessed of decided hemolytic qualities, which are evidently essential to their existence in these more exposed situations.

After a few injections of an autogenous vaccine the long-chain scrapings often got from the pharynx gradually modify through short-chain formations to diplococci enveloped by a capsule rivaling the heaviest ever displayed by that variant of this organism, the pneumococcus, with which the development is probably identical. It has been thought that permanently different varieties of this organism exist, but even the author of the most elaborate system of differentiation proposed (varying carbohydrate-media manifestations) has admitted that it is of value only to indicate the immediate derivation of the organism in hand, *i.e.* whether it probably came from the pharynx, the intestine, or the blood. Most observers, however, have found such methods futile and even deceptive. The morphological, cultural, and inoculation characteristics of the cocci isolated from the joints and occasionally from the blood in cases of rheumatism have uniformly been reported by observers to be mostly those of the common pharyngeal organisms, and as chronic foci of infection are so frequently found in and around the nasopharynx it has been presumed, with good reason, that from here come the seeds of many a joint lesion. Of course, the gastrointestinal tract, so frequently streptococcus-ridden, must contribute its quota; and since gonococci so frequently pass from the genitorurinary tract into the joints, we know that streptococci may do likewise. In fact, any focus of flourishing streptococci, sometimes a gingivitis or otitis media, is a depot from which seed is constantly dispensed, so that given a spot of suitable soil the seed is not long in arriving. It must not, however, be thought that a circumscribed focus of infection, as mentioned, need exist in every case, as the general one of chronic rheumatism (all that I have seen) has a chronically heavy streptococcus growth over the mucous membranes, as seen in smears of the fauces, owing, I believe, to that low special resistance of the individual which is also responsible for joint vulnerability.

Admitted that our common parasite, the streptococcus, under slightly varying forms of low virulence, is the cause of the malady and that the development of such is made possible only by a slight shifting of the balance between his virulence and our resistance in his favor, what are we going to do about it? While, of course, general hygienic measures are always in order and should never be neglected, special measures are available which are most effective—I refer to the gradual increase of our body's parenteral digestive powers over the microbe in question which may be brought about by the use of vaccine prepared from the offending organism. The series of 16 cases referred to were most successfully so treated, and I have under observation still others (to be reported later) in which every indication of distinct benefit appears, so I can urge actual try outs in addition to the theoretical considerations before mentioned as evidence of the method's worth.

As a first principle of such treatment no case should be given a dose of vaccine during an exacerbation, marked by acute joint swelling, attacks of pain, or temperature elevation, lest we but add to the discomfort or increase the size of the meal that the body is then struggling to digest. But we must proceed very much as we do with the alimentary tract in infancy or in conditions of extreme debility, and begin with small doses of that for which we expect to develop greater digestive power; and no meal must be repeated before the last is entirely disposed of, lest we swamp the enzymes on hand and even injure the organs which produce them, besides providing a specially favorable opportunity for the advance of the infectious process. This seems to be a great evil of vaccine therapy nowadays, the too early repetition of the dose, and I can conceive of no animal organism that can be anything but harmed by the injection of such a preparation every two or three days, a procedure we frequently hear of.

Furthermore, the vaccine must be autogenous—made from the patient's own organisms—else, for some reason depending upon slight difference in the constitution of the various strains of streptococci, probably developed by the conditions in the individual host, we may fail to strike the proper key and consequently to develop an efficient enzyme. Here one should pause to think of the poisonous effects often produced by unaccustomed protein foods upon certain individuals who take without trouble other food stuffs whose composition is, so far as chemical knowledge extends, essentially the same; and also of the marked and prompt effect surroundings exert on the constitution of even the higher plants, such as digitalis, even though they may remain outwardly entirely similar.

Provided these rules be adhered to, the size of the first dose may be varied within wide limits. I have given anywhere from 100,000,000 to 1,000,000,000 killed organisms and have rarely had a focal (joint) reaction, except where I have violated the rules in giving the dose before the entire disappearance of an acute exacerbation. The direct and immediate effect of such a dose, as is well known, is depression of the specific resistance, strength, just as in the exercise of one's muscles, and it is the reaction to this extra use, this new call for the specific enzyme that stimulates its production. But time must be allowed for this, and we must wait at least until the supply has been restored to what it was or, better, till it has had time to accumulate in still greater quantities; otherwise a repeated dose may have a cumulative effect and depress the reactive powers beyond their elastic strength, enfeebling or even paralyzing the rebound.

A week is the shortest period that should elapse between doses, and it would be better to count the

seven days after all reaction from the last dose has disappeared—local, focal (if by mischance such should occur), and constitutional. The size of the second and subsequent doses should be guided by the effect of the last preceding. If reaction was slight and only local (at puncture) dose may be as much as doubled, but unless the total number of possible injections are unduly limited (under five) as much good with greater conservatism and less risk of painful reaction may be accomplished by a 25 per cent. increase. A constitutional reaction, as indicated by a rise of more than 2° F. lasting over two days, usually calls for a doubled interval, as do likewise focal symptoms, when the preceding dose should be repeated without increase.

No one will doubt that even a prize winner in a beafsteak-eating contest has his digestive limitations, so we should not try to push our doses too far. So soon then as we have effected the desired improvement, treatment should be stopped, and not resumed till definite indications, renewed symptoms, arise.

It is remarkable how the patients improve in general health, some putting on 2 to 4 pounds in weight per week, but then, often when the dosage has been increased too much or repeated too soon, they will lose even faster. I prepared a vaccine for a woman of 35 years of age who had but slight knee involvement, but who looked old and worn, whose weight ran up from 119 to 140 pounds in six weeks, but when given a double dose, as a final of eight injections, she lost 7 pounds in one week, and took a month to regain them. As her color and general appearance had improved to such an extent as to make her look, as she said, fully ten years younger, and as all rheumatic symptoms had disappeared, I advised against pushing the treatment further.

Observing the above cautions one will never do a patient harm; and in the series referred to, varying in severity from occasional attacks of pain and stiffness in one or more joints to disabling swelling of both knees often lasting for weeks, universal improvement was effected. This ranged from total cure, in the mild cases, to disappearance of all symptoms except transitory slight stiffness in the most severe, which improvement has now endured from six months to a year. Of course, such patients may experience other attacks, but, if they should, a repeated treatment would soon pick them up again, and as it is neither painful nor expensive it would not be feared. Entirely similar results are now being obtained in the other cases referred to, and now under the same treatment.

In regard to the source of the vaccine. As it is apparent from the remarkably large masses of streptococci that can be scraped from the pharynx of most of these patients that such abnormal quantities must be consequent upon diminished specific general resistance, and as in all cases a vaccine prepared from them gives diagnostic focal reactions, under conditions aforementioned, it is hardly worth while to attempt the difficult and sometimes impossible isolation from the blood or the joint. However, if one prefers, a similar and equally effective streptococcus may be isolated from the urine, I think in all cases. Of the fifty-three vaccines which I have prepared for such treatment during the past year, five only were from the blood and some fifteen from the urine. As there appeared to be no difference in effectiveness between these and those made from the pharynx I took all others from the latter and, unless especially requested to do so, would hardly think it worth while to attempt the first more difficult and more uncertain procedures. If taken from the urine, however, and a plant can always be got therefrom as I have said, some are possibly apt to feel more certain of the organism's specificity. Furthermore, by examining this fluid and the genitourinary mucosa, we may undoubtedly often find an unexpected organism, such as the gonococcus, which may be later determined to have caused the joint lesions. Of course, should this be the case an appropriate vaccine would have to be used.

While acute inflammatory rheumatism is due to the same cause, as previously explained, it is in common with other acute processes showing constitutional symptoms entirely unsuited for vaccine therapy which can only harm. This could have been deduced from what has been said, but the importance of not attempting vaccine treatment of such cases is so great as to justify an otherwise superfluous statement. Cautious prophylactic vaccination after the entire subsidence of such an attack would, of course, be reasonable. As to cases that have advanced to the arthritis deformans stage, while no amount of vaccine treatment can restore cartilages that have been destroyed nor detach bones which have united, careful attempts to arouse special resistance can do no harm, should certainly be able to arrest the progress of the disease and relieve suffering, and may often do more, since much of the apparent ankylosis and bony deformity is due to involvement of the soft parts and to constractures of adjoining muscles.

I append a list of recent literature on the subject which I hope all specially interested readers will make use of, both for corroboration of my statements and for further information on this most interesting and important subject, for there is hardly a disease more frequently brought to the attention of the general practitioner than is chronic rheumatism—brought so often in the past almost fruitlessly, but for which, if he will take advantage of the opportunities offered by present-day specific therapy, he can do so much.

## THE CLINICAL AND PATHOLOGICAL STUDY OF LYMPHOGRANULOMATOSIS.

In 1898 Sternberg described a condition in which he discerned a close parallelism to pseudoleucemia, but which he regarded as tuberculosis of the lymphatic apparatus. In the cases studied by him various parts of the lymphatic system were affected, including the lymph nodes and particularly the spleen, and in addition there were nodules in the liver and kidneys. This condition which had been termed by Benda malignant granuloma and by Chiari lymphogranulomatosis or Hodgkin's disease, has been clearly defined as the result of Sternberg's discovery of characteristic histological changes. These changes which involve chiefly the lymphatic system depend upon the development of a granulation tissue in which there are numerous uni- or multinuclear cells rich in protoplasm and in large round or oval granules that stain like the nucleus and are disposed around it. In addition there are multinuclear giant cells which give the granulation tissue a characteristic appearance.

Otto Steiger contributes an important study of this subject to the *Zeitschrift für klinische Medizin*, Vol. 79, Nos. 5 and 6. He finds that the blood in lymphogranulomatosis reveals an essential relative and absolute leucocytosis. In the beginning there is a relative lymphocytosis, in the florid stage there is a polymorphonuclear neutrophile leucocytosis, and in the last stage there is a pronounced lymphopenia. These changes in the blood correspond to three distinct stages of the disease: First, the lymphatic hyperplasia; second, the formation of a granulation tissue which consists of polymorphic cells rich in epithelioid elements with one or more nuclei and necrotic foci, and which is chiefly characterized by the presence of the Sternberg giant-cells with central nuclei and basophilic cytoplasm; and third, the presence of a fibrous and hyaline induration of the lymph nodes with amyloidosis.

As regards the clinical features of this disease, Steiger points out that there is no typical fever characteristic of lymphogranulomatosis. In his eight cases there was either a continuous or an intermittent fever and only one of them displayed the Pel type of chronic relapsing fever. At autopsy lymphogranulomatosis shows an enlargement of the lymphatic glands and nodular deposits in the spleen, liver, lungs, kidneys, and bone marrow. The generally slow, chronic, and fatal process may infiltrate the neighboring tissues and may give rise to a lymphosarcomatous new formation. This extension occurred in a small group of the author's cases. The granulomatous deposits in organs other than the lymph nodes are not to be regarded as genuine metastases, such as occur in malignant growths, but are to be looked upon as coordinate autocthonous inflammatory processes that arise in the lymphatic structures of the affected organs. Lymphogranulomatosis is a chronic infectious process as may be noted from the hyperleucocytosis, the fever, and the typical granulation tissue, which process may unfold itself in any part of the lymphatic system and by virtue of its gradual and progressive course may assume the character of a malignant condition.

The etiological cause of lymphogranulomatosis, according to Steiger's observations, comprises syphilis and particularly tuberculosis. In most of his cases animal experiments gave a clue to the morbid factor, inasmuch as guinea-pigs that had been inoculated succumbed to an acute miliary tuberculosis. In three instances, in addition to this experimental tuberculosis, the author succeeded in producing the typical Sternberg granulation tissue by means of intraperitoneal inoculations of emulsions of granulomatous tissue. The fact that rabbits that were immune to the human type of tubercle bacilli were inoculated by the author in the same manner as the guinea-pigs, indicates that lymphogranulomatosis is not caused by the human type of tubercle bacillus. One cannot regard the inoculated disease as evidence of an attenuated tuberculous virus, for the guinea-pigs succumbed rapidly within four to five weeks, just as in the case of inoculation with the fully virulent human tubercle bacilli. Moreover, in all of the cases clinically studied the various tuberculin reactions were negative. It is therefore concluded that the purely tuberculous changes in the guinea-pigs were caused by the human type of tubercle bacillus which has a slighter capacity to form necrotic and caseous foci. It is mentioned parenthetically that guinea-pigs are equally susceptible to the human and to the bovine types of tubercle bacilli. It is concluded in general that in the guinea-pig experiments the author was dealing with a mixed infection of the human and bovine types of tubercle bacilli. This is probably the explanation why it has not been possible to produce in guinea-pigs inoculated granulomata by means of pure cultures of the bovine type of bacilli.

The fact that rabbits inoculated with human granuloma tissue intraperitoneally and subcutaneously developed general tuberculosis, while control animals inoculated with highly virulent human tubercle bacilli remained healthy, strengthens the supposition that the bovine type is the exciting cause of human lymphogranulomatosis. The virus of the latter condition is closely related to human tubercle bacilli and has a particular affinity for the lymph nodes in which it evokes inflammatory processes that later cause the disappearance of the

lymph cells and lead to the formation of new connective tissue. The macroscopic and to a certain extent at least the microscopic appearance of the granulomatous deposits strikingly resembles the calcified deposits found in tuberculous cattle.

A series of experiments were undertaken by Steiger with the view of further strengthening his hypothesis. He found that whereas his patients did not react to the various tests with human tuberculin, they nevertheless did react if bovine tuberculin was used. In this manner he revealed a valuable means of making a differential diagnosis in cases of malignant granuloma.

## FLEAS AND PLAGUE.

The question of the modes of transmission of plague are of considerable interest in this country owing to the fact that plague is present among the ground squirrels of California. It has been proved by animal experimentation that the disease could be spread from rat to rat by fleas and further that the puncture in the skin made by the flea in the act of feeding affords a wound through which it is possible for plague bacilli to enter, and animals have been infected by the application of infectious material to areas upon which fleas had been allowed to feed. The Commission for the Investigation of Plague in India, in discussing the possible methods by which fleas may transmit plague mentions that it may be "by regurgitation of the stomach contents through the esophagus and pharynx, the bacilli being then injected with the saliva, or on the pricker, or being rubbed into the wounds made by the pricker." The commission, however, found that the infection could be conveyed by smearing recent flea bites with infectious blood or virulent cultures of plague bacilli and considered that the possibility of the transmission of infection among rodents by rats rubbing flea feces into recent flea bites had been demonstrated. Nevertheless, the commission did not feel justified in expressing an opinion as to whether this was the usual method of infection.

The Public Health Reports, May 8, 1914, is an abstract of a report by A. W. Bacot and C. J. Martin, of the Lister Institute, which appeared in the *Journal of Hygiene*, Plague Supplement III, giving the results of certain experiments carried on regarding the mechanism of transmission of plague by fleas. The authors summarized their work as follows. Under conditions precluding the possibility of infection by dejecta, it was found that two species of rat fleas, *Xenopsylla cheopis* and *Ceratophyllus fasciatus*, fed upon plague blood, can transmit plague during the act of sucking, and that certain individuals suffering from a temporary obstruction at the entrance of the stomach were responsible for most of the infections obtained and possibly for all.

In a proportion of infected fleas the development of the bacilli was found to take place to such an extent as to occlude the alimentary canal at the entrance to the stomach. The culture of pest appears to start in the intercellular recesses of the proventriculus and grows so abundantly as to choke this organ and extend into the esophagus. Fleas in this condition are not prevented from sucking blood as the pump is in the pharynx, but they succeed only in distending an already contaminated esophagus, and on the cessation of the pumping act some of the blood is forced back into the wound. Such fleas are persistent in their endeavors to feed, and this renders them particularly dangerous. Fleas suffering from obstruction do not necessarily perish, and in the course of some days the culture obliterating the lumen of the proventriculus may autolyze and the passage again become pervious. They are, however, incapable for the time being of imbibing fresh fluid, and are, therefore, in danger of drying up if the temperature is high and the degree of saturation of the atmosphere low. Although so far as the authors' observations go, such fleas withstand desiccation quite as well as normal fleas which are not fed, their length of time must be short, directly hot dry weather sets in, and the investigators are led to wonder whether this fact may not, to some extent, explain why in India epidemic plague is confined to the cooler and moister seasons, and particularly why in Northern and Central India the epidemics are abruptly terminated on the onset of the hot dry weather. It appears then that while fleas may be instrumental in spreading plague among certain rodents there has been no direct proof that they have been the means of infecting members of the human species. Yet it seems as if this were probably the case.

## GASTRIC AND DUODENAL ULCERS.

Possibly gastric and duodenal ulcers are more frequent than was formerly the case. At any rate, if these ulcers are not more common, they are more often diagnosed and treated than in times not long passed. Their importance was emphasized by the fact that at the Congress of the International Society of Surgery held recently in New York they were made the subject of discussion and evoked more general interest than the other matters selected for debate. Also those who took part in the discussion were acknowledged authorities, and from the standpoint of surgical treatment the matter was threshed out in a satisfactory manner.

As Dr. F. de Quervain of Basle pointed out in his paper, the advances made in the radiological diagnosis of ulcers of the stomach is too well known to require repetition, but there are still some moot points with regard to their diagnosis which need to be made clear. More than one of the speakers criticised adversely the symptomatology of duodenal ulcers described by Moynihan, and it was to be regretted that Moynihan, who had been expected, was not present to defend his contentions. Mayo appears to be in favor of Moynihan's symptomatology, while the European surgeons seem inclined to attach but little weight to this method of diagnosis.

Perhaps the feature of the discussion on gastric and duodenal ulcers was the announcement made by A. D. Bevan of Chicago of the work that Rosenow of Chicago has been doing with regard to their

etiology. If Rosenow is correct as to the results of his investigations it would appear that a long step has been taken in the direction of determining the etiology not only of gastric and duodenal ulcers, but of other diseases, and therefore successful treatment, or better yet, satisfactory preventive measures, should follow. At present, surgical treatment of gastric and duodenal ulcers is generally attended with good results, and the progress made in perfecting technique during the past few years has been remarkable.

### Medical Society Proceedings Among the Turks.

Clinical meetings in remote localities conducted almost solely by native practitioners should possess interest from several angles. Naturally, a purely European culture must be represented, and it is readily apparent that science must break down all barriers of race and religion. In a recent number of the *Deutsche medizinische Wochenschrift* we find clinical transactions selected from a society publication entitled "Scientific Evenings in Gülhane-Stambul, January-February, 1914." Aside from one of the presidents of the society, Professor Wieting, all the membership appears to be Turkish. Abdul Kadir presented at one session cases of Banti's disease, Addison's disease, and myelogenous leucemia. Murad showed a case of noma of the face. Feridun cured a severe case of pyemia by quinine and subcutaneous injections of collargol. The latter caused large abscesses which were evacuated. Abdul Kadir at another session showed a case of scurvy and reported a decortication of the kidney for acute nephritis, death occurring some time after from causes not traceable to the intervention. Exotic diseases are represented by Aleppo boil, while a case of syringomyelia—said to be a very common disease in Turkey—was regarded as a form of lepra nervosa. Judging from this report and others of equal interest, Constantinople should possess clinical advantages which might well be utilized by foreigners.

### Ophthalmophobia.

The old bourgeois teaching that any normal man should be able to look frankly into the eyes of his fellows, and that inability to do this act reflects somehow upon the gazer, can hold good only within very narrow limits. We know that many sound subjects resent instinctively the stare of another. It disconcerts, because the one stared at believes, for example, that his clothing is disarranged. In a higher degree, those "fixed" by the eyes of another are visibly perturbed, and perspire, tremble, and even collapse on such occasions. Such subjects, evidently abnormal, also strive to protect their eyes from fixation by glasses, newspapers, etc. In a paper by Seeligmann on "Eye Fear," read recently before the Aerztlicher Verein of Hamburg (*Deutsche medizinische Wochenschrift*, 1914, No. 13) the author gives his opinion that this second degree of eye fear must be due to an evil conscience (as in the case of sexual perverts), accompanied by a high degree of self-consciousness. This coincidence occurs chiefly in those of the highest social status. A third degree of eye fear is bound up with the evil eye and similar superstitions. A literature of vast extent has grown up about this subject.

### Tubercle Bacilli in the Circulating Blood.

The much disputed question of the presence of tubercle bacilli in the blood has been subjected by Felix Klemperer to critical and experimental analysis. His article appears in the *Zeitschrift für klinische Medizin*, Vol. 80, Nos. 1 and 2. He finds that in a large proportion of cases of tuberculosis in human beings there are present in the blood a very few acid-fast bacilli. These are not found in the blood in healthy or non-tuberculous individuals. In the case of tuberculous animals only a small proportion have tubercle bacilli in the blood. The presumptive evidence is strong that the acid-fast bacilli in the blood of tuberculous individuals are tubercle bacilli. But for all practical purposes their detection is of but slight diagnostic and prognostic value.

## News of the Week.

**Health of the Army.**—The Secretary of War on June 1 issued the following bulletin: "On the 30th day of May the United States Army completed one month's occupancy of Vera Cruz. There have been ashore more than 7,000 soldiers and marines, and not one death from disease has occurred during that period."

**Private Hospitals Protest.**—At a meeting of the Hospital Alliance of New York on June 3, it was decided that a committee be appointed to see the Commissioner of Charities and protest against the present overburdening of private hospitals and the evasion of payment to these institutions for the handling of emergency cases. The committee will inform the Commissioner that out of a total of 114,000 ambulance calls last year 72,000 were answered by private hospital ambulances, and that now three-fourths of the hospital patients in the city suffering from non-contagious diseases are in the private hospitals.

**Milk Depots Opened.**—Mr. Nathan Straus on June 2 opened ten milk stations in New York City for the summer months, in addition to the eight maintained throughout the year, thus making eighteen which he supports. At all these stations pasteurized milk suitably modified for infant feeding is furnished at less than cost price. This charity has been carried on by Mr. Straus since 1892.

**Street Accidents.**—The National Highways Protective Society reports that during the month of May forty-five persons were killed by vehicle traffic on the streets of New York City. Thirty-two of the victims, or more than 70 per cent., were less than sixteen years of age. During the month of April 5,352 accidents occurred on the railroads and street railways under the jurisdiction of the Public Service Commission of New York. As a result of these there occurred twenty-six deaths, as compared with seventeen in April, 1913, and twenty-two in April, 1912. In addition, nine persons had their skulls fractured, three lost an arm or a leg, and 142 others were seriously injured.

**Gift of a Hospital.**—Mr. Henry Ford, the automobile manufacturer, in a letter to the directors of the Detroit General Hospital, now in course of construction at Detroit, has offered to take over the property on West Grand Boulevard, complete the building, and present the whole to the city of Detroit. The offer, which will involve

the expenditure of about $3,000,000, has been unanimously accepted.

**Charitable Gifts.**—By the will of the late Elizabeth Swift Shippen of Philadelphia the following bequests are made: the Contributors' Fund of the Pennsylvania Hospital, $50,000; the Pennsylvania Institution for the Deaf and Dumb, the Polyclinic Hospital and College for Graduates in Medicine, the Pennsylvania Epileptic Hospital, Christ Church Hospital, the Philadelphia Lying-In Charity and Nurses' Training School, the Seaside Home for Invalid Women, Atlantic City, Seashore House for Invalid Children, Atlantic City, Children's Hospital of Philadelphia, the Women's Medical College of Pennsylvania, the Rush Hospital for Consumptives, the German Hospital, the American Oncologic Hospital, and the Chestnut Hill Hospital, $10,000 each; the University of Pennsylvania for the endowment of scholarships in medicine, the Bryn Mawr Hospital, the Pottsville Hospital, for the endowment fund, St. Agnes' Hospital, the West Philadelphia Hospital for Women, the Women's Hospital and Dispensary, Friends' Asylum for the Insane, the Philadelphia Home for Incurables, Home of the Merciful Saviour for Crippled Children, Philadelphia Visiting Nurse Society, Pennsylvania Institution for Feeble-Minded Children, Jefferson Medical College, in memory of the late Dr. Da Costa, St. Christopher's Home for Children, Howard Hospital and Infirmary for Incurables, and Kensington Hospital for Women, $5,000 each.

The Babies' Hospital, New York, has received from Mrs. Andrew Carnegie a gift of $5,000 for the endowment of a bed in memory of her nephew.

**Dr. Bryant's Will.**—By the will of the late Dr. Joseph D. Bryant of New York, a bequest of $1,000 is made to the University and Bellevue Hospital Medical College, the income to be devoted "to instilling into the minds of the senior class the principles of ethics of the American Medical Association." On the death of Mrs. Bryant, portions of the residuary estate, the value of which has not been stated, are to go to the Norwich, N. Y., Hospital, the New York Academy of Medicine, for the maintenance of the library, and New York University, for the establishment of scholarships. In the event of the death of Dr. Bryant's daughter before Mrs. Bryant, shares in the residuary estate will go also to St. Vincent's Hospital, the American Medical Association, the Bellevue Hospital Alumni Association, St. John's Guild, and the Medical Society of the State of New York.

**Civil Service Examination.**—The United States Civil Service Commission announces an open competitive examination, for men only, on July 8, 1914, to fill vacancies in the position of bacteriologist in the Bureau of Chemistry, Department of Agriculture, at salaries ranging from $1,200 to $2,000 a year. The duties of the position will be the examination bacteriologically of food products which are subject to the food and drugs act, in order to determine their sanitary condition. An educational training equivalent to that required for a bachelor's or an M. D. degree from a college or university of recognized standing, including at least two years' training in bacteriology, is a prerequisite for consideration for this position. The examination will include practical questions in bacteriology, 30 points, and chemistry, 15; a thesis to be delivered to the examiner on the date of the examination, 20; and education and experience, 35. Persons desiring to take the examination should apply at once for Form 1312 to the United States Civil Service Commission, Washington.

**Not Bubonic Plague.**—Dispatches from Bogota state that it has been determined by bacteriological tests that the epidemic now prevailing in Colombia is not the bubonic plague.

**Investigate Hospitals.**—The New York State Hospital Commission, in cooperation with the Attorney-General, began last week an investigation of the Central Islip State Hospital. Following this a similar investigation of the Long Island State Hospital will be carried out.

**Milk Supply.**—The Department of Health reports that at the present time the pasteurization of the milk supply of New York City is very satisfactory, about 99 per cent of the total being effectively pasteurized. The pasteurizing plants are subject to close supervision by the department, and large numbers of samples of milk are being examined bacteriologically to check up efficiency of operation.

**Traffic in Drugs.**—As a result of a careful investigation into conditions in the workhouse on Blackwell's Island, N. Y., the resident physician has been charged with selling habit-forming drugs to the inmates and has been removed from office by Commissioner Davis. The charge against him will be investigated by the Grand Jury. Dr. Elihu Katz has been appointed to fill the vacancy, and as the immediate need of a woman physician in the workhouse was also apparent, Dr. Anna Hubert, a graduate of the Johns Hopkins Medical College, has been appointed. This is the first appointment of a woman physician to the New York workhouse.

**Typhus in Turkey.**—Dr. Clarence D. Ussher, an American physician in charge of the hospital of the American Board of Commissioners for Foreign Missions in Van, Turkey, has received hearty and public thanks from Turkish officials for his zeal and care of the sick during a recent epidemic of typhus fever among Turkish soldiers quartered in the city. Over 2,500 soldiers died of the disease which made rapid headway because of the indifference of the military authorities to the enforcement of proper sanitary precautions. Dr. Ussher is a graduate of the Kansas Medical College and has been in Turkey since 1898.

**Clinical Congress of Surgeons of North America.**—The fifth annual session of this Congress will be held in London, England, from July 27 to August 1, 1914, under the presidency of Dr. John B. Murphy of Chicago. A large number of clinics will be given during the morning and afternoon hours in various London hospitals, while the evening will be devoted to the scientific program, sessions being held in both the Hotel Cecil and the Savoy. The first meeting of the General Surgical Division, which will be held at the Cecil on July 27, will include addresses of welcome from Sir Rickman J. Goodlee, honorary chairman of the London Committee, and the American Ambassador, as well as addresses by the retiring president, Dr. George Emerson Brewer, and the president-elect, Dr. Murphy. Prof. A. von Eiselsberg of Vienna will discuss the choice of the operative method for ulcer of the stomach. Subsequent meetings of this di-

vision will include papers on typhoid perforation, by Dr. G. E. Armstrong of Montreal; on the results of operations for exophthalmic goiter or hyperthyroidism, by Dr. Charles H. Mayo, and on the transplantation of ovaries, by Prof. Tuffier of Paris; a symposium on the operative and non-operative treatment of cancer, participated in by Prof. Krönig of Freiburg, Dr. J. F. Percy of Galesburg, Ill., Dr. T. Wilson of Birmingham, and others; and a symposium on intestinal stasis, the speakers being Sir William Osler, Sir Berkeley Moynihan of Leeds, and Dr. J. C. Bloodgood. The meetings of the division of surgical specialties will be held at the Savoy, and for these an interesting and varied program has been prepared, including a symposium on the surgery of cleft palate.

**Contagion Among Hospital Employees.**—A study of the incidence of contagious diseases among employees of the hospitals of the Department of Health, was recently made at the request of the Commissioner of Health. It was found that during the seven years 203 employees out of a total of 3,879 had been infected, the resulting deaths numbering four. The percentage of infection for the period was 5.2, ranging from 9.4 in 1907, to 3.2 in 1913. The Department aims at a further reduction of morbidity among its hospital workers, and will attempt to lessen the contact between the patients and the domestic employees. The larger part of the cases occurred among the nurses, whose risks are the greatest and the least easily controlled.

**Yale Medical School.**—At the coming Commencement of Yale University, June 15 to 17, the Yale Medical School will celebrate the one-hundredth anniversary of the first conferring of degrees. The occasion will be observed by special exercises to be held June 15 at which addresses will be presented by Professor William H. Howell of Johns Hopkins University and Dr. Walter R. Steiner of Hartford. It is hoped that the University will be able to announce at this time the consummation of the plan for affiliation with the New Haven Hospital and gifts to the endowment of the school.

**Medical Schools Graduate.**—At the annual commencement exercises of Columbia University, New York, seventy-one students of the College of Physicians and Surgeons received the degree of Doctor of Medicine from the President of the University. The students were presented and the Hippocratic Oath was administered by the Dean of the College, Dr. Samuel W. Lambert.

Fifty-four graduates of the Medical Department of the University of Louisville received diplomas at the Commencement exercises on June 1.

The Commencement exercises of the College of Physicians and Surgeons of San Francisco were held on June 4, eight students receiving the medical degree. The degrees were conferred by the president, Dr. William F. Southard.

The graduating exercises of the University of Texas, Medical Department, Galveston, were held on May 30, the chief speaker of the evening being Dr. H. Gideon Wells of Chicago.

**Health Work of the Public Library.**—The Department of Health, through its Bureau of Child Hygiene, has furnished to the New York Public Library 5,000 copies each of the circulars on "Care of Babies" and "Ten Reasons Why a Mother Should Nurse Her Child," the library authorities agreeing to distribute these circulars through the branch libraries.

**A Valuable Accession to the Library of the New York Academy of Medicine.**—Dr. Rowland G. Freeman has presented to the library of the New York Academy of Medicine a fine copy of Bidloo (Godefridus), Anatomia humani corporis, 105 plates, folio. Amstelodami, vid. J. à Someren, 1685.

**Personals.**—Dr. ARISTIDES AGRAMONTE of Havana received the honorary degree of doctor of science from Columbia University, New York, on June 3. In bestowing the degree, President Butler of the University spoke as follows: "Aristides Agramonte—Bachelor of Arts of the University of Havana and Doctor of Medicine of Columbia University of the class of 1892, sole survivor of a famous group of scientists and public servants who, in order to test the theory of the transmission of yellow fever by mosquitos, began the experiments on themselves, and who have lived to see your native island freed, largely through your own efforts, of its worst scourge, Professor of Bacteriology and Experimental Pathology in the University of Havana, I gladly admit you to the degree of Doctor of Science."

Health Commissioner GOLDWATER of New York sailed last week for Panama, where he will spend a short vacation.

Sir WILLIAM OSLER, Regius Professor of Medicine at Oxford University, London, has been elected a Foreign Associate of the Academy of Medicine of France.

Dr. JAMES M. ANDERS has been appointed a member of the Board of Health of Philadelphia, in succession to Dr. William H. Andrus, resigned.

Dr. S. W. NEWMAYER of Philadelphia has been appointed assistant chief of medical inspection in the Philadelphia Bureau in place of Dr. Charles A. Groff, who has resigned.

Dr. A. R. MOULTON has resigned as senior physician to the Pennsylvania Hospital for the Insane because of ill-health.

Dr. WALTER C. FEELEY has been appointed bacteriologist to the Board of Health of Boston, to fill the vacancy caused by the death of Dr. Allan F. Barnes.

Surgeon-General WILLIAM C. GORGAS, U. S. A., was the guest of honor at the meeting of the Alumni Association of the School of Medicine of the University of Alabama, which was held at Mobile on May 27.

Dr. G. FRANK LYDSTON of Chicago received the honorary degree of Doctor of Civil Law from the Hamilton College of Law at its annual convocation on June 3.

**American Gastroenterological Association.**—The seventeenth annual meeting of this association will be held at Hotel Chalfonte, Atlantic City, on Monday and Tuesday, June 22 and 23.

**Jersey Physicians Dine.**—The eleventh annual dinner of the Physicians and Surgeons Club of Jersey City was held on May 28 at the Hotel Astor, New York. Forty-three guests were present.

**Medical Society Elections.**—MIDDLE TENNESSEE MEDICAL ASSOCIATION: Annual meeting at Bell Buckle on May 22 and 23. Officers elected: *President*, Dr. Otey James Porter, Columbia; *Vice-President*, Dr. Oval U. Bryan, Nashville; *Secretary-Treasurer*, Dr. Roy W. Billington, Nashville.

IOWA HOMEOPATHIC MEDICAL ASSOCIATION: Forty-fifth annual convention at Iowa City on May 19 to 21. Officers elected: *President*, Dr. Frank C.

Titzell, Iowa City; *Vice-Presidents*, Dr. Charles W. Ihle, Cleghorn, and Dr. Theodore A. Willis, Clear Lake; *Secretary*, Dr. George A. Huntoon, Des Moines; *Treasurer*, Dr. M. A. Royal, Des Moines.

Homeopathic Medical Society of Wisconsin: Fiftieth annual meeting at Milwaukee on May 21. Officers elected: *President*, Dr. Fay T. Clark, Waupun; *Vice-President*, Dr. S. W. Murphy, Kenosha; *Secretary*, Dr. Minnie M. C. Hopkins, Oconto; *Treasurer*, Dr. Frank E. Brown, Milwaukee.

Yonkers' Practitioners Club: Annual meeting at Yonkers, N. Y. Officers elected: *Members of Executive Committee*, Dr. A. N. Benedict and Dr. C. A. Sweet, Yonkers, and Dr. Francis R. Lyman, Hastings; *Treasurer*, Dr. Buel Latcher, Yonkers; *Secretary*, Dr. Clarence W. Buckmaster, Yonkers.

**The Late Dr. Gruening.**—At a special meeting of the Board of Surgeons, of the New York Eye and Ear Infirmary, held on June 1, 1914, the following minute was adopted: "The Board of Surgeons of the New York Eye and Ear Infirmary record with profound sorrow the death of their colleague, Dr. Emil Gruening, who had been a member of the Board of Surgeons for nearly thirty-five years, and at the time of his death was one of the consulting surgeons of the infirmary. Dr. Gruening was esteemed and beloved by all who knew him, and his loss will be felt not only by the members of this Board, but by his many other friends and admirers. The Board of Surgeons desires to extend to his family their heartfelt sympathy. [Signed] Gorham Bacon, M.D., Edward B. Dench, M.D., Walter Eyre Lambert, M.D.

The Medical Board of Mt. Sinai Hospital having learned with deep regret of the decease on May 30, 1914, of their colleague, Dr. Emil Gruening, met in special session at the Hospital on June 1 and passed the following resolutions: "Whereas the death of Dr. Emil Gruening has removed from among us a distinguished and admired colleague who for thirty-five years gave his best efforts to the Hospital. Resolved, That the Medical Board of Mt. Sinai Hospital desires to express its sincere appreciation of the high professional attainments of Dr. Gruening, its loss of his wise counsel and honored friendship, and its profound sympathy with his bereaved family. Resolved, That in the death of Dr. Gruening, ophthalmology and otology have lost the services of a brilliant practitioner who was at all times a conscientious student, an ornament to his profession and a colleague through whose scholarly contributions medical science had been advanced and medical literature notably enriched. Resolved, That his unusual attainments in other fields than those of his chosen specialties, and a natural courtesy and grace of manner, lent particular charm to association with him. Resolved, That these resolutions be spread upon the minutes of the Medical Board of Mt. Sinai Hospital and that a copy of the same be transmited to the family of Dr. Gruening. For the Board: Abraham Jacobi, Charles H. May, Alfred Meyer, Frederick Whiting.

**Obituary Notes.**—Dr. George W. Hosmer of Summit, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1864, and a member of the Medical Society of the State of New York, died at his home, from general debility on June 2, aged 83 years.

Dr. Carl D. S. Fruh of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1885, and of the Philadelphia College of Pharmacy, died at his home from nephritis on May 13, aged 65 years.

Dr. Clarence Weston Tolles of Claremont, N. H., a graduate of the Bellevue Hospital Medical College, New York, in 1868, and a member of the New Hampshire and Sullivan County Medical Societies, died at his home on May 28, aged 69 years.

Dr. Samuel Caldwell Benedict of Athens, Ga., a graduate of the Miami Medical College, Cincinnati, O., in 1878, a member of the Medical Association of Georgia, and the Clarke County Medical Society, secretary of the latter, and a former president of the Georgia State Board of Health, died in a sanatorium at Macon, Ga., on June 1, aged 58 years.

Dr. Bret Nottingham of Lansing, Mich., a graduate of the New York Homeopathic Medical College and Hospital in 1901, and a member of the American Medical Association and the Michigan State and Ingham County Medical Societies, having served as president of the latter, died at the Harper Hospital, Detroit, after a long illness, on May 26, aged 36 years.

## Correspondence.

### VINCENT'S ANGINA.

To the Editor of the Medical Record:

Sir:—In the Medical Record of May 9, 1914, I note an article on "A Case of Vincent's Angina Treated with Neosalvarsan," by Dr. H. H. Amsden, Concord, N. H. He states that the disease was first recognized by Vincent in 1898, and that Bruce (*Lancet*, Jan. 12, 1899) gave a thorough résumé of the disease.

The latter statement came as a very great surprise to me, as I was under the impression that I was the first to call attention to Vincent's work in the English language. I had presented the facts at the meeting of the Section on Laryngology of the New York Academy of Medicine, Nov. 27, 1901, W. K. Simpson, chairman. This is recorded in the *Laryngoscope* (Vol. XI, 1901, p. 479), and the full article appeared in the *American Journal of the Medical Sciences* for February, 1902, p. 187.

On investigation I find that H. W. Bruce presented his article on Vincent's Angina in the London *Lancet* for July 16, 1904, p. 135, and not in January, 1899, as stated by Amsden, nearly *three years* later than my own article.

May I ask you to publish this as a correction and also to voice a protest? Our work is often ignored by foreign writers, who claim an alleged inaccessibility of our journals, but we have a right to expect that credit should be given to our own countrymen when the facts warrant and are so easily obtained from our exact medical indices.

New York. Emil Mayer, M.D.

### DIVULSION OF THE ARM.

To the Editor of the Medical Record:

Sir:—The interesting case of divulsion of the arm and scapula reported by Dr. G. K. Dickinson in a recent number of the Medical Record, calls to mind a somewhat similar case which occurred two years ago at the mine in Honduras where my son, S. H. Wilcox, was manager.

A young native while working in the mill was caught by one arm in the machinery and whirled around the main shaft, effecting a complete divulsion of the arm at the shoulder joint. With assistance he picked himself up and walked to the house, a distance of about 100 yards up a steep hill. There was very little bleeding but fearing secondary hemorrhage, my son and his partner looked over the anatomical charts in their first-aid book and tied everything that looked to them like a blood-vessel with catgut. Then applying a mass of absorbent cotton soaked in a bichloride of mercury solution, they made him as comfortable as possible although they had no idea that he could survive.

They sent to a distant town for a doctor who did not arrive until four days after the accident. The dressing was not changed in the meantime and when the doctor arrived there was nothing to do except to apply a fresh dressing. There was no tissue for flaps. The wound healed by granulation and an uninterrupted recovery ensued.

SIDNEY F. WILCOX, M.D.

41 WEST FIFTY-SECOND STREET,
NEW YORK.

## OUR LONDON LETTER

(From Our Regular Correspondent.)

SLEEPING SICKNESS REPORT—KING AND QUEEN AT R. M. C. A.—THE ROYAL SOCIETY—OPHTHALMOLOGICAL CONGRESS AND SECTION AT ROYAL SOCIETY OF MEDICINE—CHADWICK LECTURE—PROFESSOR ROGET—CONSUMPTION HOSPITAL'S APPEAL FOR RESEARCH FUND—OBITUARY.

LONDON, May 22, 1914.

THE report of the Inter-Departmental Committee on Sleeping Sickness was obtainable yesterday (formally issued the day before). They insist on the difference of the problem of trypanosomiasis as seen in Nyassaland and Rhodesia from that presented in Uganda. In the latter the factors are pretty well known—not so in the other. As to how far wild animals, which are a reservoir of the disease affecting domestic stock are a danger to man, the evidence is not complete. The arguments in favor of destruction of game, at least experimentally in a localized area are stated and the objections to so costly and uncertain a plan. As to the Nyassa and Rhodesia form its incidence on the population is slight and not increasing and there is no reason to expect it to become epidemic. If the tsetse fly could be got rid of from human settlements the sleeping sickness would disappear, infection from other flies being practically nil. The committee therefore urge a thorough equipment of entomological research into the bionomics of the incriminated flies. Medical research as to treatment and prevention is also strongly recommended.

The King and Queen have this week been visiting military stations. On Tuesday they witnessed a demonstration of medical service in the field given by three sections of a field ambulance. Two sections were shown at work receiving the wounded, applying dressings, and disposing them for conveyance by motor-ambulances down the line of communications to the clearing hospital. An action close by was supposed to be going on and the wounded to be collected and forwarded to dressing stations which had been set up by the sections. Complete operating marquees were set up and the wounded were being brought in wagons. The cases were labeled with their injuries, deftly handled by the orderlies, brought each separately to the surgeons, bandaged, and carried away to improvised bivouacs or tents to be in readiness there for removal to hospital. Their majesties were then shown the services for lighting the operating marquee by night, for sterilizing instruments and utensils in use in the field, for administering anesthetics and rendering everything light, portable, and capable of quick packing and rapid transport. A section, ready packed for the road, was also shown.

Dr. A. D. Waller has been for many years engaged in the study of the electrical behavior of the heart. Last week he had a paper at the Royal Society on the various inclinations of its electrical axis. The movement upwards of the diaphragm he found changed the direction of the heart's axis, and in consequence altered both the electrical results that could be observed and the interpretations which must be put upon them. As a result of deep breathing he said it was possible to predict and to obtain a complete reversal of the effect—a negative current being reduced to zero or even changed to a positive one.

At the same meeting the effect of other hostile organisms on soil bacteria was the subject of a paper by Messrs. Thornton and Smith. They found a condition necessary to the growth or, at any rate, too vigorous growth, was the presence of amido-acids which acted as auxiliaries or stimulants rather than as food.

Our ophthalmic brethren have had a busy time of late with their congress, partly reported in my last and their section of the R. S. M. To complete my notice of the former, on the last day Mr. Henderson demonstrated his device for measuring changes in intraocular pressure as a test of the tension. Mr. Goulden recorded cases of optic neuritis and spinal myelitis to show the usual progress. One member held that we knew no more about the disease than our predecessors of the last generation, and another hoped that as careful an account would be made by others as Mr. Goulden's. Mr. Brooksbank James had a paper on "Iridosclerotomy in Glaucoma," and showed some cases illustrating the value of his modification in the operation. Dr. Hawthorne showed perimeter charts from cases in which homonymous hemianopia was the principal or only evidence of intracranial disease. Mr. Mayou read a paper on "Eye Diseases in Animals" and showed photos.

Mr. Clegg related a case of senile cataract with two nuclei. Ordinary method of extraction was done. After rupturing the lens capsule he expressed a dark brown nucleus and on some stroking to clear away the cortex a second nucleus appeared and was removed. Mr. Clegg also read a commentary on a case of death after open evisceration. The patient's eye was struck by a chip of hot metal in 1906 and treated in hospital. Useful sight lost. In 1913 he came again to hospital with panophthalmitis and the evisceration was done. He became so restless he was removed to a general hospital, where he died of acute postoperative mania. The diagnosis confirmed by post mortem. Mr. Maddox showed instruments he had had made of the light metals, aluminum and magualium. Mr. Coats reported a case in which, after a blow the pigment epithelium disappeared from a sector-shaped area in the temporal half of the iris and described the appearances under ordinary and transmitted light.

I pass on now to the Section of the R. S. M., which was presided over by Sir A. Critchett. Here

Mr. B. T. Lang showed a stereoscopic *x*-ray photo of a case of traumatic exophthalmos, also a bottle specimen of an early stage of intraocular suppuration. Dr. Bookless showed a congenital cataract, probably of the Coppuck type. The rest of the proceedings were occupied with "Glaucoma" on which these papers were read:

1. By Mr. Greeves, gave his pathological observations on the filtration angle, in some of which there was no closure as in a group associated with an iridocyclitis; a second group with the spaces blocked by swollen cells, and a third with retinal detachment.

2. Lt.-Col. Herbert, on the "Ideal Glaucoma Incision." He advocated as the safest a limited subconjunctival one in the transverse vertical plane behind the limbus and used a very narrow, long, tapering knife. Thus the tendency to vesicular change from filtration through the conjunctiva was at a minimum.

3. Mr. Bishop Harman, on a "Variable Flap Operation," he had devised to allow some latitude in the grading of effects to be produced, for he found the methods in use too rigid—the same being done for all sorts of cases.

4. Mr. Laws, in a paper on "Herbert's Small Flap," inclined to return to the original type of operation and make lateral cuts with a knife, considering that scissors must crush and injure the tissues, which were already lowered in vitality, for which reason he did not apply antiseptics to the sac or even douche it, but just cleansed the edges of the lids with perchloride, 1 in 3,000.

Mr. Whitehead of Leeds discussed the preceding papers with care and in the course of doing so said that when the operation failed it was due to new fibrous tissue forming and closing the incision whatever the operation might do.

Professor Roget of Geneva came here last week and delivered a Chadwick lecture at the Royal Society of Medicine, Sir Bertrand Dawson presiding. His subject, "Altitude and Health." While he approved of ascents to moderate altitudes, he held that the strain produced by unreasonable heights induced lactic intoxication, cerebral anemia, and irregularities of innervation.

The Board of Royal National Hospital for Consumption is desirous of starting an up-to-date research department, but is advised that the cost of such an extension of their work cannot be legally charged on the funds of the charity under the terms of their Royal charter. They, therefore, are appealing for a separate fund to be devoted to a special building and the payment of the cost of the necessary appliances and the remuneration of skilled investigators who will give their whole time to the research. They think a beginning might be made when £5,000 is collected, but estimate that at least £15,000 will be ultimately required.

Colonel W. A. Corkery, late principal medical officer, Lahore Division, has died at Eastbourne. He qualified at Edinburgh and Glasgow and entering the Indian Medical Service was in the Burmese expedition of 1885-7, for which he held the medal and clasp. He became colonel in 1909, retiring in 1912.

Santonin Poisoning in Infants.—A. Chassevant reports the case of a child who had received two centigrams of santonin in the evening and the following morning a dose of castor oil. Following this medication the child developed convulsions, fever, and somnolence, which lasted for several days.—*Journal de Médecine de Paris.*

6. Anaphylactic Reactions Occurring in Horse Asthma After the Administration of Diphtheria Antitoxin. J. L. Goodale.

**3. Minimal Macroscopic Gastric Stasis.**—A. E. Austin concludes that a limited number of rice grains visible in the wash water only by means of the microscope, twelve hours or later after the evening meal, when accompanied by marked hydrochloric acid reaction or bile, means a spasmodic closure of the pylorus or a myasthenia, and is rarely permanent. Currants or raisins may be retained for this period in a myasthenic stomach or sometimes pass through a moderate narrowing of the pylorus. A distinct amylaceous residue made visible to the unaided eye by means of Lugol's solution, which is not accompanied by bile, but is accompanied by hydrochloric or organic acids, if persistent, means a mechanical hindrance to the egress of food from the stomach. A wash water containing hydrochloric acid freely and microspocic starch remnants may indicate an old ulcer scar without a trace of gastric stenosis. A minor gastric retention detected by lavage and unconfirmed by the radiograph is proof of pyloric spasm rather than of stenosis, and will often disappear upon appropriate medical treatment. A radiographic demonstration of gastric stasis, not substantiated by lavage, is most frequently due to myasthenia since the weakened gastric walls cannot free the stomach from the heavy bismuth within the accepted time.

**6. Anaphylactic Reactions Occurring in Horse Asthma.**—J. L. Goodale presents a preliminary communication regarding the local phenomena occasioned by horse serum in individuals suffering from so-called horse asthma. In order to determine whether horse serum was capable of producing local disturbances at the point of contact, patients with a history of vasomotor disturbances were examined in one or both of the following ways: (1) The lobe of one ear was moistened with a drop of diphtheria antitoxin and a superficial cut was made with a needle, just sufficient to cause blood to appear but not to flow. (2) A drop of the same antitoxin was placed in one nostril upon the anterior end of the lower turbinate. Eighteen cases were examined. These were grouped as follows: (1) Cases in which horses had been known to excite nasal vasomotor symptoms or an asthmatic attack. (2) Cases showing no reaction to horses, but in whom the asthma was apparently associated with bronchitis alone, or occurred only during the summer in connection with hay-fever. In three cases of horse asthma the application of horse serum to the nasal mucous membrane (in one case pollantin) or to a cut of the skin gave rise to an immediate reproduction in miniature of the phenomena of anaphylactic shock, namely, spasm of the arterioles, with edema and surrounding congestion. One case of horse fever gave a delayed but otherwise typical skin reaction, but no disturbance in the nose. One case of horse fever gave a delayed reaction to the nasal test, but was negative for the skin test. Four of the horse fever cases without asthma were negative for both tests. Five cases of bronchial asthma and five cases of hay fever without sensitiveness to horses gave negative results. As to the value

of these tests in detecting the existence of a state of sensitization to horse serum, the author notes that they should be of assistance when one is in doubt as to whether in a given case it is safe to administer antitoxin. So far as these tests go they would indicate, that in horse asthma, an anaphylactic reaction may occur after the administration of horse serum, in horse fever with nasal symptoms alone, this danger is less or not at all to be feared, and in other types of asthma and of vasomotor rhinitis it is not present.

10. Capital Punishment in the Electric Chair. S. R. Klein.

**1. Habitual Constipation.**—M. Einhorn states that the importance of autointoxication has been exaggerated. Dunin of Warsaw was one of the first to emphasize the fact that nervous phenomena said to be caused by autointoxication, are not due to constipation, as such, but, quite the reverse, bring on the constipation. Constipation may develop as the result of the suppression through hurry or inconvenience of the normal daily desire which is developed by training. Constipation may arise in otherwise healthy people through medication. Habitual constipation may be developed through dieting. Constipation can develop from a lack of fluids. One theory regarding the etiology of constipation is that the muscle of the bowel is thinner than normal, *i.e.* it is congenitally abnormal. Another theory is that constipation may be due to an abnormal position of the large bowel, either to a kink or a ptosis, or a too long colon. Adolf Schmidt brought out a new point, namely, that habitual constipation may be due to a better process of digestion and assimilation, so that there is very little fecal matter remaining. The author does not quite agree with him with regard to the general acceptance of this theory. While it is true that in habitual constipation the bulk of fecal matter is diminished and the absorption is very good, perhaps too good. This is not the cause of the constipation but rather the consequence. In the treatment of habitual constipation the first point is to reassure the patient and tell him that constipation is not such a great misfortune. One should try to interfere as little as possible and to bring back the lost habit of daily regularity. The diet should be arranged to facilitate the bowel movements. This is done in the majority of cases by giving bulky foods, fruit, and salads that contain a great deal of organic acids and cellulose, matter which is not digested, bulky foods serving to bring no more efficient peristalsis. Enough water should be given to the patient. Butter should be used freely. The author has prescribed a combination of phenolphthalein and agar, containing 3 per cent. of phenolophthalein and taken twice a day, or sometimes three times a day in teaspoonful doses. One advantage of these agar preparations is that the remedy in the agar does not come out quickly from the agar substance, but is absorbed slowly through osmosis, and in this way covers a large area of the intestine. A teaspoonful to a tablespoonful of liquid paraffin given twice a day acts well in some cases. There are physical means of treatment, hydrotherapy, exercise, massage of the abdomen, etc. Electricity has been successfully applied.

**7. Trained Nurses in the Administration of Anesthetics.**—A. C. Vandiver favors the following proposed amendment to the Public Health Law of New York State, specifically including the administration of anesthetics within the definition of the practice of medicine. The language of the suggested amendment is the following: "The administration by any process of any substance, liquid or gas, commonly known as a general anesthetic, for the purpose of producing unconsciousness, shall constitute the practice of medicine and surgery, even if such administration is undertaken in the presence of and by direction of a registered physician or surgeon, with the following exceptions: (1) A registered dentist may administer general anesthetics for dental operations, such as the extraction of teeth, but not for any operation that is unconnected with dentistry, even if a registered physician is present and directs the dentist to administer such anesthetic, except as is hereinafter provided. (2) In any case of sudden or severe illness or sickness in which the registered physician or surgeon in attendance upon the patient conscientiously believes that the delay necessary to obtain the services of another registered physician to administer a general anesthetic will endanger the life or health of the patient, that attending physician or surgeon may employ any reliable person to administer such general anesthetic in his presence and under his instructions, but not in his absence. The employment in this manner of any person other than a registered physician to administer any general anesthetic must be limited to emergencies, and must not be habitual." The legal status of nurses administering anesthetics should be fixed, definite and certain, and should be established by the Legislature. If nurses are permitted to administer anesthetics, proper courses of study in nurses' training schools should be prescribed with proper practical experience thereafter.

11. A Satisfactory Local Anesthesia for the Submucous Resection of Nasal Septum. J. J. King.

**1. Abderhalden Test in Dementia.**—C. E. Simon concludes that a sex-gland reaction may be obtained in nearly, if not all, cases of dementia præcox at some stage of the disease, but that the reaction is not specific of dementia præcox, as Fauser would have one believe. It may, of course, be debatable whether the relatively small percentage of cases in which the clinical history pointed to manic-depressive insanity, but in which a reaction was obtained nevertheless, were in reality manic-depressive cases, but the fact remains that in other types of insanity the reaction may also be obtained, even though one admits that it is observed far less constantly. Of special interest is the fact that

in a large percentage of alcoholic cases a sex-gland reaction seems to be obtainable. No reaction was obtained in any one of the author's eleven cases of paresis. These results thus seem quite in accord with those of Fauser, but just as he notes that at one time one of his associates obtained a positive reaction in an isolated case of paresis, so also did Judd in another series of mental cases note a positive reaction in a few instances. The significance of these divergent findings may of course be manifold.

**2. Radium in Cancer.**—H. H. Janeway notes that the true position of radium in the treatment of cancer, with the present methods of application, is a settled matter. While radium will destroy cancer tissue in a dosage not affecting normal tissues, it does not cure the disease unless the latter is quite superficial or of a variety peculiarly susceptible to its influence. The establishment of the fact that radioactivity is an agent which specifically affects cancer is of very great importance, particularly since no other agent has thus far been discovered which in any degree approaches radium in effectiveness. A knowledge of these facts indicates that a more successful method of applying this remedy may yet be discovered. The whole question hinges upon the even distribution of the proper dosage throughout all involved tissues. At present radium may only supplement, but not replace, the knife.

**6. Paraffin Cancer.**—B. F. Davis states that the similarity of the lesions following types of chronic irritation suggests the probable similarity or possible identity of the irritating agent or agents concerned. Is this factor merely the mechanical effect of the presence of minute foreign bodies, soot, on and in the skin? Probably not, and the best argument against the idea seems to be furnished by the fact that workers in blast-furnace tar escape cutaneous involvement while workers in gas-works tar usually suffer from skin lesions and the exposure to tar or pitch-dust is the same in both cases. Can the lesions be the result of prolonged exposure to heat and repeated burns? Probably not, because this would never account for the bladder tumors of anilin-workers, and most of the labors of paraffin and tar-workers and chimney-sweeps are carried on at room temperature or outdoors and these men are not the victims of frequent burns. This brings one to the assumption that there is a chemical body or there are chemical bodies resident in certain coal and petroleum products which are capable of inducing inflammatory productive reactions in tissues and eventually an atypical, unrestrained proliferation of epithelial cells. In favor of this suggestion the author recites several facts. Physicians of large experience of paraffin prothesis demand paraffin of the very highest purity for their work, because it seems that paraffinomas, that is, inflammatory tumors which occasionally develop at the site of a paraffin injection, are especially apt to appear following the use of paraffin of inferior grade. Epithelioma develops earlier and with greater malignancy in workers in fluid tar and in paraffin than in those who are subjected merely to the dry dust and soot. This observation agrees with the generalization that substances are most active chemically when in solution. None other than a chemical cause seems possible in relation to the bladder tumors of anilin workers, and to the betel-nut and tobacco cancers. Ross, Cropper, and Ross assert that they have demonstrated the existence of a number of chemical bodies, twenty-five or thirty, which are capable of inducing cell division in vitro, these bodies they term "auxetics." Auxetics have been demonstrated in gas-works tar but not in blast-furnace tar. Moreover, Bayon was able to induce atypical epithelial overgrowths in animals by the use of gas-works tar containing auxetics, while experiments with the auxetic-free blast-furnace tar resulted negatively. Ross, Cropper, and Ross place certain products of tissue decomposition among the auxetics and suggest that the latter may be responsible for the proliferation of tissue which occurs in healing wounds and that their continued presence in tissues for a long period, as in areas subjected to "chronic irritation," may be the factors which determine malignant degeneration in such areas. Schamberg suspected radioactivity as the possible exciting force in tar products, but its presence could not be demonstrated in specimens examined for him at the University of Pennsylvania.

11. Niton as a Therapeutic Agent. Sir William Ramsay.

**2. Besredka's Antigen in Tuberculous Disease.**—A. C. Inman tested the diagnostic value of the complement-fixation test of the blood in the presence of a tubercle antigen prepared by growing tubercle bacilli in a liquid medium consisting of veal broth and the white and yellow of the hen's egg. No peptone, glycerine, or salts are employed. After the growth has proceeded for from three to four weeks the culture is heated to 115 C., filtered free from bacteria, and should contain sufficient tuberculin to kill a tuberculous guinea-pig in a dose of 1.5 c.c. to 2 c.c. The author found that the antihemolytic power of tuberculous serum can be made manifest in a hemolytic experiment by introducing Besredka's antigen into the mixture. Repeated positive reactions especially with a 32-fold serum dilution, in the absence of a positive Wassermann reaction, indicates the presence of an active tuberculous lesion. Repeated negative reactions indicate the absence of an active tuberculous lesion if cases of under 12 months' duration be excepted.

**4. Experimental Nephritis.**—H. Oertel concludes from his experiments that definite lesions result in the liver after the administration of cantharidin, bichloride of mercury, and uranium nitrate. These lesions bear a more or less close resemblance to the changes in the kidney. Cantharidin produces a rapidly progressing and general parenchymatous degeneration and necrosis associated almost from the beginning with tremendous hemorrhagic vascular engorgement and cellular exudation. These lead, even in small and moderate doses, to a marked and rapid disorganization of the liver. The accompanying constitutional symptoms are severe and lead to speedy death. In mercury the picture is controlled by parenchymatous and fatty degenerations with which an edematous swelling is associated. These lead, according to the dose and to the susceptibility of the animal, to rapid or retarded solution of the cells, especially in the central parts of the lobules. Somewhat similar to mercury are the changes brought about by uranium, but a much greater inflammatory edema or serous exudation and a greater swelling, vacuolization, and cytolysis of the parenchyma in kidney and liver distinguish uranium from mercury poisoning. The fatty changes are less marked than

after mercury, due, in all probability, to the greater and more rapid edematous dissolution of the cells. But in both lesions the central parts of the lobules are most severely involved. The conclusion is drawn that cantharidin, mercury, and uranium are not selective posons, that they affect not only the kidney but also the liver, and that they involve in both organs the parenchyma as well as the circulatory system. Functional changes which have been observed in these instances cannot therefore be regarded as solely due to injury of one or the other part of the kidney, for the alterations in the liver make it probable that these changes are at least partly dependent upon metabolic disturbances, caused by these poisons.

9. **Bacillus Coli as a Cause of Septic Onychia.**—T. Houston and W. W. D. Thomson report three cases of septic onychia due to infection by the *Bacillus coli*. One of these cases occurred in a medical man who was attending a case of *Bacillus coli* cystitis, which he was treating by lavage of the bladder. He developed a very painful swelling, red, tender, and edematous, around the roots of two nails. In both the affected fingers there was a history of a minute abrasion. The condition was treated by incision and cauterization without effect. Two doses of stock staphylococcus vaccine produced no improvement. A culture taken from the seropurulent discharge which exuded from beneath the swelling contained in addition to staphylococci and diphtheroids colon bacilli which were morphologically and culturally typical. The patient's opsonic index to the *Bacillus coli* was found on two occasions to be raised above two. His serum did not agglutinate the *Bacillus coli*. A vaccine of this microorganism was administered, and after the first dose of two and a half millions immediate improvement set in, and it was only necessary to administer a second dose to secure a complete cure. Both nails were lost.

1. **The Incomplete Operation for Cancer of the Breast.**—C. B. Lockwood notes that the inefficacious and uncommendable incomplete operation usually consists of an elliptical incision, including the nipple and areola, and a varying quantity of skin; the mammary gland, but not always in its entirety; the pectoral fascia; and the fat and lymph glands from the axilla up to the pectoralis minor. This operation is rightly called the incomplete operation because it almost invariably leaves part of the growth in the axillary lymph glands and lymph vessels, not infrequently in the pectoralis major, in the skin, or in the fascia of the chest and abdomen. This operation does not fulfill the conditions; it is not calculated to remove the whole of the cancer, and is therefore almost inevitably followed by a recurrence. The incomplete operation removes the pectoral fascia, but it does not take away the pectoralis major or the pectoralis minor. A cancer which is adherent to the pectoral fascia has certainly grown both into the pectoral fascia and into the pectoral muscle. There is a further anatomical reason for the removal of the pectoralis major and of the pectoralis minor. The axillary lymph system is the main road by which the growth spreads from the mammary gland. Its progress is quick and it may soon arrive in the lymph glands beneath the costocoracoid membrane. In the incomplete operation no attempt whatever is made to take away any of the lymph vessels and lymph glands about the upper end of the axillary vein. There is only one condition under which an incomplete operation might cure the cancer, namely, when the carcinoma is confined to the mammary gland, and has not yet infected the lymph vessels or lymph glands.

2. **Work at the Radium Institute, London, in 1913.**—A. E. H. Pinch presents a report which deals with the cases which presented themselves at the Radium Institute, from January to December, 1913, inclusive. Epitheliomata of the buccal, lingual, and pharyngeal mucous membrane still prove both refractory and disappointing in their response to radium, but a new method of treatment has recently been devised, which in instances of cancer of the tongue has given distinctly encouraging results. It consists in the burying within the carcinomatous nodule of a very small but intensely powerful radium emanation tube possessing an initial activity equivalent to that of 80 to 100 mg. of radium bromide enveloped in a screen of 1 mm. of silver, or 0.3 mm. of platinum, and giving an exposure of twenty-four hours' duration. A fairly severe reaction follows, and in some cases the nodule ceases to grow and becomes replaced by dense fibrous tissue. Uterine cancer still continues to yield most gratifying results, and the effects of radium treatment in inoperable cases are far in advance of those obtained by any other known medical or surgical methods. The number of patients with carcinoma of the breast, applying for treatment far exceeds that of any other malignant condition. The policy of declining to treat operable cases is still rigidly adhered to, unless the patients have absolutely refused to submit to operation and radium is used as a last resort. In carcinoma of the thyroid encouraging results have been obtained. In a few instances that have come under notice, the progress of the disease has been arrested, and a decrease in the size of the existing growth has been obtained, the general discomfort and dysphagia when present being greatly relieved. The superficial lesion in Paget's disease is usually speedily cured by one hour's exposure to a half strength plate unscreened, but the underlying induration and affection of the glands, if present, require prolonged treatment with heavily screened applicators if any real benefit is to be obtained. In cases in which the patient is willing to submit to operation this procedure should always be adopted. Carcinoma of the rectum displays much variation in its response to radium therapy, and numerous factors have to be considered in prognosis. Speaking generally, the soft annular and vascular type of growth is much more favorably affected than the flat, hard, non-annular plaque with much subjacent induration. The number of cases of carcinoma of the prostate which have been treated up to the present is not very large, but benefit has been noted in all of them. Nine cases of carcinoma of the bladder have been treated and in six instances the results have been most gratifying. As regards sarcomata, speaking in general terms, these growths, if taken in their early stages, and before dissemination has occurred do very well under radium treatment. The burying with the growth of tubes of radium salts or radium emanation should be resorted to whenever practicable, and the action of these tubes may be much helped by the external application of radium plates heavily screened. In almost every instance of mediastinal tumors that has come under observation the rate of growth has been very markedly checked by the use of radium, and in one or

two cases a definite decrease in the size of the tumor, as seen by *x*-ray screening has undoubtedly occurred. In fibroid disease of the uterus radium exerts a most beneficial action upon the distressing menorrhagia and metorrhagia, which are the almost invariable concomitants of this condition, though it seldom produces any very great diminution in the size of the uterus. Leucoplakia patches on the tongue, cheek, or vulva are speedily removed by radium, but they tend to recur sooner or later. Cavernous nevi do excellently under radium, especially when of such shape that "cross fire" radiation is possible. In tuberculosis of the glands in which surgical measures have been declined for cosmetic reasons, radium often proves of considerable value, either when used alone or as an adjunct to vaccine treatment. In skin disease, keloid continues to give most excellent results when treated with radium, and a great improvement if not a complete cure can be safely predicted. In exophthalmic goiter the results obtained are sufficient to justify a trial of radium when other treatments have failed to produce any results. In arthritis deformans the daily administration of 250 c.c. of radium emanation solution of a strength of not less than 1 millicurie per liter to patients suffering from this obstinate and painful and crippling disease is sometimes attended by very remarkable results.

**Physiology and Pathology of Caisson Life.**—Bornstein writes in a general way of life in compressed air. The caisson was introduced in 1830 by Triger. In 1857 Hoppe-Seyler and Bert, physiologists, described and explained the socalled caisson disease. Among recent authorities are von Schrötter, Zuntz, Haldane, and Quincke. No further dates are given and the author is silent on the important American labors on the "bends." This term was known to the laity in this country in the 70's of the past century, although not found in the earlier reports of the St. Louis and East River bridges. The author credits it to the English. Despite the elaborate work of the German and English scientists there remain many gaps in our knowledge. Treatment throws little light on the nature of the disease, for it simply consists in putting the patients back into compressed air—in other words the treatment is recompression. The "bends" which make up 90 per cent. of caisson disease is now believed to be peripheral in nature, due to the formation of gas bullæ in the loose superficial tissues, notably the subcutaneous cellular tissue. The lower extremities suffer much more frequently than the upper. In 10 per cent. of cases the liberation of gas occurs in the central nervous system. Patients with a well developed layer of subcutaneous fat seem to be especially predisposed to caisson disease. Many individuals develop a tolerance to compressed air. Prophylaxis consists in gradual decompression. The higher the pressure and more prolonged the sojourn the more gradual must this be—the socalled decompression by stages.

**Hyperglycemic Obesity.**—Röth discusses in full this well known association. While in true diabetes we see even under a rich diet a rapid loss of flesh, in the present condition we see even on a light diet a rapid putting on of flesh. In hyperglycemia there is further an increased tendency to arteriosclerosis and arteriosclerotic contracted kidneys. Upon this basis we see develop apoplexy, cataract, eczema, furunculosis, and gangrene. Here, therefore, as in true diabetes, we rely on an antidiabetic diet to reduce the excess of sugar, with the added reduction of obesity. A marked diabetes or hyperglycemia may occur if the kidneys are already contracted, in which case we must test for alimentary glycosuria. It is in the so-called fat diabetic that carbohydrates are chiefly contraindicated.

**Abortive Treatment of Erysipelas.**—Kumaris relates five cases of erysipelas occurring in Athens. The modern watchword in treating erysipelas is "do nothing." This, of course, has reference to rational plans of treatment, to specific treatment. A highly virulent type of streptococcus is concerned in an intensive invasion of the lymph spaces of the skin and mucosæ. The first four cases were treated in the classical manner, including the indicated serotherapy and the course of the disease was uninfluenced. The condition was apparently spread among patients with wounds. When a fifth patient had become infected, the author made a single thorough punctiform cauterization with the paquelin and no further treatment was required. The idea is not claimed as new. In fact Larrey used the actual cautery freely, as did also Pelletan, in a multiple fashion. The cautery must be used early and the entire inflamed area must be attacked as thoroughly as possible.

**Albumin Storage by the Liver after Feeding with Final Cleavage Products of Protein.**—Berg refers to the experiments of Abderhalden and others along the line of N-retention after feeding with these cleavage products. Believing that the seat of retention must be the liver, the author has studied liver cells from a great variety of animals, cold and warm blooded, and came to the conclusion that the substance stored is not protoplasm as we understand the term. It occurs in the form of droplets which are very little in evidence in starvation while numerous after albumin feeding. These fluctuations occur independently of the protoplasmic contents of the liver cells. These the author terms "fixed protoplasm." The fluctuating drops are replaced by vacuoles during starvation. While albumin feeding causes these droplets to appear, this is not the case when a carbohydrate or fat diet is used. Very recently Tichmeneff has not only applied chemistry to this problem with success, but he has been able to secure results of a quantitative character. Broken up albumin used by the author comprises in part meat which has been digested in succession by pepsin HCl, trypsin and erepsin. The preparation was free of biuret and gave only a very slight clouding with phosphotungstic acid. This solution is believed to consist of amino acids, with which Abderhalden was able to create albumin in the organism.

**Paratyphus in Munich Children.**—Breuning believes that in not a few cases of dyspepsia, diarrhea with numerous mucous fetid stools—in other words of gastroenteritis we simply have before us a paratyphus affection, which can be identified only by bacteriological and serological methods. As a rule we have to deal with milk-borne infection. Paratyphus milk may be recognized not only by the usual tests, morphological and cultural, but because a thermostable toxin is produced therein. Statistically the paratyphus bacillus is less frequently at fault than the various forms of dysentery bacillus, but more frequently found than Gartner's bacillus. In the first year or two of life we know little of the *B. paratyphus*, so that it need not be accused of summer mortality. Of the paratyphus disease *per se* we know of two, perhaps three forms. One simulates typhoid, a second gastroenteritis and a third cholera. These forms are due largely to the site of the bacilli, the typhoid form being associated with Peyer's patches, while the gastroenteric form acts on the super-

ficial structures. The typhoid form is more benign than the gastroenteric. To come to an abrupt close—we should suspect any febrile gastroenteritis in a young child and at once make bacterial studies.

*May* 17, 1914.

**Causes of Late Eunuchoidism.**—Schwaer reports a single case. A man of 45 lost at the age of 22 his entire hairy equipment without apparent cause. Such a condition until recently would have been termed by dermatologists alopecia areata universalis, and no other diagnosis would have been possible for many years. When about 38 he began to flesh up rapidly, which was of course a normal behavior. For the past three or four years attacks of facial spasm, probably psychogenic. Quite recently attacks of precordial pain, sense of oppression, and dyspnea. These recalled somewhat similar attacks in childhood. The patient, a single man, had seminal emissions every four weeks, and his potency was weak. He was well nourished, and his fat was accumulated about the hips, abdomen, breast, and neck. His face was red, slightly cyanotic, but there was nothing wrong in the thorax. Penis small, testicles normal. The loss of hair, and abnormal distribution of the fat suggested dystrophia adiposo genitalis, but the radiogram showed a normal sella turcica, and the superior physical development was opposed to such a view. The author was compelled therefore to regard the case as one of late eunuchoidism. It now remains to be mentioned that patient had a double variococele. The symptoms of late eunuchoidism as described by Falta comprise the eunuchoid distribution of fat, the loss of hair, red and slightly bloated face, and anatomical and functional insufficiency in the genitals. This disease picture seems feebly outlined, for the patient's red face may have been due to his frequent abuse of alcohol. The distribution of fat is natural in the elderly, the total loss of hair is a condition *per se*, and the genital anomalies are sufficiently common in men of any type. According to Falta this condition appears after trauma, especially in the external genitals; hernia; gonorrhea and syphilis; infectious diseases, etc. If we follow Falta, the only apparent cause in this case is local, the double varicocele; and in the future the relationship between the two should be studied.

**Etiology of Psoriasis.**—Jaerisch refers to Menzer's claim that this dermatosis is only a tuberculide which induced him to test this subject in soldiers. Ten of the latter were studied, eight patients being psoriatics, while the two controls had eczema. Menzer's claim that the staphylococcus was a determining factor in the psoriatic eruption was chiefly investigated. This was demonstrated by the alleged curative action of staphylococcus vaccine. Naturally soldiers are vigorous subjects, and psoriasis is rare among them—about 2 cases per 1000. While, therefore, unsuited for Menzer's tests, the author obtained in several cases both a staphylovaccin reaction and temporarily good results. He seems to be about the first writer to believe in the possibility that Menzer's contention can be supported partially by facts.

### Deutsche medizinische Wochenschrift.

*May* 14, 1914.

**Secondary Narcosis Death.**—Keil refers to death attributable to narcosis but occurring after the latter. Primary narcosis death means death from the anesthetic and during the narcosis. The secondary death presents no constant picture but varies greatly in accordance with the organ chiefly involved. We see it in weak constitutions, in the status thymico lymphaticus, in the obese, in cardiacs and nephritics. This does not mean that sound internal organs protect. To avert this form of death we should take the blood pressure, study a drop of blood, and cause the patient to climb stairs at a moderate pace—the increase of pulse rate, with the time required to regain equilibrium giving us an idea as to the functional power of the heart. The secondary narcotic death does not usually appear before the second or third day, when the pulse becomes rapid and shallow, while the temperature shows fluctuations not traceable to any inflammation. Patients become restless and have a sense of precordial oppression along with cyanosis, anxious expression, and at times slight icterus. There are labored breathing, oliguria with sediment of nephritis. The pulse rapidity increases and the original cyanosis gives way to a waxy pallor, the face falls in, the nose is pinched, etc. There is now no hope of recovery and death occurs from circulatory and respiratory failure. In a few cases there is rapid collapse with coffee ground vomiting. All the analeptics may be tried to save these cases. Improvement under these resources does not of course mean recovery. Generally speaking the measures used are those proper in collapse from any cause. Early washing out of the stomach is a special resource, as the coffee grounds vomiting is not only specific for this affection but indicates a grave prognosis. The author selects 4,000 narcoses, almost wholly chloroform or ether or both, in which there was not a single case of primary narcosis death and finds 10 cases of secondary death. In 9 the simple drop method was used and in the other there was mixed narcosis with the Roth-Dräger apparatus, in which oxygen is superadded. Death occurred on an average 4 days after the narcosis. Most of the patients were fat, elderly women. In Münich women become fat while still young. It is only necessary to add that the narcosis material comes from Professor Klein's gynecological clinic.

**Treatment of Disturbances of Motility of the Stomach.**—Winternitz concludes a thorough study of this subject with special reference to gastrectasia. When simple atony has brought about the latter, a permanent cure may result from the use of internal measures. Diet comes first in these cases, then follows gastric lavage. The socalled secondary gastrectasia, due to pyloric obstruction suggests early operative intervention. But in just such cases even measures for simple primary gastrectasia have prevailed to a certain extent. Naturally in cancer, actual or suspected, a pyloric resection or gastroenterostomy is indicated. An indication for these operations is also present in gastric stasis of the third degree, irrespective of cause, when a high degree of subnutrition has resulted. Strychnia is given in combination with calcined magnesia as a stomach tonic. Alkalies may be required in hyperacidity, creosote in fermentative cases. Gastric lavage, systematically practised, is the best medical resource. Rectal feeding is sometimes necessary to rest the stomach.

**The Stages of Tuberculous Infection in the Human Being.**—L. Bernard states that the first stage of infection occurs in the child. The manifestations in the adult are the result of a reinfection. The bacillary infection is in reality an immunizing one. The stage of immunity or rather of allergy is variable, unequal, and unstable. Tuberculous allergy resulting from the initial infection governs the evolution of the reinfections.—*La Presse Médicale.*

## Insurance Medicine.

American Association of Medical Examiners.—The annual meeting of this Association will be held at the Dennis Hotel, Atlantic City, June 22, at 10 a. m. The following papers will be read: "Blood Pressure," by Dr. J. W. Fisher, Medical Director, Northwestern Mutual Life Insurance Company, Milwaukee. Discussion by Dr. Henry Wireman Cook, Medical Director, Northwestern National Life Insurance Company. "The Special Value of a Few of the More Refined Methods of Diagnosis in the Rating of Impaired and Large Risks," by Dr. Fred M. Hodges, Assistant Medical Director, Atlantic Life Insurance Company, Richmond. "Reliable Methods of Uranalysis," by Dr. C. A. McCollom, Minneapolis, Chief Examiner for Prudential Life and Mutual Benefit Life Insurance Company. Discussion by Dr. Henry L. Ulrich, Minneapolis. "Chronic Discharging Ears and Life Insurance," by Dr. Wm. Mithoefer, Instructor in Rhinology, Laryngology, and Otology, College of Medicine, University of Cincinnati. "Periodic Re-examinations," by Dr. Charles H. Castle, Member Hygiene Reference Board, Cincinnati.

**The Effect of Alcohol and Tobacco on Life Expectancy.**—T. D. Crothers points out that alcohol and syphilis are coming into greater prominence as factors in disease and death, and call for new study and examination. Evidently the managers of the life insurance companies are not clear concerning the influence of alcohol on mortality. They have a general consciousness that it is an important factor in disease, but concerning its exact relation there are conflicts of opinions. Some companies cling to the Anstie theory, namely, that a certain amount of spirits is harmless and may be consumed in the body with little or no danger, provided the amount is below a certain limit. A very few companies insure only total abstainers and are emphatic against taking any other risks. Most companies accept applicants who acknowledge the moderate use of spirits such as wine at meals, and occasionally the use of stronger alcoholic beverages on special occasions. When other requirements are satisfactory the companies consider the use of alcohol of little or no importance. Medical examiners differ widely in their estimates of the danger from this source. Some of them regard beer as of no influence on the mortality rates. Many of them consider spirits taken as a medicine, even for a long time, as harmless. Some companies assert that there is less danger in accepting moderate drinkers, under certain circumstances, than persons who are classed as total abstainers. The alcohol habitue suffers from an autointoxication in addition to the intoxication from alcohol. The inebriate is a neuropath and a psychopath, subject to morbid impulses and obsessions, with defective and degenerate brain control. Both are exceedingly dangerous risks and are not to be judged by the average mortality tables. These facts are very significant and are confirmed by mortality statistics. Several studies of the mortality statistics in this country and abroad have pointed to one conclusion, namely, that alcohol is the most distinct and prominent of all the particular causes of death in persons under fifty years of age. There is no question about the effects of alcohol in large doses, used continually or at intervals. Laboratory work has shown its paralyzing effects in doses of from half to one ounce, and also that it has a special action on the vasomotor centers, deranging the circulation and dehydrating cells and tissues. Cells exposed to one-tenth of one per cent. of alcohol become shrunken and changed in appearance. Tobacco does the same thing, only in a lesser degree, and is more corroding. These facts are confirmed by the clinical experience of the histories of persons; by studies of symptoms, and by comparative studies of alcohol and tobacco on cell growth in plants and animals, which studies show degenerative physiological effects that are unmistakable. Policyholders to-day are subjected to strains and drains unknown a half century ago. There are certain occupations and certain environments that strongly predispose to the use of narcotics like alcohol and tobacco. There are certain causes, some of them psychic, that should be the subject of distinct and exhaustive examination. Medical examiners should be laboratory and clinical judges of the deductive and inductive studies of the entire phenomena of living. If the companies are unable to limit their business to total abstainers there are already data sufficient to indicate the possibility of insuring moderate drinkers on a practical commercial basis. Thus a man at forty years who asserts that he is drinking alcohol in moderation, should be rated with the same expectancy as a man of fifty or fifty-five years, and should pay premiums accordingly. A periodic drinker thirty years of age should be charged the same premiums as an individual forty or fifty years of age. This is on the supposition that the drinker is free from the ordinary symptoms of physical disability. The central fact is that the drink and drug taker has discounted the future and is prematurely aged, and that the company can estimate this premature aging and issue policies accordingly. All persons acknowledging the moderate or occasional use of spirits should pay the same premium as persons from ten to twenty years older, depending on circumstances and conditions. The present system of making all classes pay the same rates is an injustice to the abstainer, who must pay, too, the increased risks which the company assumes by insuring the moderate drinker. Life insurance is a commercial business without sentiment and should recognize the changing conditions and discoveries in science as well as in business.—*N. Y. Medical Journal*, April 25, 1914.

**"Hereditary Disease" in Application.**—An application for life insurance, after containing numerous questions as to the applicant's physical and mental condition, inquired whether any intimate associate or any person in the applicant's immediate household was then ill with consumption, whether any one of them had recently been ill or died of that disease, and then asked whether any of the applicant's uncles or aunts had consumption or any "hereditary" disease. In an action on the policy it was held that the last question should be construed as inquiring concerning physical ailments and condition and not to refer to hereditary insanity. (South Atlantic Life Ins. Co. v. Hart's Adm., Va., 79 S. E. 401.)

**Significance of a Family History of Diabetes in Life Assurance.**—In discussing a paper with this title, read by Dr. Otto May on March 4, 1914, before the Life Assurance Medical Officers' Association of Great Britain, Dr. De Haviland-Hall suggested that the family history of diabetes was much more important if the brother or sister, especially the brother of the proponent, had been affected with diabetes.

# Book Reviews.

LEHRBUCH DER ORGANOTHERAPIE. By WAGNER v. JAUREGG and GUSTAV BAYER. Price 13 marks. Innsbruck and Leipzig: Genz Thieme, 1914.

THIS book of organotherapy includes chapters by Dr. L. Borchardt on the pituitary body and by Prof. Friedrich Pineles on the parathyroid glands, but the bulk of the matter is contributed by Gustav Bayer on his special subjects, the suprarenal bodies, the chromaffin, system and on organotherapeutic experiments with other organs than the ductless glands. Professor von Jauregg, the authority on cretinism, writes the chapter on the thyroid gland. The authors beg the reader in their preface to make no comparison between this book and Biedl's "Innere Sekretion," since the latter presents an exhaustive review of the theory of inner secretion, and is therefore primarily intended for the research work, while this v. Jauregg-Bayer work is addressed to practicians, and therefore only contains as much as is necessary for the understanding of the therapy.

PATHOGENIC MICROORGANISMS. A Textbook of Microbiology for Physicians and Students of Medicine. By WARD J. MACNEAL, Ph.D. M.D., Professor of Pathology and Bacteriology in the New York Postgraduate Medical School and Hospital, New York. (Based upon Williams' Bacteriology.) With 213 illustrations; price $2.25 net. Philadelphia: P. Blakiston's Son & Co., 1914.

THE basis of the present work is the well known manual of Williams, and its subsequent revisions by Bolton. The title of the work has been changed, owing to the importance of the parasitic protozoa, a consideration of these being now included. The text has been largely rewritten, much new material has been inserted, and some obsolete matter omitted; but the work is no larger than its immediate predecessors. The reader will find in this volume all that the practising physician is likely to require on this special topic. The subject is handled in a broad and general way, and the author has produced a book which is readable as well as useful.

THE CLINICS OF JOHN B. MURPHY, M.D. Vol. III, No. 1. Octavo of 190 pages; 91 illustrations; published bimonthly; price per year, paper $8.00; cloth, $12.00. Philadelphia and London: W. B. Saunders & Co., 1914.

THIS is an extremely interesting number and a vast improvement over the final number for 1913. A large part of the book is taken up with the consideration of bone and joint surgery, a field in which Murphy has "shown the way" perhaps to a greater degree than any other American surgeon in recent years. He also discusses tuberculosis of the testicle, and tumors of the breast, with a description and illustrations of his technique. There are also chapters containing remarks made at one of Murphy's clinics during the week of the meeting of the Clinical Congress of Surgeons by certain of the visiting surgeons as follows: Lord Lister and Antiseptic Surgery, by Sir Rickman J. Godlee; Nitrous Oxid Anesthesia, by George W. Crile; Metastatic Infections, by George E. Brewer; Gastric Ulcer and Gastric Carcinoma. by Herbert Paterson, F.R.C.S. All things considered, this is one of the most interesting of the more recent volumes of this series.

INFECTIONS OF THE HAND. A Guide to the Surgical Treatment of Acute and Chronic Suppurative Processes in the Fingers, Hand, and Forearm. By ALLEN B. KANAVEL, M.D., Assistant Professor of Surgery, Northwestern University Medical School; Attending Surgeon, Wesley and Cook County Hospitals, Chicago. Second Edition, thoroughly revised. 463 pages: illustrated with 147 engravings; price $3.75. Philadelphia and New York: Lea & Febiger, 1914.

WHEN the first edition of this book appeared it was immediately recognized as the most important contribution to the proper understanding and treatment of the infections of the hand and forearm that had appeared up to that time, and since then it has held its position as the standard work on this subject. The present edition has been thoroughly revised, a few new illustrations added, and résumés have been inserted at the ends of several of the chapters. The original study of the subject at the hands of the author had been so thorough that there was little that really needed revision. Some of the illustrations have more extensive explanatory legends in this than in the former edition. Still further elaboration along this line in some instances would add materially to their value.

This is an extremely valuable book and one that may very profitably be studied by every physician who is or may be called upon to treat infections in these areas, no matter how simple they may appear to be. Those who adopt the lines of incision and apply the principles as laid down by the author will find their results much better than under the old methods of treatment.

THE EARLY DIAGNOSIS OF TUBERCLE. By CLIVE RIVIÈRE, M.D., F.R.C.P. 260 pages; price $2.00. London and New York: Oxford University Press, 1914.

To the medical ear of the American physician this title sounds peculiar. The book deals with tuberculosis of the chest only, its symptoms, physical signs, differential diagnosis, and the special diagnostic means, such as Roentgen rays, tuberculin test, sputum examination, and opsonic index. One would presume that the peculiar name indicated a diagnosis of all diseases in which the tubercle is to be found. Aside from this criticism and the additional one that the adjective "tubercular" is used instead of "tuberculous," the former being correct since tubercular applies only to the form of the pathological unit and not to the disease due to the tubercle bacillus, the book is not without considerable merit. It is a splendid review of our present knowledge of early diagnosis of pulmonary tuberculosis by physical examination and other means.

Of particular interest is Chapter II, which deals with the subject of tuberculosis of the thoracic glands which to the mind of the reviewer has not received sufficient attention in most of the modern textbooks on tuberculosis. This part of the book is made valuable by topographic descriptions, some *x*-ray photographs, and the complete report of four cases of glandular and pulmonary tuberculosis in children (ganglio-pulmonaire of the French). As a whole, the book deserves the careful study of specialists and practitioners interested in tuberculosis of the adult and the child.

MEDICAL RESEARCH AND EDUCATION. By RICHARD M. PEARCE, the University of Pennsylvania; WILLIAM H. WELCH, W. H. HOWELL, FRANKLIN P. MALL, LEWELLYS F. BARKER, the Johns Hopkins University; CHARLES S. MINOT, W. B. CANNON, W. T. COUNCILMAN, THEOBALD SMITH, Harvard University; G. N. STEWART, Western Reserve University; C. M. JACKSON, E. P. LYON, University of Minnesota; JAMES B. HERRICK, Rush Medical College; JOHN M. DODSON, University of Chicago; C. R. BARDEEN, University of Wisconsin; W. OPHÜLS, Stanford University; S. J. MELTZER, Rockefeller Institute for Medical Research; JAMES EWING, Cornell University Medical College; W. W. KEEN, Jefferson Medical College; HENRY R. DONALDSON, Wistar Institute of Anatomy; the late C. A. HERTER, Columbia University; the late HENRY P. BOWDITCH, Harvard University. Edited by J. McKEEN CATTELL. New York and Garrison, N. Y.: The Science Press, 1913.

THIS is the second of a series of volumes on "Science and Education" for the promotion of scientific research and educational progress. The subject of the first volume is "Foundations of Science." The present volume is a collection of lectures and essays by the above named educators, all of whom are well known authorities on the phases of the subject which they handle. The subjects of some of these essays are "The Interdependence of Medicine and Other Sciences of Nature," "Medicine and the University," "The Relation of the Hospital to Medical Education and Research," "Liberty in Medical Education," "Some Tendencies in Medical Education in the United States," "Certain Ideals of Medical Education," "The Career of the Investigator," "The Outlook in Medicine," "Problems, Methods and Organization of Research with Special Reference to Physiology," "On the Improvement of Medical Teaching," "The Educational Function of Hospitals and the Hospital Year," "The Addition of a Fifth Year to the Medical Curriculum," "Medicine and Sociology," "Research Foundations and Their Relation to Medicine," etc. Such a range of subjects has left no phase of medical education past or present untreated, and the chapters of "Imagination and Idealism" and "The Medical School of the Future" show forth admirably those broad fundamentals upon which the future of medicine must be constructed. While these essays have all appeared in various periodicals their grouping together in this way gives the most comprehensive view of the subject yet presented.

# Society Reports.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held April 16, 1914.*

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Surgery.

**Some Medical Aspects of Pyloric Stenosis in Infancy.**—Dr. L. EMMETT HOLT presented this paper. He said that it was surprising that pyloric stenosis in infancy had gone so long unrecognized, nearly all that was known of the condition having been contributed since 1897. His personal experience with pyloric stenosis included 57 cases, of which 18 were seen in private practice and 39 in among the inmates of the Babies' Hospital. The steadily increasing number of cases seen would indicate that this condition was now being recognized where formerly it was overlooked. Pyloric stenosis occurred nearly always in breast fed infants. In his series of 57 cases, 52 were breast fed, and 40 of these had nothing but breast milk; hence, bad feeding could not be invoked as the cause of this condition. The predominance of the male sex had been noted by all writers. Of his 55 cases in which sex was noted 49 were males and but six females. In four-fifths of the series under consideration the first symptoms of the disease were manifested during the third, fourth, or fifth week, and in only two during the first week of life. The symptoms were usually abrupt in onset. Pyloric spasm played an important part in the production of symptoms and the disappearance of all symptoms in a few weeks in a certain proportion of the cases pointed in the same direction. On the autopsy there had invariably been found marked hypertrophy of the pylorus, principally involving the muscular layer. According to his view the symptoms had an organic rather than a functional basis. It was difficult to reconcile the clinical symptoms and the pathological findings with either of these views alone. Dr. Holt believed that definite persistent spasm of the pylorus without hypertrophy was yet to be proven. At autopsy in his experience, hypertrophy had been invariably present. No sharp division into spasmodic and hypertrophic types was possible. The real question was whether there existed an obstruction sufficient to endanger the child's life and how it might best be relieved. The better division was into mild and severe cases. Many points in the pathology of pyloric stenosis were still obscure, but when it came to the clinical aspects of the disease there was no such divergence of views. The typical case suddenly began to vomit persistently and forcibly, had marked constipation, steady loss of weight, and all the symptoms belonging to failing nutrition. Careful examination revealed definite peristaltic waves and in nearly all cases a palpable tumor in the pyloric region the size of a peanut. The forcible and projectile character of the vomiting occurring soon after meals together with its persistence was characteristic, but visible gastric peristalsis was one of the most important symptoms without which one should hardly be willing to make a diagnosis. A palpable tumor could not be considered essential but would nearly always be found by a careful and experienced observer. The tumor was usually more evident just before or during the act of vomiting. The decision in regard to the advisability of operating should not rest upon finding or not finding it but upon the amount of obstruction present. One of the most important guides to the degree of obstruction was the amount of gastric retention. For this purpose the apparatus suggested by Hess for aspirating the duodenum was useful. This means of establishing the fact of obstruction was, in his opinion, more valuable than the *x*-ray. Constipation depended only on the absence of food from the intestines. Other symptoms were always present but were not diagnostic. There was a wide divergence of opinion as regarded the methods of treating pyloric stenosis. Physicians had reported quite a large series of cases treated medically with so low a mortality as to lead to the inference that nearly all these patients recovered if treated properly. Surgeons, on the other hand, considered the disease a surgical one and urged that the patient be turned over to them for operation as soon as the diagnosis was made. Pyloric stenosis in infancy was accredited with a mortality of about 50 per cent. In his series of 57 cases there were 26 recoveries and 31 deaths, a mortality of 55 per cent. There were 28 cases operated on, with 14 deaths; there were 29 cases treated medically with 17 deaths. Three-fourths of these were hospital patients and some were in a hopeless condition when admitted. The whole crux of the situation between medical and surgical treatment seemed to be that when the symptoms and the condition were such as to make it probable that the patient would live long enough for the condition to subside then medical treatment might be followed out, but if the condition of the patient was such that it seemed probable that he could not withstand the disease until the pathological process subsided than surgery offered the best solution of the problem. The medical risks were not to be ignored; they had not been sufficiently considered. There was danger from acute inanition or from marasmus. To allow the weight of the child to fall gradually from eight to seven or six pounds, or even lower, was to take great chances. There was also the risk of intercurrent disease developing while the child was in an enfeebled condition. Sudden death had been known to occur in cases that were fairly well nourished, where the vomiting had practically ceased, and where there was no assignable cause. Another question remained. If these patients got well without operative treatment did they recover completely or did the lesion remain which might give subsequent trouble? In no instance in which he had been able to follow the subsequent history of the child had there been a persistence of the symptoms into childhood. The surgical risks were partly essential and partly accidental. The essential risks were those of shock, non-union, and exhaustion. These were much reduced by early operation. Of much greater importance were the accidental risks largely due to faulty technique. There were also the additional risks of hemorrhage, leakage, obstruction, and infection. With an experienced operator and the patient in fair condition, the operative risk was much less than one would anticipate. The younger the child the less the shock appeared to be. In private practice, with the best nursing and medical attention the risks of medical treatment were small, but there would always be a certain number of cases in which surgical intervention would be required. Medical treatment consisted of careful feeding and stomach washing twice daily with water at 112° F. Breast milk was the preferable food. In default of that a modified milk mixture low in fats should be employed. The quantity and intervals of feeding must be regulated to the needs of the individual case. In children extremely prostrated the Murphy drip was valuable. They had been accustomed to use 4 per cent. solution of dextrose in a normal saline solution, giving four to eight ounces twice a day. Hypodermoclysis was of even greater value than the Murphy drip. Rectal feeding was of very little assistance, except for a short time. Drugs were of little or no value nor could more be said for local applications of heat over the epigastrium. Cases medically treated must be closely watched.

**Report of Seventeen Cases of Pyloric Stenosis in Infancy Treated by Gastroenterostomy.**—Dr. WILLIAM A. DOWNES presented this report. He stated that his series embraced twenty-one cases, sixteen males and five females. Seventeen were breast fed and one bottle fed. The symptoms appeared from three days to seven weeks after birth. In every case vomiting was the first symptom noted. It was projectile in character and occurred shortly after feeding. A marked loss of weight usually followed. The lower abdomen was retracted and usually soft, while the epigastric region was full and prominent. All cases presented at some time peristaltic waves passing from left to right, though this symptom should not lead to a diagnosis of true stenosis without other more reliable symptoms. To the right of the median line and just below the costal margin a firm, movable tumor about the size of the terminal phalanx of the thumb was felt in every case except the first. Beginning with the eighth case aspiration was practised in every case as a routine measure, and each stomach was found to have from one-half to four ounces retention three hours after feeding, even though vomiting had occurred. They did not consider it necessary or desirable to submit the babies to *x*-ray examination before operation. Upon opening the abdomen a pyloric tumor was found in every case. These tumors were hard, smooth, freely movable, and free from adhesions. The pyloric portions of the stomachs were thickened and somewhat edematous and about one-half of them were dilated. A typical gastroenterostomy was made in all the cases. Ether was the

anesthetic used. The abdominal incision should be one-half to three-quarters of an inch to the left of the median line. The reason for this was that there was so little subcutaneous tissue in these babies that it was difficult to obtain union in the median line, whereas the incision through the rectus muscle healed more readily. Another reason for placing the incision in this location was that in one fatal case a large hemorrhage was found where the needle used in closing the abdominal cavity had punctured the falciform ligament of the liver. With the exception of the first two cases stomach clamps were not used. The after care of these cases was extremely important, and much depended on the judicious use of brandy, atropine, and caffeine, and also upon the proper use of fluids by hyperdermoclysis and the Murphy drip. The after history of these cases was much like the after history in the ordinary case of gastroenterostomy in the adult. A number of the operations were done in twenty-five minutes; the longest time occupied in operating was forty-five minutes. From his experience and observation in this series of cases Dr. Downes said he felt justified in offering the following conclusions: 1. Hypertrophic pyloric stenosis was congenital to the extent that there was an increase in the thickness of the circular muscle fibers at the pylorus. The presence of this thickened muscle fiber reduced the lumen of the pylorus, therefore the stomach, in order to empty itself, contracted more forcibly than normally. This soon caused the mucous membrane to become thickened and edematous, and to assume a more or less spiral arrangement as it passed through the narrowed pyloric channel of from one-half to three-quarters of an inch. The result was a valvular action which gradually produced complete closure of the pylorus. The question as to whether or not the pylorus would admit a probe or catheter at operation or autopsy was of little consequence when weighed against the clinical evidence of obstruction. 2. There was sufficient time between the onset of symptoms and the appearance of the signs of complete obstruction for careful observation and for carrying out any medical measures likely to prove of benefit., provided, of course, that the early symptoms had been properly interpreted. The fear, however, that the condition might have existed longer than had been suspected and that the vitality of the baby was not as good as appearances would lead one to believe made him feel that operation was indicated in every case of hypertrophic stenosis as soon as the diagnosis was made. Should depression or early evidence of shock be present immediate operation was demanded. 3. Babies coming to operation in good condition suffered little or no shock, and their convalescence was straightforward. His experience in this respect corresponded with that of other operators.

Dr. CHARLES L. SCUDDER of Boston, Mass., considered the papers very interesting and congratulated the society upon having so fair a statement of the medical point of view. Dr. Downes' paper was of considerable importance in connection with the surgical aspect of the subject. Dr. Scudder said he hesitated to express an opinion at all contrary to that of Dr. Holt. If there was one thing that was difficult for the general practitioner or the internist it was to feed babies skilfully, but all men were not as competent in this direction as Dr. Holt. Therefore Dr. Holt's attitude of watchful experimentation in certain groups of cases was not one to be commended to the general practitioner. In twenty-five years of experimental work with cases of pyloric stenosis in babies it had been demonstrated that the medical treatment by feeding and by drugs in true cases of tumor stenosis had not been satisfactory. If there was a true tumor present the sooner surgical measures were instituted the better for the immediate condition and the better for the future of the baby. Cases of stenosis not due to tumor were supposed to be occasioned by a certain degree of pyloric spasm. This term pyloric spasm was introduced into medical nomenclature by the general practitioner to explain the cases of difficult feeding not occasioned by true pyloric tumor. He believed that this conception of pylorospasm should be retained. It must be constantly kept in mind, and this was important that the tumor cases of obstruction were real mechanical obstructions. Moreover the tumor was probably of congenital origin. Recently a case had been reported of a newborn baby, a fetus, in which there was a congenital pyloric tumor. This fact was of considerable importance in the proof of the congenital origin of this tumor. It was equally important to remember that the evidence all pointed to the persistence of this tumor throughout life. The evidence of the persistence of the tumor was of different kinds. The *x*-ray evidence seemed to confirm this statement. The evidence from the case of Morse-Murphy-Wolbach reported in the *Boston Medical and Surgical Journal* for April 9, 1908, demonstrated that six and one-half months following a successful gastroenterostomy for congenital pyloric tumor the pyloric tumor still existed as at operation. The evidences discovered in adult life suggested that when the obstruction was not complete the individual lived to adult life and the tumor persisted. The demonstration that the tumor was a permanent one was of more than academic interest. It demonstrated without a doubt the necessity for surgical interference when the diagnosis was first made in these cases. Dr. Scudder agreed with Dr. Holt that the amount of gastric stasis in these cases would help to determine the diagnosis, but he also believed that the value of the *x*-ray was very great and in doubtful cases was a legitimate and helpful means in determining the presence of obstruction. He took issue with Dr. Holt that if these babies were treated medically for a long enough time they would get over their difficulty without surgical assistance. The evidence which he stated for the permanence of the tumor contradicted this statement absolutely. A baby with a partial obstruction could be kept alive by the amount of food passing through the obstructed pylorus, but the obstruction would always exist. The individual living with such an obstructed pylorus would, if he grew up, become weak physically, not strong and robust. The contrast between the rapid improvement in weight, in general appearance, in growth, and in general development in the cases of pyloric tumor operated upon and those cases experimented upon by feeding and drugs was so great that one could hardly understand the attitude taken by certain medical practitioners who advocated long experimental feeding in true tumor cases. When the diagnosis of congenital pyloric stenosis was made in little babies, the earlier surgical measures were instituted, the more rapid would be the recovery from the emergency starvation and the more sure would be the saving of the life of the child. In the group of cases in which the diagnosis was doubtful it would always be justifiable and proper to experiment for a limited time with skilled feeding, in order, if possible, to arrive at a satisfactory diagnosis. Comparatively few cases of so-called pyloric spasm without the presence of a true tumor would require surgical treatment.

Dr. HENRY KOPLIK said that the difficulty encountered in handling these cases was very great; however, the more one saw of them the less difficulty one had in classifying them in his own mind as to which would probably go through without operation and which must be operated upon as quickly as possible. There was a class of cases which he believed would get well without operation, but it was not always easy to come to this conclusion. There was a certain class of cases which were rare and were described as true hypertrophic stenosis, with a hard palpable tumor; these cases should be operated upon as soon as possible. He had seen only one such case. In other cases the tumor was soft and palpable; it could be felt to soften and harden under the finger. Peristalsis was not an indication for operation; many cases had peristalsis and recoverd without operation. In others there was peristalsis long after recovery. To conclude from the presence of a tumor and peristalsis that it was necessary to operate was dangerous ground. On the other hand the amount of stenosis was very important as well as the knowledge of just how much food passed through the pylorus into the duodenum. When no great amount of food passed through the pylorus the sooner the operation the better, before the child became too exhausted. One of the best signs when confronted with a case related to the character of the symptoms from the onset, some cases being stormy so to speak. The child vomited and lost weight from the start and there were signs of intestinal intoxication. These were the cases which should not be played with too long. Dr. Holt had made the observation that if the child lived long enough many would recover without operation. That was true. The symptoms seemed to subside after the third month. As to cases of pyloric spasm with relative stenosis in later childhood, Dr. Koplik had seen one such case due to an ulcer of both the stomach and the duodenum. This case was probably congenital. It was operated upon and died. Post-mortem examination revealed a moderate hypertrophy of the pylorus probably congenital.

Dr. H. M. RICHTER of Chicago, Ill., said that if they could agree as to the underlying pathology it would be

easier to decide upon what course to pursue. Among his 24 cases, 19 were diagnosed before operation as hypertrophied pylorus with resulting obstruction, and in five cases the diagnosis before operation was spasm. Of the 19 cases, 18 showed palpable tumor before operation. In 19 cases there were certain definite things demonstrable, such as a hard fixed tumor. In five cases a diagnosis of spasm was made on the basis of the peristaltic waves of the stomach and the starvation stools. The underlying pathology was certainly quite different from that found in the cases showing hypertrophy and probably did not constitute an entity, but was variable. There was a definite intestinal obstruction in the true hypertrophic cases. The obstruction was mechanical, from a mass blocking a patent lumen and the distended stomach acted as did a distended bladder in forcing the contents through. Last November, in Chicago, Dr. Case took ten consecutive skiagraphs of cases operated upon by Dr. Richter at periods varying from a few weeks to three and one-half years and showed that the bismuth in every instance passed by way of the new opening and not by way of the pylorus. As a matter of fact it was not necessary to show that a tumor existed for years; that it lasted long enough to endanger the patient's life was the indication for operation. The mortality for gastroenterostomy was high, but it was gradually being lowered. The after history of the cases treated medically and those treated surgically should be compared. The duration of non-surgical cases was prolonged and in a large proportion of these cases the mothers lost their milk. These results should be compared with the immediate results from operative work. The point should be emphasized that the bismuth picture should not be relied upon in making a diagnosis. The presence of a tumor did not exclude the possibility of some bismuth passing through the pylorus. Operative treatment carried out early enabled the breast milk to be saved, which was in itself an exceedingly important factor.

Dr. Howard Lilienthal said Dr. Downes was to be congratulated in having the medical men who were willing to turn over the cases to him so promptly. His excellent record was partly to be ascribed to the early surgical treatment. An interesting observation was the prevalence of this disease among males and it was suggestive also that the disease in adults was more common among men than among women. Perhaps a further study of gastic chemistry would help to solve this problem. He had noted that the location of the tumor in these infantile cases was exactly at the pylorus, the pyloric veins appearing at or near the central part of the mass. He had operated on but five of these cases. Two died, one from hemorrhage following an operation upon the mastoid, which had to be performed three days after the gastroenterostomy; the other from some error in technique which resulted in the beaking down of the wound. A short time ago, through the kindness of Dr. Koplik, he had tested the Ranstedtt operation. The operation consumed but eight minutes and was very simple, and he felt convinced that this would be the operation of the future. When one considered that in all seventeen of Dr. Downes' cases he found the expected pathological condition it meant great accuracy in diagnosis.

Dr. Linnaeus E. La Fetra said that his experience with this condition comprised fourteen cases. They could be divided into two groups: First, those that had spasm alone, or spasm with more or less hypertrophy, but in which the spasm was the prominent feature; and, second, those that had spasm and hypertrophy in which the hypertrophy either was or became the most important factor. It was altogether probable that the cases changed from one group to the other. In all the severe cases more or less hypertrophy was present. It was also probable that the presence of an original hypertrophy which might be small in amount resulted in spasm which increased the hypertrophy. Eight of his patients belonged to the first group and all recovered without operation except one. In two of them operation was advised by other consultants because of marked peristaltic waves and the hard spool representing the pylorus. Three years had elapsed with one and two with the other of these children and both were in perfect health. Of the cases in which hypertrophy was the prominent feature he had had six: five of these had been operated upon and four died. The case that lived was included among those reported by Dr. Downes this evening. The other case not operated upon died while the surgeon was deciding whether or not to operate. It must be added, however, that three of these cases were operated upon when the technique of the operation was new and not so well understood as at present. Dr. La Fetra considered that operation was absolutely indicated as the only hope of recovery in all cases in which hypertrophy was the prominent feature. In regard to the diagnosis it might be said that peristaltic waves were generally pathognomonic. There were, however, exceptions to this rule. The presence of the spool at the pyloric end of the stomach, was, of course, diagnostic of pyloric stenosis. It did not necessarily mean hypertrophy, and particularly it did not mean that operation was necessary. All but two of his spasm cases had the spool very marked and yet they recovered by medical measures. In his opinion the most important indications for operation were progressive loss of weight together with the absence of any food residue in the stools. It should be remembered that after a gradual loss of an ounce or two a day for several days the infant might go into a bad collapse so that slight indication of a change for the worse in the general condition must be seriously regarded.

Dr. Elsworth Eliot thought that all were agreed that, irrespective of pathological conditions, the cases could be divided into three groups: 1. Those that were mild in their course and amenable to medical treatment and who were under the care of the pediatrician. 2. The hopeless cases that came to the surgeon in the late stage of the disease. 3. The doubtful cases in which one was undecided as to the propriety of continuing the medical treatment or resorting to surgical measures. Dr. Eliot felt that he would be willing to be guided by the advice of the pediatricians. In some cases the tumor might be present, but palpation might be difficult because of its being overlapped by the liver. With regard to the operation, it went without saying that this should be done as quickly as possible, though as was well known children bore shock remarkably well. When the diagnosis had been made before operation he did not think it necessary to waste time with palpation to determine whether a tumor was present or not. With regard to the postoperative treatment, hypodermoclysis was practically the most essential thing to do after these operations. As to the final results, one, two, or three years was not sufficient time to determine the character of these, but one had a right to assume that when the child reached adult life the results were satisfactory.

Dr. Alfred Fabian Hess said that his experience with the cases of pyloric stenosis in infancy was mainly medical. He had seen in two or three years about twenty cases of spasm of the pylorus. He judged that they were spasm and not organic stenosis because, in spite of obstructive symptoms, there was no palpable tumor, and he was able to pass the catheter through the pylorus into the duodenum. He believed that they had to deal with two groups of cases: 1. Organic stenosis with tumor. 2. Functional stenosis. Organic stenosis he believed to be of congenital origin. In the fetus the pylorus was large and formed a great part of the stomach, greater than it did in infancy, and the pictures of the pylorus of the fetus reminded one of pyloric tumors. The only way to settle this question was to find these cases in the dead born children who had pyloric tumors. Another way was to pass the duodenal catheter and then with the aid of the $x$-ray to see if we were able to pass through the pylorus. In connection with the cases reported by Dr. Holt and Dr. Scudder it must be borne in mind that there were some cases that died within one or two weeks of operation, although the operation was successful. This was due to overfeeding—to alimentary intoxication. If a gastroenterostomy was performed and then a large amount of milk was fed, alimentary intoxication resulted in fever and death. He had seen a case in which the passing of the catheter showed a marked obstruction at the pylorus and there were also clinical symptoms. Suddenly the obstruction ceased, food appeared in the stools, and passing the catheter into the duodenum showed that it entered with ease. Within a few days, however, alimentary fever developed and the child died. In other words, the pylorus had gradually become a protective factor to the child, and when it relaxed the child died of overfeeding. In addition to other medical treatment Dr. Hess believed that the continued feeding through the catheter could be advantageously employed in cases of spasm.

Dr. Max Einhorn said he had had four cases of congenital stenosis of the pylorus occuring in infants and success in the treatment was attained by stretching the pylorus in two of them. He thought this was a

method that deserved to be used more. The stretching was performed in all four of his cases. In one of Dr. Kerley's patients and in one of his own there was a real stenosis and not a spasm, and successful results followed this stretching of the pylorus. He had tried to measure the lumen of the pylorus by means of a little olive tied to a thread and left in over night. After being left in over night it was pulled out. In two of the cases in which there was a stenosis the results were remarkable and just as good as could have been obtained by surgical methods. After the stretching there occurred quite a change; the stomach began to be emptied and the children began to pick up. One child was now five years old, the other three years old; both were living and perfectly healthy. These were typical cases of pyloric obstruction. In the other two cases he succeeded in stretching the pylorus, but the patients died. There was no stenosis according to his experience, but rather a spasm. Stretching was done in these two cases, but without the desired success.

Dr. WILLIAM A. DOWNES said that no surgeon whether urged by a pediatrist or other medical advisor would attempt to operate in pyloric stenosis in infants on the basis of tumor and peristaltic wave alone. Aspiration as advocated by Hess should always be done in these cases. Data from every point of view should be had before resorting to operative interference. In the severe types with complete obstruction, the condition was comparable to obstruction in any part of the intestinal tract and should be treated as such.

---

SECTION ON PEDIATRICS.

*Stated Meeting, Held March* 12, 1914.

DR. WILLIAM P. NORTHRUP IN THE CHAIR.

**Fractured Femur Treated by Transfixation Method.**—Dr. JOHN J. MOORHEAD presented four patients illustrating his method of treating these fractures. One of the patients had sustained a fracture of both femur and pelvis; the others had had fractures of the femur only. One patient had been treated by Buck's extension before the transfixation method was used. In this instance a great deal of callus had formed which was broken up under anesthesia and an open operation had also been performed. This boy showed a little more shortening than the others. The shortening in the other three cases varied from one-eighth to one-quarter of an inch. In all four patients the knee function was good.

**Transfixation Method of Treatment of Fractured Femur in Children.**—Dr. JOHN J. MOORHEAD read this paper. He pointed out the limitations of the operative method and of the various extension methods of treating fractures of the femur. He allowed that the various suspension methods might be used with advantage in children under three years of age, but after that they were not likely to be entirely satisfactory. Dr. Moorhead's paper was based on a series of eight cases in children ranging in age from five to fifteen years. In nearly all of these children there was no shortening of the extremity, and in many there was lengthening. The first operation of this kind was done with a carpenter's bit and augur. He then devised a steel drill with a detachable cutting point. It was made of three-sixteenths-inch nickel steel. The method of procedure was as follows: The child was anesthetized and a location in the distal portion of the fractured bone was chosen for the transfixation. The field of operation was painted with iodine and the drill was introduced into the soft tissues, the bone, the soft tissues again until the skin on the opposite side was reached. The drill must not enter the medullary canal, the epiphyseal line, or the joint. The cutting point was then detached and a simple apparatus was attached to either end of the drill, to which, in turn, the cords and weights were fastened. This procedure was applicable to fractures of the tibia, the humerus, and the femur, but seemed particularly adapted to the latter. In fractures of the legs as much as 32 pounds could be applied. This method was especially adapted to cases in which other methods had failed, to overlapping fractures, comminuted fractures, old fractures, fractures of the condyle, etc. It was preferable to plating because it was a much simpler and a less extensive operation, did not necessitate a secondary operation, as plating frequently did, required that the patient be under anesthesia only fifteen minutes, was not painful during convalescence, did not interfere to any great extent with the comfort of the patient, made nursing a much simpler matter, and gave better results in respect to function and deformity.

**Guaiacol Poisoning by Absorption, with Report of a Case.**—Dr. L. A. SEXTON read this report, which, as a member of the profession, he said, he felt should be brought to their attention. After referring to the value of guaiacol in the treatment of painful and swollen joints and to the methods of its preparation, Dr. Sexton said that the poisoning which he wished to report occurred in the local application of this drug in the treatment of scarlatinal arthritis at the Willard Parker Hospital. The child was admitted to the hospital with a moderate case of scarlet fever. The disease ran its usual course until the eleventh day, when the child developed a cervical adenitis. One month after his admission to the hospital the patient developed a severe otalgia, for which myringotomy was performed, and this was followed by a profuse and purulent discharge from the right ear. Following this the urine showed faint traces of albumin and a few granular and epithelial casts. He then complained of pain in the right knee, right elbow, and right wrist. His other troubles gradually subsided but the arthritis persisted and was very painful, the joints being swollen and tender. After this condition had persisted for over a week, the painful joints were painted with a 50 per cent. solution of guaiacol in glycerin. The mixture had been used previously with no bad results, and had seemed in many cases to allay pain. The evening following the use of this mixture the patient's pulse became rapid and weak, the child became cyanosed, and vomited all nourishment taken during the night. Large quantities of dark brown urine were voided, and it was thought that the child had suddenly developed a severe nephritis engrafted on the former attack, so he was treated accordingly. The joints were again painted on the following morning with guaiacol mixture. A short time after, on this same morning, Dr. Sexton said he made the diagnosis of guaiacol poisoning from absorption. The patient was vomiting and very restless, the cyanosis had given place to deadly pallor, the pulse became imperceptible, the respirations rapid and shallow, the child's face more anxious, and at 8 o'clock in the evening of the same day the child died, just thirty-four hours after the first application. The mixture used on the child and also several specimens of the guaiacol were examined in the chemical laboratory and found to be chemically pure. The urine smelled strongly of guaiacol and responded to the chemical tests for this drug. The color was black; reaction acid; specific gravity, 1.018; albumin, sugar, and indican were negative; blood and hemoglobin negative chemically and with examinations with the spectroscope and microscope.

Dr. JOHN WINTERS BRANNAN said that during the reading of the paper the resemblance of this form of poisoning to the condition known as carboluria had suggested itself to him. In carboluria the urine was green. They used to meet with this condition when it was the practice to flush out abscesses with strong carbolic solution.

**The Peril of Delay in the Diagnosis and Treatment of Intussusception in Infancy.**—Dr. EDWARD WADSWORTH PETERSON presented this paper. He recalled the great educational effort required to place the treatment of appendicitis upon a purely surgical basis. To-day there was general condemnation if a patient with appendicitis was allowed to die without surgical interference. Acute intussusception was far more dangerous to life than appendicitis, and, theoretically at least, belonged exclusively to the surgical field. Experience had taught the hopelessness of expectant treatment and the relative futility of all aerohydrostatic measures. In intussusception the clinical picture was more constant and unvarying and the symptoms more uniform and characteristic than in any other type of intestinal obstruction. In spite of this no other class of cases was more often unrecognized and more habitually mismanaged. Because of failure to make a diagnosis or delay in treatment, the mortality was also disgracefully high. Ladd had collected 216 cases treated by hydrostatic methods with failure in 81 per cent. Leichenstern in a study of 557 cases of intussusception placed the mortality at 73 per cent., and during the first year of life at 88 per cent. Many other authorities gave equally unfavorable statistics with these methods of treatment. The statistics of the greatest interest were those giving the time of treatment, either surgical or otherwise, after the onset of symptoms, and almost invariably one was impressed with the fact that "cured" cases were diagnosed and

treated early. Cases treated during the first twenty-four hours gave a mortality, in experienced hands, of not over 10 per cent. Cases treated after two days had passed had but little chance of recovery, with but few exceptions. Clubbe reported a series of 173 cases. Of these 16 were treated successfully by enema; of the 157 cases operated upon the results were as follows: In the first 50 cases there were 25 deaths and 25 recoveries; in the second 50 cases there were four deaths and 46 recoveries; in the last 25 cases treated by laparotomy there was not a single death, and in these the average time from the onset of symptoms until operation was seventeen hours. No other serious surgical affection of the abdomen could be so early recognized. The first examination of the infant usually revealed the condition. The child was generally seized suddenly with severe abdominal pain, more or less pallor, shock, and relaxation. Vomiting usually occurred at this time. Later there was straining and blood and mucus appeared in the stools. This picture, together with the presence of an abdominal tumor, determined the diagnosis. After the first storm of pain was over the infant usually appeared perfectly well. Later the pain recurred and was of intermittent and paroxysmal nature, but it was not attended by the shock and pallor of the initial seizure. If the patient was seen during the calm period the diagnosis was apt to be mistaken unless a very careful history was obtained. Vomiting was rarely a prominent symptom until late in the disease; where it occurred early and was persistent it was significant of strangulation of the blood supply to the bowel. Rarely was it fecal. In every case of intussusception an abdominal tumor was present, but it was often difficult to palpate. The typical sausage-shaped tumor described by the textbooks was seldom felt early; when present it meant that the intussusception had progressed to a considerable extent. More often a rounded mass was felt and it might occupy any portion of the abdomen. It was generally quite movable and might resemble an enlarged gland. If the tumor could not be felt abdominally then bimanual rectal examination should be made. Under anesthesia one seldom failed to discover its presence. Later, in addition to obstruction and strangulation, toxemia developed, and the late picture was that which occurred in every variety of intestinal obstruction. Ileocolitis and the purpuric diseases had occasionally been mistaken for intussusception; in the former bile, feces, and flatus were passed and no abdominal tumor was present; in the latter hemorrhages occurred elsewhere than from the intestines as a rule, and this gave a clue to the diagnosis. The simplest, most successful, and only certain method of treatment in intussusception was early laparotomy with manual reduction of the invagination. While spontaneous reduction had occurred and recovery had taken place after sloughing of the intussusception, such results must never be expected or awaited. Like strangulated hernia or fulminating appendicitis, it was a condition demanding immediate operative interference. The operation should be performed as quickly as was consistent with safe and thorough work. As three-fourths of the cases occurred in the ileocecal region, the incision should be made through the right rectus muscle. Some operators preferred the median incision where the tumor was felt low down on the left side. In relieving the intussusception it was best to begin at the apex and to carefully "back up" to the point where the invagination started. If traction was made on the proximal end of the gut it was apt to be torn at the neck of the intussusception. If gangrene had occurred, or if reduction was impossible, resection and intestinal anastomosis should be performed. In all early operations it was a good plan where invagination had occurred in the ileocecal region to remove the appendix, as it might in certain instances be a causative factor in the production of the obstruction. In closing the wound the layer sutures should be reinforced with through-and-through tension sutures.

Dr. Leon T. LeWald said that through the kindness of Dr. Gould he had seen a case of intussusception in a child sixteen months of age. He had been called in twenty-four hours after the child was taken sick to confirm a diagnosis of intussusception, and was asked whether he thought it dangerous to administer bismuth for the purpose of obtaining an *x*-ray. There seemed to be a wrong impression as to the danger of giving bismuth in such cases. There was no danger provided the bismuth was administered carefully and in moderate amount. The child was brought to the hospital and 75 grams of bismuth in 250 c.c. of suspension medium was given and inside of thirteen minutes the *x*-ray had been taken and the diagnosis made, the exact seat of the intussusception having been located as was proved at the operation. Dr. LeWald said that this was the second case of the kind that he had seen diagnosed by the *x*-ray and bismuth, the first having been presented at the meeting of the Medical Society of the State of New York. In Dr. Gould's case the tumor could not be felt even under anesthesia.

Dr. Henry H. M. Lyle said that Dr. Peterson had succeeded in impressing upon them the importance of early diagnosis in cases of intussusception in children. Early diagnosis was the keynote of success. Dr. Lyle said that while he had not made a study of the literature he knew of four instances in which resection had been performed in children, one of them being in 1901. None of the patients were over three years of age, and one was an infant only a few days old. In regard to the danger of administering bismuth, one should be guarded as to making statements in regard to the harmlessness of this procedure. The result of administering bismuth in the face of intestinal obstruction was apt to be serious and fatalities had been recorded. One should consider very carefully, when confronted with the toxemia attendant on intestinal obstruction, of adding another element to an already serious condition. Dr. Lyle said he had been called on to operate on a case of acute intestinal obstruction which arose as the result of a bismuth *x*-ray examination.

Dr. Everett W. Gould said that in reference to the case which Dr. LeWald described, the clinical symptoms were sufficient to make a fairly definite diagnosis, but that the *x*-ray examination which was made while Dr. Walton Martin was preparing for the operation clinched the diagnosis and definitely located the lesion. The ileum had invaginated the cecum, not more than 3 or 4 inches, further invagination having been prevented by an old adhesion. The child made a good recovery and no resection was necessary.

Dr. William P. Northrup asked Dr. Gould whether he could feel the tumor.

Dr. Gould replied that when he examined the child the previous evening he thought he felt a very slight resistance in the right iliac fossa, but the following morning he was unable to make out any tumor, and after the anesthetic had been administered, Dr. Martin had been unable to make out any definite mass.

Dr. J. Finley Bell of Englewood, N. J., said the general practitioner found himself in something of a quandary when confronted with the apparent danger of a major operation in a young child as compared with the lesser risk of treatment by the introduction of air or water. Many physicians were laboring under a false impression as to the ability of young children to stand operative measures. This impression was strengthened by the fact that in cases in which operation seemed advisable so much time was consumed by consultations and manipulations that by the time the child actually came to operation, he was in no condition to withstand the ordeal. With early diagnosis and early operation it would probably be found that children bore operations much better than had been supposed.

Dr. John C. A. Gerster said that he could not agree with Dr. Peterson in regard to the use of the right rectus incision. There was no question but that the median incision offered the most advantages. As had been said the intussusception might be in any part of the abdomen and the median incision gave readiest access to all parts of the abdomen with least trauma. Time was an important element and hence removal of the appendix unless it was gangrenous had better be left for a second operation in which speed was not such a vital necessity.

Dr. Northrup said he had the misfortune many years ago to report two favorable cases of intussusception as having been cured by the introduction of water. He had since considered this a great mistake and had been trying to make amends. The first patient was taken sick at about 2 o'clock in the afternoon and by 6 o'clock in the evening a diagnosis of intussusception was made and water was introduced. Dr. Northrup said that he had assisted on this occasion and under the pressure of the water one could feel the invagination give away. The child made a good recovery. The second case came under his observation about a week later and was almost identical. Here, too, under the same treatment, the child re-

covered. These two cases illustrated everything brought out by Dr. Peterson, the acute stage of crying, severe pain, and pallor, followed by a period of quiescence and relaxation, and then the recurrence of severe symptoms. One could pick up the sausage-shaped tumor and feel it disappear under the pressure of the water. Dr. Bell had struck the right note in what he said regarding procrastination, that by the time the decision was made the child could not stand the operation. Speaking of the shock of operation, Dr. Northrup said it had been shown that in a child a few weeks old a gastroenterostomy could be done successfully.

**The Prevention of Gross Deformities in Pott's Disease.**—Dr. PERCY WILLARD ROBERTS gave a lantern slide demonstration of his method of treating Pott's disease and of the results that he had secured. He first showed the results in patients inefficiently treated by plaster jackets and the vertical suspension methods and also the result in an untreated deformity that might have been prevented by proper treatment. The method presented had its greatest field of usefulness in the prevention of deformities below the eighth dorsal vertebra. The treatment of Pott's disease theoretically was to put the bones at rest and to protect them against friction and rotation. The routine method of carrying out this theory had been by means of braces and plaster jackets. The Sayre jacket and the Taylor brace had been devised fifty years ago and while they had been modified at different times they had not been improved upon until recently. These appliances could be relied upon for the correction of deformities in the high dorsal and cervical regions if used in connection with the chin brace. The Sayre jacket immobilized perfectly, and appeared to accomplish the desired end, immobilization of the spine and relief from weight. The vertebræ were separated somewhat and the patient received some relief, but when the patient got on his feet again the body sagged or telescoped and permitted pressure at the point of deformity, necessitating a new jacket and thus it went from jacket to jacket. This was not always the case but when it did happen the result was a deformity such as had been shown. When there was any considerable deformity the upright suspension did not overcome it; this could be demonstrated by an ordinary carpenter's rule and weights. In order to accomplish the hyperextension that was desirable in the correction of Pott's disease, Dr. Roberts said he had devised a simple apparatus consisting of an ordinary automobile jack to which was attached a horizontal bar. From this bar was suspended a sling, which was passed around the patient's body at the point of deformity and the hyperextension applied. While the patient was in this position the jacket was put on. This "jacket and sling" method was particularly effective in correcting slight deformities and preventing gross ones. Its application was so simple that one person could apply it where if done by the vertical suspension method it would require a number of assistants. When the plaster was applied in the hyperextension position there was not the same tendency to telescope that had been observed in other methods. Dr. Roberts illustrated the method of adjusting the sling and applying the jacket and showed slides which demonstrated the gap between the vertebræ when the patient was in the hyperextension position. There was extreme lordosis in some instances after the jacket was removed, but Dr. Roberts said that this would not be maintained. In the cases treated early there was very little deformity. The point might be made here that had been made in other fields, that if the cases came to treatment early they did better. With the institution of this method of treatment, Dr. Roberts said, the symptoms disappeared earlier, fewer abscesses developed, and the patient's comfort was enhanced during the application of the jacket and during the time of treatment.

Dr. HENRY H. M. LYLE said that Dr. Moorhead's cases spoke for themselves. The treatment of fractures of the femur in which there was overriding gave considerable trouble and the ordinary extension methods often failed to overcome the deformity. In the Steinmann extension method they had a valuable means which could be regarded as being conservative when compared with open operation, plating, etc. The method was neglected in old neglected fractures, in certain cases of malunion, and was the method of choice in all severe compound fractures. The method was simple, quickly performed, and the patient was strikingly comfortable. Four cardinal points were to be observed in inserting the pin. The fracture hematoma must be avoided, and the pin must not be allowed to enter the medullary canal, the joint, or the epiphyseal line.

Dr. JOHN C. A. GERSTER stated that his experience comprised a series of 30 cases, of which 11 were in children ranging in age from four to 15 years. He said he could not agree with Dr. Moorhead about certain minor points of technique. The rod carrying a detachable drill on its point was an unnecessary refinement. The sharp pointed nail bored through the bone without any difficulty. A preliminary incision was also unnecessary and had been given up in Germany. Steinmann had given up hammering the nail; he used it as a drill fixed in a brace. The pin was simply a bit of steel rod, pointed at one end. Dr. Moorhead spoke of the anesthesia lasting fifteen minutes. Dr. Gerster used nitrous oxide anesthesia only during the three or five minutes required to actually transfix the limb. Pain and discomfort were less than with an efficient Buck's extension. Nursing was also easier as the child could raise the hips clear of the bed without fear of getting a bad result. In neglected fractures of some weeks' standing, nail extension was extremely valuable. In malunion with much shortening brilliant results had followed exposure and separation of the malunited fragments with simple closure of the wound and application of nail extension. Naturally more weight was required than in recent cases. The chances of union were much better with nail extension than with Lane plating, because in the former none of the osteogenetic tissue was removed, and massage and passive motion might be begun as early as the fifth day.

Dr. HENRY LING TAYLOR expressed himself as much interested in the cases shown and thought the results were admirable. The positive manner in which Dr. Moorhead had condemned plating as a routine measure was particularly interesting. Personally he believed that the introduction of plating had done much harm, because the man practising in a small town was led to use this method and might keep it up long after the man with greater experience had seen the bad results and given it up. Plating was really valuable in only a few cases, while there were many cases that had gone wrong through this procedure. There were one or two methods of treating fracture of the femur not mentioned by the reader of the paper. One was Van Arsdale's triangular splint to hold the thigh in the flexed position; this was applicable to fractures in the upper half of the femur, and the same result could be obtained by flexing the leg, reducing the deformity, and putting it in a plaster spica in that position. This was done quite frequently in babies at the Hospital for the Ruptured and Crippled and gave good results. The other method was by the use of Hawley's table, which was marvelously efficient in fracture cases, and by it the deformity could be reduced in early cases and a plaster splint could be applied without moving the patient. Dr. Taylor said he was interested in Dr. Roberts' work as well as in the operative method of treating Pott's disease. The principles for the treatment of Pott's disease as laid down by Taylor and Sayre were correct. Better results were obtained in private practice than in clinical work though many cases did well in the clinics. He recalled the case of a girl who had been treated by C. F. Taylor from 1871 to 1879 and cured with recession of the deformity, who returned in 1909, thirty years after her cure and having been married and had children, she had no deformity and was perfectly well. This showed what was possible in favorable cases, but all cases were not so favorable even in private practice. The brace treatment required a long time, though it was not necessarily irksome to the child or the parent as the pain and discomfort of the patient were usually promptly relieved and the general condition of the patient improved, but it was necessary to wear a brace for many years; in even these instances the result was often mediocre. Dr. Taylor referred to the furor over Callot's method of treating Pott's disease some years ago and thought that the method presented was a rational Callot. It applied a gentle force and one that could at the same time be effectually controlled and undoubtedly it was a step in advance. One should bear in mind, however, that cases might be over corrected and therefore too much force should not be applied. He heartily endorsed this method if it was used with discretion.

# State Medical Licensing Boards.

## STATE BOARD EXAMINATION QUESTIONS.

PENNSYLVANIA STATE BOARD OF MEDICAL EXAMINERS.

*December* 2, 3, and 4, 1913.

PHYSIOLOGY, PATHOLOGY, AND BACTERIOLOGY.

1. In acute lobar pneumonia, describe the local lesion and the disturbed functions.

2. Name two heart lesions that might result in broken compensation and show how the normal functions of the heart would be disturbed.

3. Describe two lesions—one of the gall bladder and one of the liver—that will cause lessening of the supply of bile to the duodenum. Describe the effect of this loss on digestion assimilation.

4. Describe the lesions, name the usual causes, and give the laboratory technique for demonstrating the varieties of urethritis.

5. In carcinoma of the female breast, describe the gross and the microscopical appearance of a common variety and give the usual points of metastasis.

6. In examining a specimen of urine from a pregnant woman, state the findings that would suggest oncoming uremic convulsions.

7. Given a case of malaria, describe the lesions and detail the laboratory tests for making the diagnosis positive.

8. Describe the lesion in tabes dorsalis (locomotor ataxia), and show how the functions of the cord are disturbed.

9. Given a case of meningitis, give your technique for demonstrating the determining causes by means of lumbar puncture. Discuss the disturbance of function that would result from such a case.

10. Given a suspected case of typhoid fever: by laboratory tests differentiate the case from septic infection.

DIAGNOSIS, SYMPTOMATOLOGY, MEDICAL JURISPRUDENCE, AND TOXICOLOGY.

1. Describe the symptoms and course of chorea.

2. Enumerate the symptoms of varicella. Name a disease with which it may be confused and differentiate them.

3. Enumerate the symptoms and physical signs diagnostic of pleurisy with effusion.

4. Enumerate the diagnostic symptoms of chronic eczema, and differentiate it from scabies.

5. What is pyemia? How is it characterized clinically? Enumerate the general symptoms.

6. Enumerate the symptoms of tubercular joint disease, and differentiate it from acute articular rheumatism.

7. Give the etiology of, and enumerate the symptoms of acute nephritis. Name four toxic drugs that may produce it.

8. Describe in detail the symptoms of strychnine poison, and differentiate it from uremic convulsions.

9. How would you differentiate a case of severe ptomaine poisoning from the conditions produced by arsenical poisoning?

10. As a witness in court, what would be your evidence in substantiating the fact of a death by drowning?

---

## ANSWERS.

PHYSIOLOGY, PATHOLOGY, AND BACTERIOLOGY.

1. *Lobar pneumonia.* "(1) *Stage of engorgement.*—This is the stage of inflammatory hypermia and edema, and it is characterized microscopically by overfullness and slight tortuosity of the pulmonary capillaries, and by swelling of the alveolar epithelium. The lung is of a dark red color; it is heavier and less crepitant than natural; it pits on pressure; and its cut surface yields a reddish, frothy, tenacious liquid.

(2) *Red hepatization.* "Here there is an exudation of liquor sanguinis and blood corpuscles. The exuded liquids coagulate within the alveoli and terminal bronchioles, the coagulum enclosing numerous white and a few red blood corpuscles. The alveolar epithelium is swollen and granular. The lung is now much heavier than in the preceding stage, and is increased in size, so as to be often marked by the ribs. It is quite solid; sinks in water, and cannot be artificially inflated. It is remarkably friable, breaking down with a soft granular fracture. The cut surface has a markedly granular appearance, seen especially when the tissue is torn, and due to the plugs of coagulated exudation-matter which fill the alveoli. The color is of a dark reddish-brown, often here and there passing into gray. This admixture with gray sometimes gives a marbled appearance. The pleura covering the solid lung always participates more or less in the inflammatory process. It is opaque, hyperemic, and coated with lymph.

(3) *Gray hepatization.*—"This stage is characterized by a continuance of the process of inflammatory cell-emigration, and by more marked changes in the epithelium. The white blood corpuscles continue to escape from the vessels, and the alveolar epithelium becomes more swollen and granular. The alveoli thus becomes more completely filled with young cell-forms, so that the fibrinous exudation is no longer visible as an independent material. The fibrinous exudation now disintegrates, and the young cells rapidly undergo fatty metamorphosis. The alveolar walls themselves, with few exceptions, remain throughout the process unaltered, although very occasionally, when this is unusually advanced, they may be found here and there partially destroyed. Owing to these changes, the reddish-brown color of the lung becomes altered to a grayish or yellowish white. The granular appearance is much less marked; the solid tissue is much softer and more pulpy in consistence, and a puriform liquid exudes from the cut surface of the organ. This stage, when advanced, has been termed "suppuration or purulent infiltration" of the lung.—(Quain's *Dictionary of Medicine.*)

*Disturbances of function:* Chill, pain, fever, dyspnea, cough, delirium, rapid pulse.

2. Aortic stenosis and mitral regurgitation may result in broken compensation. "Aortic stenosis leads to an obstruction to the outflow of blood. The first effect will be an extra strain upon the valve and chamber behind (left ventricle). Under the extra strain the chamber at first dilates slightly, as the ventricle has no previous preparation for the sudden establishment of a lesion in front of it. But the reserve energy of the myocardium is soon called into play, the ventricle contracts more forcibly to overcome the obstruction, and its walls begin to hypertrophy. As the obstacle is always present, the hypertrophy increases daily until in course of time it may come to be very great. The obstruction to the onflow of blood is thus overcome by more forcible and more prolonged contractions, the arterial system remains well supplied, and for a time no bad symptom may develop. This is known as the "Stage of Compensation" of the valvular lesion. Finally, however, the reserve energy of the ventricle becomes exhausted, owing to prolonged overwork, aided perhaps by external causes, such as faulty regulation of habits, diet, or exercise, or mental worry and anxiety. Then the exhausted muscle yields to the strain, and dilatation becomes more prominent than hypertrophy. The walls of the ventricle are carried apart, and in consequence the curtains of the mitral valve, though healthy, are no longer able to close the orifice ("relative insufficiency"). Regurgitation of blood into the auricle (mitral regurgitation) follows, and upon that engorgement of the pulmonary circulation. The right ventricle is now called upon to force the blood through the engorged lungs to the left side of the heart, and it must obviously pass through changes similar to those that affected the left ventricle. But, as it is a less muscular structure, these changes are completed sooner. Relative tricuspid insufficiency is established, and with it the last stage, known as "failure of compensation."—(Wheeler and Jack's *Handbook of Medicine.*)

3. Cholelithiasis, and hypertrophic cirrhosis of the liver will cause lessening of the supply of bile to the duodenum. In *cholelthiasis,* while the calculus remains free in the gall-bladder, usually there are no symptoms. Impaction of the stone in the common duct gives rise to intermittent jaundice, following sharp pain in the right hypochondriac or epigastric region, frequently radiating toward the right scapula, nausea, vomiting, sweating, depression, and often intermittent fever (Charcot's intermittent fever). When the stone is impacted in the cystic duct, jaundice is less common, but the hepatic colic is severe, and dropsy of the gall-bladder may occur. The diagnostic points are the age, sex, history of previous attack, with jaundice and intermittent fever, location of the pain, dark, amber-colored urine, containing bile, and sometimes the finding of the stone in the feces.

*Hypertrophic cirrhosis of the liver* is a chronic disease characterized by a hyperplasia of the connective tissue and a destruction of the secreting cells of the

liver. It is characterized by jaundice, increased size of the liver and spleen, sudden onset, coated dry tongue, hepatic tenderness, moderate fever with rapid pulse, and anemia. The jaundice may be very great, the whole cutaneous surface and the conjunctivæ being greenish-yellow, and may persist for several weeks.—(*Pocket Cyclopedia.*)

"As a digestive secretion, the most important function attributed to the bile is the part it takes in the digestion and absorption of fats. It accelerates greatly the action of the lipase of pancreatic juice in splitting the fats to fatty acids and glycerin, and it aids materially in the absorption of the products of this hydrolysis. A number of observers have shown that when a permanent biliary fistula is made, and the bile is thus prevented from reaching the intestinal canal, a large proportion of the fat of the food escapes absorption and is found in the feces. This action of the bile may be referred directly to the fact that the bile acids serve as a solvent for the fats and fatty acids. It was formerly believed that bile is also of great importance in restraining the processes of putrefaction in the intestine. It seems to be generally true that in cases of biliary fistula the feces have a very fetid odor when meat and fat are taken in the food. But the increased putrefaction in these cases may possibly be an indirect result of the withdrawal of bile. It has been suggested, for instance, that the deficient absorption of fat that follows upon the removal of the bile results in the protein and carbohydrate material becoming coated with an insoluble layer of fat, so that the penetration of the digestive enzymes is retarded and greater opportunity is given for the action of bacteria. We may conclude, therefore, that, while there does not seem to be sufficient warrant at present for believing that the bile exerts a direct antiseptic action upon the intestinal contents, nevertheless its presence limits in some way the extent of putrefaction."—(Howell's *Textbook of Physiology.*)

4. *Urethritis* is specific when the gonococcus is found in the discharge, and non-specific when the infection is due to pyogenic cocci, or in which no bacteria are found. Additional causes are gout, traumatism, eczema, rough instrumentation, foreign bodies, strong injections, alcohol and certain drugs and sexual excesses. *Lesions:* "Early in the disease the surface of the urethra is reddened, with a catarrhal secretion, which rapidly becomes purulent. Desquamation of the superficial cells follows, and sometimes ulceration, which may bleed, and the infection may spread backward to the prostate, and the bladder; in the female the vagina may be affected throughout, and the uterus and tubes attacked; not infrequently the latter become diseased while the former escapes. In the female Bartholin's glands are certain to be infected; in all these out-of-the-way situations the infection may remain for a long time. The inflammation may become chronic, and in the male, after the lapse of time, the secretion becomes scanty and less purulent, perhaps only cloudy or even clear to the naked eye (gleet). In the process of healing the fibrous granulation tissue, if abundant, is apt to subside to fibrous masses or even bands, which impede the passage of urine (stricture of the urethra). Behind such bands and in irregularities of the surface the gonococci may lurk for a long time, the urethritis disappearing in the meantime."—(Adami and McCrae's *Textbook of Pathology.*)

The laboratory technique consists in finding the gonococci in the discharge. On a cover-glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismarck brown; wash in distilled water, dry with filter paper, mount and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes,* which have been *decolorized by Gram's stain,* and have taken the counterstain.

5. "*Scirrhous cancer of the female breast* is of somewhat slow growth, and is usually very hard; the skin is firmly attached to the tumor, and the nipple is usually retracted. On section the tumor is found to be of a firm, fibrous, and somewhat translucent character; extensions of the growth are seen radiating in various directions from the body of the tumor. Microscopically the growth consists of fasciculated connective tissue, enclosing round or elongated collections of cancer-cells. Cancer of the breast may extend directly to the subcutaneous tissues and the skin, on the one hand, or to the walls of the chest and pleura on the other hand. Metastasis frequently takes place through the lymphatics, the axillary glands, as a rule, presenting the first evidences of metastasis. Malignancy varies with the softness or hardness of the tumors, the scirrhous form frequently having a comparatively benign character. Sometimes the increasing growth of connective tissue in this variety leads to practical cessation of the growth of the tumor."—(Stengel's *Pathology.*)

6. Prior to uremic convulsions the urine of a pregnant woman might show: Diminution in quantity, the presence of albumin and casts, the presence of blood corpuscles; the total output of nitrogen is low and the urea is diminished.

7. *Malaria.* "During the paroxysms the principal changes are: (1) Enlargement of the spleen, sometimes very great. In recent cases the organ is soft; in older cases firm ('ague cake'). (2) Enlargement and congestion of the liver. (3) Congestion of the bone-marrow, the brain and meninges, and the kidneys. In all these organs the vessels are full of plasmodia and of melanin. There is also present a yellow pigment, not confined to the vessels, which consists of altered hemoglobin. Marked diminution of the number of red cells and pigmentation of the leucocytes are conspicuous features. The lymphocytes are also relatively increased for some time after the paroxysm, but leucopenia, not leucocytosis, is a feature of malaria. In malarial cachexia the spleen is not necessarily pigmented. The enlargement is mainly due to thickening of the capsule and trabeculæ and the organ is hard. The liver is frequently enlarged. Anemia is a conspicuous feature."—(Wheeler and Jack's *Handbook of Medicine.*)

The laboratory test for making the diagnosis positive consists in finding the plasmodia in the blood, either in fresh blood or in stained films. The blood should be obtained some hours before the chill. If no plasmodia are found, the presence of pigmented granules within the leucocytes (large mononuclears and polynuclears) may be taken as presumptive evidence of malaria.

8. *Locomotor ataxia* is a disease of the spinal cord, characterized by loss of coordination, characteristic and unsteady gait, a tendency to stagger when standing up with the feet together and the eyes closed, sharp and paroxysmal pains called *crises,* girdle sensation, Argyll-Robertson pupils, and loss of knee-jerk and other reflexes. In locomotor ataxia the posterior columns of the spinal cord and the posterior nerve roots are involved. The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion. The spinal ganglia may also be affected and the membranes over the affected parts are adherent and opaque.

9. *Meningitis.* "The patient should lie on the side, with the back bent forward as far as possible, in order to separate the vertebræ and make the lumbar region prominent. The sitting posture may also be assumed with the back bent forward. A local anesthetic is usually all that is necessary. Very often the patient is comatose and requires none. A long, strong, aspirating needle is introduced midway between the second and third or third and fourth lumbar vertebræ, either straight in from the mid-line of the back or about an inch to the side and directed a trifle inward. It should be inserted from 2 to 3 c.m. in a child and from 7 to 8 c.m. in the adult. As soon as the subarachnoid space is entered the fluid makes its appearance, usually drop by drop; but when large in amount and under pressure, in a stream. The fluid should be centrifugated, spreads made from the sediment, stained, and examined for the various bacteria with the oil immersion. The tubercle bacillus, *Diplococcus intracellularis meningitidis, Micrococcus lanceolatus,* staphylococcus, streptococcus, pneumococcus, bacillus of influenza, and typhoid bacillus are the chief causes of meningitis. The spread should be stained by appropriate methods. If the microscopical examination is unsatisfactory, cultural methods or animal inoculation should be resorted to."—(Arneill's *Clinical Diagnosis.*)

The *disturbances of function* are: Nausea, vomiting, vertigo, chills, opisthotonus, muscular cramps, delirium, inability to straighten the leg completely when the thigh is flexed at a right angle with the pelvis when the

patient is recumbent; there is furthermore loss or impairment of the special senses of sight, hearing, smell, and taste.

10. In a *true typhoid*, laboratory tests will give a positive Widal reaction, the presence of the typhoid bacilli in the urine, blood, and feces. In *septicemia*, all of the above are absent.

DIAGNOSIS, SYMPTOMATOLOGY, MEDICAL JURISPRUDENCE, AND TOXICOLOGY.

1. "Chorea is a functional disorder of the nervous system; characterized by irregular spasmodic fibrillary movements of groups of muscles, with weakness, more or less approaching paralysis of the affected parts. Excitement increases these movements, while sleep causes their cessation. It is essentially a disease of childhood, and its production may be greatly influenced by female sex, rheumatic diasthesis, habit, neurotic temperament, heredity, mental excitement, spring season, and reflex disturbances such as produced by adherent prepuce, masturbation, worms, dentition, eyestrain, etc. The affection may be observed at times during pregnancy and after hemiplegia. *Symptoms.*—The onset is usually gradual, the child apparently grimacing or jerking the arm or hand, as if in imitation, followed soon by decided irregular jactitations of the muscles of the face (histrionic spasm), of the eyelids (blepharospasm), eyeballs (nystagmus), and the shoulder, arm, and hand finally extending to the lower extremities, interfering greatly with motility; in severe cases there is inability on the part of the patient to feed himself or to hold anything in the hands. The speech is often unintelligible, the tongue constantly moving in an irregular manner. The heart's action is tumultuous and irregular, associated often with a soft, blowing, systolic murmur, most distinct at the base. The muscles are usually quiet during sleep, although this is not always the case. The mind is somewhat blunted, the temper irritable, and the memory impaired."—(Hughes' *Practice of Medicine.*)

2. *Varicella* is characterized by a moderate fever, thirst, loss of appetite, and the appearance of a vesicular eruption in the first twenty-four hours. This eruption dries up and disappears in from three to five days. The vesicles usually appear in crops, and they are not umbilicated. Varicella may be confused with variola.

(1) Very young children are attacked with varicella, whereas variola usually shows itself in adults. (2) Vaccinated children readily take varicella; not so variola, even in the modified form. (3) Children who have had varicella may contract variola, even soon afterward; or the two diseases may coexist. (4) Varicella is noninoculable, whereas variola is notoriously so. (5) The eruption of varicella appears in 24 hours; that of variola not till the third day. (6) The febrile symptoms continue after the eruption appears in varicella; those of variola subside. (7) In varicella the spots come out in successive crops; this is never seen in variola. (8) The spots in varicella are unilocular, and collapse on being punctured; the spots in variola are multilocular, and do not collapse on being punctured. (9) In varicella the eruption is very irregular, and appears over the body generally; in variola it appears in groups of threes and fives, and is always seen on the limbs. (10) The papule in varicella is soft, and disappears on stretching the skin; in variola it is hard and shotty, and does not disappear on stretching the skin.—(From J. W. Moore's work on *Variola and Varicella.*

3. *Pleurisy with effusion* begins with a chill, sharp pain in chest or axilla, made worse by coughing or breathing, shallow and rapid respiration, moderate fever, dyspnea, cyanosis, embarrassed cardiac action, the patient lies on the affected side. *Inspection* shows bulging on the affected side with obliteration of the intercostal spaces. *Palpation* shows absence of vocal fremitus over the effusion with exaggeration of the same above the fluid. *Percussion* gives a dull or flat note over the fluid, while above the fluid it is tympanitic. The fluid changes its level with different positions of the body. *Auscultation* reveals a diminution or absence of vocal resonance over the fluid, with an increase above the effusion, egophony being attained at the upper margin.

4. The distinctive features of *eczema* are: Serous exudation, gradual merging of the patches into the surrounding skin, the symmetry of the lesion, the variety of forms in which the eruption can appear, and the pronounced itching or burning.

| SCABIES. | VESICULO-PUSTULAR ECZEMA. |
|---|---|
| 1. Characteristic distribution; webs of fingers, flexor surface of arms, axillary folds, nipples, umbilicus, penis, buttocks, and inside of thighs and legs. | 1. No characteristic distribution. |
| 2. Presence of burrows. | 2. Absence of burrows. |
| 3. Presence of itch-mite. | 3. Absence of itch-mite. |
| 4. Itching much worse at night. | 4. Itching variable. |
| 5. Communicable. | 5. Not communicable. |
| 6. Except in children, face is exempt. | 6. Face frequently involved. |
| 7. Treatment rapidly effective. | 7. More refractory to treatment. |
| 8. Other members of family often affected. | 8. Not the case. |

—(Schamberg's *Diseases of the Skin.*)

5. *Pyemia* is a form of septic infection in which the pathogenic organisms form thrombi or emboli in the small blood vessels, with the development of multiple abscesses. The symptoms are much the same as in septicemia: chill, high and persistent fever, drenching sweat, rapid pulse, great depression, scanty urine with albumin, toxins and bacteria, and the presence of multiple abscesses. The disease may run its course in a few days, and is generally fatal.

6. *Symptoms of tuberculous joint disease:* "In the early stages the signs are not at all well marked, especially in those where the primary stage is osseous, and consist of slight aching after use. Soon, however, the cardinal signs appear: (1) Increased heat over the joint; (2) the presence of some fluid in the joint; (3) impaired mobility; (4) *wasting of the muscles which move the joint.* The joint is usually maintained in the position of ease, viz., slightly flexed. In the late stages abscesses form, and the pain becomes severe, even to 'starting pains' at night. If the abscesses burst and are allowed to become septic, a hectic temperature follows, and amyloid degeneration may lead to death from exhaustion. The joint itself may be disorganized, the relaxation of the ligaments allowing dislocation to occur."—(*Aids to Surgery.*)

In *acute articular rheumatism* the pain is more definitely localized and the whole course of the disease is more acute, the fever higher, the pain more severe; acid sweats are more pronounced.

7. ACUTE NEPHRITIS. *Etiology:* Cold, exposure, infectious diseases (such as diphtheria, scarlatina), traumatism, burns, and drugs (such as turpentine, cantharides, phosphorus, ginger). *Symptoms:* gradual or sudden onset with nausea, vomiting, weakness, fever, anemia, and characteristic urine (smoky, albuminous, scanty, with casts and epithelium, also blood, diminished urea, phosphates, and chlorides). Dropsy is marked, and uremia is frequent.

8. The *symptoms of poisoning by strychnine* are "a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."—(Witthaus' *Essentials of Chemistry and Toxicology.*)

In *uremic convulsions* there will be a general history and condition of uremia; the urine will show the characteristics of that condition (see PHYSIOLOGY, PATHOLOGY, AND BACTERIOLOGY, Question 6). Premonitory symptoms such as headache, vertigo, nausea, drowsiness, may be present; vomiting, diarrhea, and Cheyne-Stokes breathing may be observed.

9. The only ground for a positive diagnosis is in the detection of arsenic in the urine, dejecta or vomitus in the case of arsenical poisoning—and its absence in the case of ptomaine poisoning.

10. As a witness, my evidence would depend on what I knew to be the facts in the case. In all such cases, two questions arise: (1) Was the death caused by drowning? and (2) Was the submersion the result of accident, or suicide, or homicide? When a person is drowned he dies of asphyxia; water may be found in the stomach

and lungs; blueness and paleness of the skin are generally present if the water is cold, also cutis anserina; stones, gravel, weeds, or wood from the water may be found in the hands or under the nails. The latter question, as to accident, suicide, or homicide, has to be determined by circumstances, and as a rule is not capable of substantiation by medical witnesses.

*(To be concluded.)*

## Books Received.

*The* Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

## Miscellany.

**Success in the Practice of Medicine.**—Sir John Collie states that in these days wealth not knowledge, ostentatious display not ability, is worshipped by the majority of mankind. It has been said that physicians are judged by the creases in their trousers, not by the creases in their brain. Wealth determines status. To make money is therefore a necessity. The physician should remember that the cards must always be shuffled, and if patients leave him, from a business point of view it does not really matter if his total income for the year is as large or larger than the year before. His object should be not to have the largest but the best practice. If the physician attends patients gratuitously he should take as his reward the pleasure he is entitled to if he is seeing them without any hope of benefit; but he should remember that this is charity not business. Successful men never neglect the treatment of a patient's personality. It is always difficult to listen to the recital of an irrelevant family history and of details which are obviously unimportant. The details may be trivial but it is a fundamental truth that the physician cannot succeed in treatment unless he has the confidence of his patient, and this he certainly will not have if he does not listen to the recital of the patient's woes. The torrent may often be stopped by a well-directed remark which shows that the physician has divined the whole history.

Success may take the form of financial gain, social aggrandizement, or self-satisfaction. Apart from the proper provision for one's old age and for one's dependents, financial success is not desirable in the medical profession, for it cannot be attained (except by the few) without making sacrifices which are inimical to the growth of those qualities which ennoble one's work. Social success is Dead Sea fruit. The success which brings true self-satisfaction is the Mecca to which the practitioner should be guided, for unlike the above ephemeral successes, but like the heaven and hell of the new theology, she is with him now; if he would woo her successfully she is his abiding portion. To be successful the practitioner should know how to depute work to others—work of which they are capable but which if performed by the practitioner himself would interfere with the proper development of his career. The hard-worked general practitioner who does his own dispensing or his own bookkeeping has much to learn, but he is probably one who never will.

An important detail in medical economics is the precaution that in arranging for partnership or assistant agreements the physician should commit the bargain to paper at the earliest possible date, and this should always be done before the new arrangement is entered upon. In matters of agreement most people mean to act fairly by one another, but no one has a memory which is perfect, and verbal contracts are apt to be remembered only in part.

The road to success is well described in the following pointed paragraph from Claye Shaw: "Whatever way success is achieved, there are four mental necessities, namely, a clear view of the end, a judicious indifference to the sentiments aroused by the sweeping away of obstacles, and indomitable energy, a power to resist the temptation to rest on the soporific plains of mediocrity."—*British Medical Journal.*

### URIC ACID OVERPRODUCTION.*

BY WILLIAM HENRY PORTER, M.D.,

NEW YORK.

PROFESSOR EMERITUS OF PATHOLOGY AND GENERAL MEDICINE IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE fundamental principle in connection with the uric acid problem is the fact that this acid is one of the normal products of protein metabolism. It is absolutely essential to a perfect physiological state, as expressed in the animal economy of the human species. Up to this point uric acid is a normal and essential constituent of perfect health. It is, therefore, the overproduction of uric acid that represents the pathological problem and the only one which calls for therapeutic action.

To comprehend fully the true significance of overproduced uric acid, we must first understand the true physiological position of uric acid. The first question which naturally presents itself is: Why is uric acid an essential end product of protein oxidation, and where and how is this acid normally produced? The first part of this question is comparatively easy to answer. It is known to all students of chemico-physiology that the uric acid acts upon the neutral phosphate of soda, with the formation of a urate and an acid phosphate—thus $C_5H_4N_4O_3 + Na_2H(PO_4) = C_5H_3N_4O_3Na + NaH_2(PO_4)$. Coupled with this fact it has been proved that the acid phospate is the normal and essential acid of the urine. It therefore becomes necessary to produce some acid which will transform the neutral phosphate of the blood into the acid form in the urine. Thus we find by the observed laws of nature that uric acid in the human species is the only one produced for this purpose under normal conditions. Hence, uric acid should be classed primarily as a secretory product and an essential constituent of the urine as it is first found in the lumen of the uriniferous tubules, but which under normal conditions becomes a urate, with the formation of the acid phosphate, before the urine escapes from the uriniferous tubules—the urate alone being the true and final excretory end-product in the urine as it is expelled from the bladder. See Fig. 1, which illustrates how, technically speaking, the fluid contained in the lumen of the uriniferous tubules always contains—for an instant, at least—free uric acid, while that found in the ureters and bladder does not. Therefore, the statement that urine does not contain free uric acid normally, is correct.

Accordingly, we are fully justified in asserting that uric acid, pure and simple, is an essential secretory product of the renal cells, but only a true and excretory end-product when united to soda or some other alkali to form a urate. The soda salt being the normal alkali of the body, it is the most common and abundant urate found in the urine. Why it is a fact that when the system is working with its normal perfection and precision only such an amount of uric acid is produced as is required to transform the requisite amount of the phosphate and other alkalies, is hard to fully explain, but such is the observed law of nature.

This brings us to the second and more difficult part of our question, to wit: Where and how, or how and where, is uric acid formed?

Regarding this point, there is no end of theoretic speculation and experimental research work re-

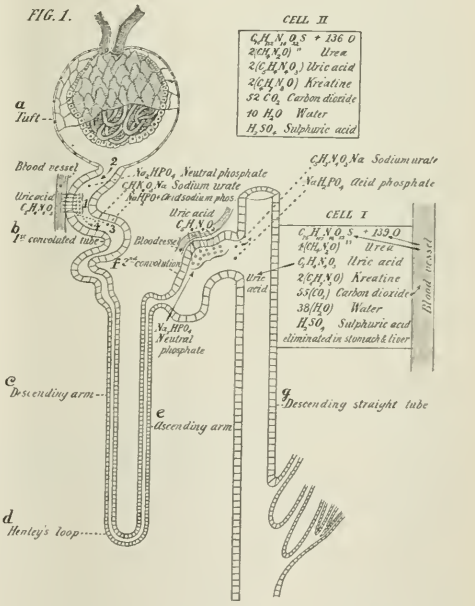

FIG. 1. Schematic drawing showing single uriniferous tubule from Malpighian tuft to papilla or its outlet. (*a*) Malpighian tuft and blood vessels. (*b*) First convolution. (*c*) Descending arm of loop. (*d*) Henley's loop. (*e*) Ascending arm of loop. (*f*) Second convolution. (*g*) Straight or collecting tube. 1. Uric acid molecule dropping into lumen of tube. 2. Neutral phosphate of soda molecule as it unties with the uric acid to form. 3. The acid phosphate of soda; and 4. The urate of soda formed by this chemical mutation. Cell I. Magnified single renal cell, with lumen of the tube on one side and the blood vessel on tbe opposite side, illustrating normal oxidation of proteid molecule within the protoplasm of the cell. The proteid and oxygen coming from the blood into the cell, where it breaks up into its reduction products. The uric acid dropping into the lumen of the tube, while the carbon dioxide flows back into the blood. All the other reduction products dropping into the tube as does the uric acid. The sulphur being eliminated as a sulphate. Cell II. Magnified cell illustrating abnormal or suboxidation in the renal cell. Urea diminished one half while the uric acid is overproduced fifty per cent. In both the normal and abnormal oxidation the sulphur is found in the urine as a sulphate.

*Read at a meeting of the Northwestern Medical and Surgical Society, April 15, 1914.

corded, much of which seems to lose sight of the well-known chemico-physiological laws and disregards absolutely some of the simplest laws of chemistry, one of which is the putting of this strong uric acid molecule and carbonate of soda compound in the same fluid menstruum, the blood. Two such bodies, one strongly acid and the other strongly alkaline, according to all the known laws of chemistry, must, under such conditions, unite to form a salt or urate of soda. But all chemists and all physiologists declare that a urate has never been found in the blood. Therefore we are justified in making the assertion that red meat (or any other kind of meat) does not contain uric acid. Assuming even that it does, the chemical transmutations going on continually in the lumen of the intestinal canal, which contains many alkaline substances, would speedily convert the uric acid into a urate. All this being true, the weight of evidence substantiates the fact that uric acid cannot exist under its own form, normally, in the blood or tissues of the body. This being the case, it seems absurd to argue that uric acid is made in some distant portion of the body—as the spleen, liver, etc.—far away from the renal glands, and that from these remote points the uric acid is in some mysterious and unknown manner—and in defiance of all chemical laws—carried from these distant parts of the body to the renal glands.

That the antecedents of uric acid exist in the blood no one can deny. The form in which they exist in the blood, however, is that of a protein compound, or leucomain product which, when isomerically transformed and released by a process of oxidation in the renal cells, results in the production, under normal conditions, of the requisite amount of uric acid and prevents an overproduction of this acid. Under these conditions the antecedent substance is one which has no perceptible irritating or toxic properties. Thus we find that under normal conditions uric acid is a simple oxidation reduction product of protein metabolism. (See Tables I and II.)

they all carry waste nitrogen out of the animal economy. Hence, it should be borne in mind that if we reason by analogy alone and observe the common laws of nature, we find that all secretory substances are formed by a process of isomeric transmutation or oxidation reduction in the protoplasm of the cells of the gland or glands closely adjacent to the point at which these secretory substances are said to perform their functions. Therefore, uric acid is made by the same laws of nature—by isomeric transmutation and oxidation—in the epithelial cells of the uriniferous tubules, which are closely adjacent to the point at which it is to perform its further function—before it becomes a fully formed excretory product in the form of a urate.

At this point of formation in the renal cells the uric acid molecule is dropped from the cell into the lumen of the tubules, there to unite with the neutral sodium phosphate or other alkalies, chiefly the former, contained in the fluid portion of the urine as it flows down the lumen of the tubules from the Malpighian tufts. (See Fig. 1.) This, then, is the point and the manner at or in which uric acid is produced when the animal economy is working normally.

All this has been accomplished along lines of well-known and definite chemical laws, and without bringing in any mythical and unexplained phenomena.

At this point it may not be unreasonable to make a passing reference to the purin base or body ($C_5N_4$) theory, first brought to the attention of the profession by Prof. Emile Fischer in 1899. The purin bases, as we all know, have figured very extensively in medical literature since that time. While it cannot be denied that uric acid can be reduced in the laboratory to a less complex molecule—one of which is the purin substance—it does not follow that starting with this base, by a process of synthetic action a uric acid molecule can be, or ever is, so constructed in the animal economy. At this point it should always be remembered that

TABLE I.—POSSIBLE PRODUCTS OF OXIDATION OF THE PROTEINS OR "C H N O S" COMPOUNDS.

| Oxidation | Protein | Oxygen Used | Urea | Uric Acid | Creatinin | Oxalic Acid | Lactic Acid | Glucose | Hippuric Acid | Carbon Dioxide | Water | Sulphuric Acid* |
|---|---|---|---|---|---|---|---|---|---|---|---|---|

*Appears in the urine as a sulphate.

It has already been shown that uric acid is primarily a secretory product, so far as its function is concerned—the same as ptyalin, pepsin, and the enzymes of the pancreatic and intestinal glands are secretory, so far as their functions are concerned—yet they are all excretory in this fact, that synthetic construction unquestionably belongs to the vegetable kingdom, while the chief function of animal life is to reduce the complex molecules to their simplest forms. Therefore, the common law of vegetable life is synthetic construction; that of animal life, isomeric transmutation, multiplication

of molecules, and, finally, their oxidation reduction.

This, Halliburton admits, is unquestionably true, but he says further that it must not be pushed too insistently. Why? Because it forces us at times and at some points to say that we do not know, and leaves no chance for escape through mythical and synthetic speculation.

Thus we find very little reason for believing that uric acid is synthetically constructed from a purin base within the animal economy. Even Emile Fischer makes this statement regarding purin: "It may occur in the body, but on account of its ready decomposibility, has not been discovered there." This being the case, why spend so much time and printers' ink, as has been done, in discussing a substance that probably cannot be found in the animal economy?

Certainly many of the deductions which have been built up upon the purin base theory do not fit well with the practical facts as they are observed daily by clinicians in connection with their cases of disturbances in metabolism. All theories that do not fit well with facts are misleading and soon lead to disaster. One theory which is constantly promulgated in this connection is that to have an excess or overproduction of uric acid one must partake of food which is highly charged with purin bases, while the undeniable clinical fact is that a liberal indulgence in potatoes—which are classed as purin-free—will produce the largest amount of over-produced uric acid of any of the known food substances. Hence the purin base theory does not fit with well known clinical facts. The least that can be said regarding it is that it needs much reconstruction before it can be made to fit facts.

Having thus definitely established the normal position of uric acid, we can much more intelligently begin the study of one of the greatest problems in connection with clinical medicine, to wit, the overproduction or pathological aspect of uric acid.

By overproduction is meant the formation of all uric acid in excess of that required as a secretory product to maintain a perfect physiological state of the animal economy, as already outlined. Having thus established uric acid as an oxidation reduction product of the protein molecules, as illustrated in Tables I and II, its overproduction must be worked out along similar lines.

As compared with urea, uric acid is a lower oxidation product of protein metabolism. Apparently, however, both are produced independently, a slight difference in the number of the atoms of oxygen used, or 2 per cent. less oxygen, being all that is necessary to produce this marked suboxidation, lowering the production of urea 50 per cent. and raising the output of the acid 50 per cent. This acid, as already stated, is first a secretory product, while urea is a final and finished reduction product, so far as the animal economy of the human species is concerned. Uric acid, therefore, should be considered as a suboxidation product, and when overproduced, is caused by an unusually large number of protein molecules being imperfectly oxidized, so much so that the output of urea falls as the uric acid rises.

The interesting point in connection with clinical medicine is: What are the methods or etiological factors by which uric acid is produced in unduly large quantities and the output of urea diminished? and how can the condition be most effectively overcome?

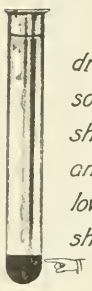
There are several somewhat dissimilar conditions under which uric acid is over-produced, yet in a measure they all act alike. The first is a condition in which we find an overproduction of uric acid in those who have abnormally small lungs—as in one very marked instance in which the writer performed the necropsy and found that the two lungs weighed respectively five and seven ounces, instead of twenty and twenty-two. From an anatomical standpoint, this diminishes the aerating capacity by nearly 75 per cent. This might be compensated for in a measure by a high hemoglobin blood content, also by a more active blood current with low vascular tension. With all conditions most favorable, however, including a careful regulation of the diet, it is impossible to compensate fully for this anatomical defect. Subjects with such a build cannot, even under the most favorable conditions, supply sufficient oxygen to oxidize fully the protein substances and maintain the requisite caloric units, and a more or less incomplete oxidation of the proteins is the final result. Such persons are very prone to become overfleshy and to have a large overproduction of uric acid, which, as a rule, is not held in solution in the urine, as is the case in some instances to be cited later. In these cases the uric acid is readily deposited in the urine without the aid of any chemical reagent, and forms the typical brick-dust deposit. This is always the result when the antecedent protein molecules in the blood follow what may be called their normal or physiological course in transit through the system, but in which there is not sufficient oxygen supplied to fully oxidize them when they reach the renal cells.

Such patients often appear to retain, in a large measure, a fair degree of good health, even in the face of this large overproduction of uric acid. This is explained by the fact that it requires a diminution of only 2 per cent. in the oxygen supply to double the output of uric acid. So long as this is the case and the system remains free from toxic invasion of all kinds no serious damage occurs.

The second class of cases are those in which the oxygenating capacity is fairly normal, so far as the pulmonary anatomical condition is concerned, but in which there is more or less constantly an overindulgence of food, as estimated by sound physiological standards, the overindulgence being usually in starches, sugars, and fats—principally the two former. It may also include an excessive use of the protein group, but not necessarily so. In fact, this is not the rule. While the uric acid is always produced from the protein class only, its overproduction is always a question of defective oxidation, and this is more frequently due to the excessive use of the hydrocarbons and carbohydrates than of the proteins. The former being very easily oxidized if taken in too large quantities, will exhaust the oxygen supply, or capacity of the system in burning these more easily combustible compounds; so much so that there is not sufficient oxygen left with which to accomplish the more difficult task of perfectly oxidizing the protein substances. The reduction of the proteins, being a slower and more difficult task, uric acid is produced to a varying extent, sometimes in very large amounts; at others, to a limited extent only.

Here, as in the former instance, the protein antecedent substances undergo a nearly normal transmutation in their passage through the ani-

mal economy, but without sufficient oxygen to fully oxidize them. Hence there are but few, if any, typical abnormal symptoms, even though there is often a very large overproduction of uric acid. Even though there are no well pronounced or ab-



TEST FOR INDICAN
Take 10 C.C. of urine. 10 C.C. hydrochloric acid and 5 drops of ½% solution potas. permangan. and shake. Then add 5 C.C. chloroform and shake. Purple coloration followed by deposit of blue pigment shows presence of indican.

FIG. 2

normal symptoms in these two instances, an overproduction of uric acid always indicates imperfect oxidation reduction of the protein compounds. If this faulty oxidation is continued, it can represent only one thing—faulty assimilation and imperfect nutrition, a condition which, if allowed to continue, will ultimately be followed by more pronounced pathological conditions in due course of time.

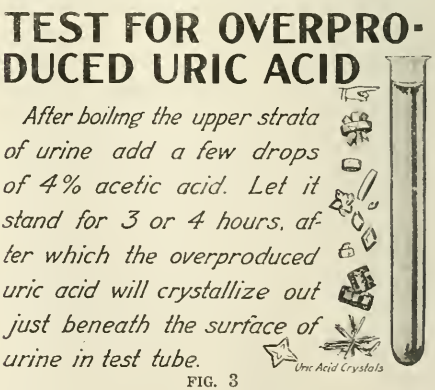
This, then, is a very common form of disturbance in metabolism, that in some subtle manner undermines nutrition and causes many an untimely death.

A continuation of these two establishes what may be called a *third type* of uric acid overproduction. In this *third* form, following or resulting from the impaired nutrition, there is developed a defective flow of the digestive secretions and their ferments. This results in a putrefactive fermentation of the foodstuffs in the alimentary canal, causing the indicanuric condition (see test for indican, Fig. 2), often with the formation of various toxins. These toxins, which have not yet been fully studied and named, when they gain access to the blood stream and reach the nervous system appear to disturb the normal isomeric transmutation processes and cause the imperfect oxidation reduction of the protein substances. Under these conditions the antecedent protein bodies, which ultimately give rise to the overproduction of uric acid in the renal cells, assume more and more the type of toxalbumins, which are irritating or decidedly toxic in nature; so much so, that alone, or in conjunction with the toxins absorbed from the alimentary canal, they give rise to a large variety of ill-defined symptoms or sensations which persist so long as the overproduction of the uric acid lasts and the toxic condition of the system is maintained—symptoms which disappear completely when the overproduction of uric acid is arrested and the digestive processes rendered normal, and the uric acid is again produced within physiological limits only.

There is a *fourth type* of cases in which there is an impairment of the hepatic function, such as occurs with a mild type of intralobular occlusion jaundice, while the intestinal digestive functions remain fairly normal. In these cases the faulty hepatic action is a pronounced factor in exciting the imperfect transmutation and oxidation reduction of the protein bodies, with an overproduction of uric acid in the renal cells. In all cases in which there is a faulty digestion, faulty hepatic action, or with the two combined—which latter may be classed as a *fifth type*—instead of the overproduced uric acid being spontaneously deposited, as before mentioned, it is usually held in solution in the urine in considerable quantities and quite persistently. This is a very curious fact. What the element or elements are that hold the uric acid so positively in solution in the urine has not been discovered; but such is the fact, and in many instances, owing to this strange phenomenon, the overproduced acid is often overlooked by those who analyze urine.

In most instances the overproduced uric acid thus held in solution can be detected quite easily by a very simple and certain method. Porter's test for overproduced uric acid (see Fig. 3) is one the author originated and has employed for more than twenty years, in thousands of specimens. Fill a test tube with urine; boil the upper strata only, then add a few drops of a 4 per cent. solution of chemically pure glacial acetic acid, reboil, and set the tube aside in a cool place. If only the physiological amount of uric acid is being produced no change will be observed, no free crystals of uric acid will develop in the fluid so tested, because the acetic acid is not strong enough to decompose the urates and liberate or set the uric acid free.

If, on the other hand, there is an overproduction of uric acid which is free but being held in solution, if the urine is treated as already described, the uric acid will be gradually crystallized out. The crystals will first form directly under the free surface of the urine in the test tube (see Fig. 3). The amount so formed indicates the amount of free uric acid produced above what is required to maintain a perfect physiological state and form the normal urates. If there is a very abundant formation of these crystals it indicates a very large overproduction of uric acid. Judging by the amounts so brought out, one can read off practically the degree or percentage of overproduc-



TEST FOR OVERPRODUCED URIC ACID
After boiling the upper strata of urine add a few drops of 4% acetic acid. Let it stand for 3 or 4 hours, after which the overproduced uric acid will crystallize out just beneath the surface of urine in test tube.
Uric Acid Crystals

FIG. 3

tion of this acid. This test can be made an absolute quantitative test by collecting all the overproduced uric acid on a weighed filter; when re weighed the difference will be the actual overproduction. For all practical purposes, however,

the differences as observed in the test tube is all that is required. By it one can tell whether the overproduction is increasing or decreasing. So far as known this is the only practical method for estimating the overproduced uric acid. As it is the determination of the overproduction that is the chief problem in connection with this uric acid question, it is absolutely necessary to have some practical method by which the estimate can be made by every practising physician. In some instances the free uric acid will so crystallize out in a few hours, but it more often takes from twelve to twenty-four or even forty-eight hours before the full amount comes out. In some very rare instances it takes from four to five days before the crystals make their appearance, at which time they will appear in very large amounts. In one case that has been under my observation for a number of years, it is usually the fifth day before the crystals appear, and then a very large number will be seen in the urine so tested. In those cases in which the uric acid comes out slowly there is usually an associated faulty hepatic action, already described, a highly toxic condition of the blood, with marked neurotic or neurasthenic symptoms.

As a rule, the more positively the uric acid is held free and in solution the greater the toxicity of the system, the more persistent the symptoms, and the harder they are to overcome. In fact, it is this complex form that is the most difficult type we are called upon to treat. This, too, is the type which tends to maintain an unduly high vascular tension of the arterial system, a condition that is often wrongly diagnosticated as arteriosclerosis, while in reality it is simply an overtension without any pathological changes in the vascular walls. A high arterial tension of this kind, if it continues, becomes in itself a further factor in decreasing oxidation and in augmenting the overproduction of uric acid, for it further interferes with the free distribution and utilization of oxygen by the renal cells. This, naturally, further reduces the possibility of a perfect and full oxidation.

Imperfect oxidation, together with a continued high tension, is always followed by a decreasing nutritive activity, in consequence of which the continual struggle going on within the system between the higher, noble, or functionating cells and those lower, ignoble, or connecting cells fails to be maintained in a normal physiological manner. Under these conditions, the ascendency of nutritive activity passes from the *microphages* or higher cells, to the *macrophages* or lower order of cells, so graphically described by Metchnikoff in his admirable article entitled, "What is Old Age?" (St. Petersburg *Novista*). This is little else than a modification of the theory advanced by Weigert in reference to histological changes in Bright's disease and accepted by Cohnheim and C. Wagner, which is to the effect that connective tissue proliferation is, in most cases, secondary to and excited by destruction (degeneration) of the renal epithelial elements. The same holds true in sclerosis of the liver, more commonly called cirrhosis.

Thus we find a well-defined law by which all our sclerotic changes are produced; in fact, most, if not all, the chronic pathological changes, which, as they advance progressively, become well-defined macroscopic pathological lesions. With this faulty nutritive activity and high vascular tension, the struggle constantly going on between the higher, or muscle cells, and the lower, or connective tissue cells, in the vascular walls results in an exhaustion of the higher, and the preponderance of nutritive activity passes to the common cells. The noble cells are crowded out more and more, the common ones growing in size at the expense of the higher. This progressively interferes with the functions of the vascular walls; thus, in a progressive manner, bringing about what finally is a true arteriosclerosis, the higher cells having given place to the lower, thus coverting the arterial wall into a fibrous inelastic structure. This is probably the most frequent method by which arteriosclerosis is produced.

It is through the same law of suboxidation, toxemia, vascular modification, and faulty nutrition that we find the true explanation for all our so-called rheumatic conditions, which range from what are best termed rheumatic neuralgic pains to pronounced local congestions in the deep intermuscular planes and to the ligamentous structure in and around the joints, with varying degrees of pain and impairment of function. If this rheumatic condition becomes more intense around the joints, there will be a very pronounced edematous swelling, with great pain, and partial or complete loss of function, yet without any true inflammatory changes. This is the most common form of joint rheumatism. In a few instances, the changes in and around the joints assume the character of a true inflammation. To produce such changes, however, there must be not only suboxidation and vascular changes, with a modified nutritive activity, as already outlined, to make it a rheumatic condition, but there must be an associated toxemia.

The toxemia of rheumatism is now considered by our best bacteriopathologists to be due to the presence of a modified streptococcus.* The term modified is used with emphasis because it has been proved conclusively, by these investigators, that one form can be transformed into another form. This change from one form to another is produced by modifying the soil or medium upon which they are grown or cultivated. So that, for instance, a pneumococcus can be transmuted into a streptococcus and vice versa.

When these microorganisms are in certain states of transmutation they have a selective power, which enables them to attack by preference special kinds of tissues or structures.

As, for instance, the pneumococcus attacks by preference the tissues of the lungs and thus excites a pneumonia. While in other stages of their transmutation the modified streptococci attacks by preference other tissues and structures.

At some point in this circle of change the microorganism develops into a condition or form, in which it attacks, by preference, the tissues and structures commonly involved in rheumatism, when the biotic processes of the animal economy have been previously impaired, as already described.

The positive reason for this microbic theory of rheumatism is the fact that this specially modified form of streptococcus is always found in the lesions in and around the joints, the endocardium and valves of the heart, the membranes of the brain, and in all the structures involved. This is especially true in all the acute cases and in a goodly number of the less acute and chronic cases.

*"Streptococcus Transmutation," E. C. Rosenow, *Journal American Medical Association*, November 29, 1913, LXI, No. 22, p. 2007.

So much so, that the presence of this modified streptococcus is considered just as essential to rheumatism as the pneumococcus is to pneumonia or the tubercle bacillus is to tuberculosis.

In some cases the toxemia is so mild that the pathological process is simply a congestion and stasis of the blood in the capillary system of the part implicated, associated with a varying degree of localized edematous swelling, but without all the changes essential to a true and complete inflammatory process. In some cases, on the other hand, the toxemic condition has an intensity so great that it will cause an injury to the capillary blood vessels in and around the joints sufficiently severe to destroy their normal function and cause in them all the characteristic changes belonging to a true inflammation. To this condition alone is the term inflammatory rheumatism justly applicable. It is not a frequent condition.

The vascular overtension may be so excited and kept in motion in connection with suboxidation conditions from truly extraneous sources, but they are more frequently intrinsic in origin, as already described.

A profound anemia is often a cause of defective oxygen supply, and thus augments or causes overproduction of uric acid, but much that has already been outlined goes before and is, in large measure, the cause of the anemia. These complex conditions are so often intertwined that cause and effect are easily confused, yet they are readily distinguished if one keeps the complete chemicopathological picture clearly in mind. Viewed in this light, uric acid becomes not so much the true pathological problem, but its overproduction is the true index to a very large series of serious and complex chemicopathological problems, changes which it is most important to understand thoroughly in connection with this great field of disturbances in metabolism and clinical medicine in general, if we are to give our patients the best that scientific medicine affords.

With this conception of the problem of uric acid and its overproduction, we can more intelligently consider the management of all the disturbances of which it is the index or representative. Each case presenting an overproduction of uric acid must be carefully analyzed, and its cause and effects accurately determined. Then a suitable line of treatment can be instituted which will yield satisfactory results to both patient and physician. The management of these highly complicated problems is no easy undertaking and often taxes the physician's ability to its utmost extent. It is not a simple question of increasing the production of uric acid, or even of the elimination of an excess of uric acid from the system. This is not the problem at all. The true goal, from start to finish, is how best to decrease the producton of uric acid and maintain its formation within the exact physiological limit, as previously outlined. This, and this only, is the task that confronts the truly scientific practitioner.

As there are so many factors constantly arising to baffle us in our very best efforts, one has to be constantly on the alert when attempting to manage this class of cases. To say that the whole problem is to bring the body oxidation processes within physiological limits is correct, simple, and easy. To accomplish this satisfactorily is one of the most difficult tasks in modern therapeutics.

In the first type of cases—those due to anatomical differences—it cannot be accomplished perfectly. We can very materially improve the condition, but can never absolutely cure it.

In the second type—those cases in which the overproduction of uric acid is due solely to overindulgence in food, or in that of faulty composition—the abnormal conditions can be set right, from a theoretical standpoint, with ease; but when one tries to regulate the diet according to practical and scientific laws and to maintain it within physiological limits, it usually proves to be no easy undertaking, simply and chiefly because a large number of patients will not do their part, no matter how well the physician may accomplish his.

When we come to the more complex types—those in which the digestion is faulty, the hepatic functions incompletely performed, the blood stream highly charged with toxins—the nervous system is in consequence in an undue state of irritability, and as the result of all these disturbances there is established a state of unduly high or low blood pressure. A condition is produced in which the nutritive processes are decidedly abnormal. This is followed by changes which will result in more pronounced pathological lesions in the near future, if, indeed, they are not already under way.

Here we find our ability as scientific therapists taxed to the very utmost limit, even when the patient does his or her very best in carrying out instructions. All the conditions mentioned have to be met with scientific precision, and this calls for consummate skill on the part of the practitioner. Each and every faulty point must be recognized in its full relation to cause and effect. One by one each deviation from the normal must be corrected in mathematical order, and brought back to a perfect physiological state. This once fully accomplished the overproduction of uric acid disappears, and its production within physiological limits only is again reestablished and can then be maintained. We must not attempt to increase uric acid production, even though this is advocated by some.

Time will not permit taking up in full detail all that can or must be done to set these abnormal conditions right, nor would it be wise to attempt to do so if time would permit, for there are so many different methods by which each and every deviation from the normal standard can be met. That which may work well in one case will not do so in another. In like manner, different practitioners will differ in their opinion as to how best to meet these conditions, and as there is no question but that they can be met full well by different agents and methods, there never can be any specific medication in these profound disturbances in metabolism. The varying factors and the inflexible laws entering into this great problem must be fully understood, and all forms of treatment brought into conformity with these laws, otherwise the very best efforts will prove futile. The more perfectly this is accomplished the more certain and rapid will be the success attained in the management of this great class of disturbances in metabolism. Under these most favorable conditions cures can be effected which upon their face appear little short of miracles.

The deductions to be drawn from this study are:

1. Uric acid in the human species is a normal product of protein metabolism.

2. It is derived from protein substances only.

3. It is a normal oxidation reduction product formed and secreted by the renal cells only.

4. It is never present in any food substance.

5. It could not retain its identity in passing through the digestive process.

6. It is never found normally in the blood.

7. Primarily, uric acid should be regarded as an essential secretory product of the renal cell.

8. It is only a normal and final end-product when united to some alkali within physiological limits.

9. It is absolutely necessary to have uric acid produced in the renal cells.

10. When produced beyond physiological limitation it indicates suboxidation.

11. All not required for physiological purposes is an overproduction.

12. The overproduced uric acid is the true index to a large variety of disturbances of metabolism.

13. The determination of the overproduction is very essential to an accurate interpretation of this class of diseases.

14. The overproduced uric acid can be determined easily and accurately by Porter's test.

15. By this study of the normal and overproduction of uric acid we have the explanation for many conditions hitherto little understood.

16. By following the laws here established our therapeutic measures can be more intelligently applied.

## THE LANGERHANSIAN HORMONE, AND THE HORMONE TREATMENT OF DIABETES.

By HENRY R. HARROWER, M.D.,

LONDON, ENGLAND.

LATE PROFESSOR OF CLINICAL DIAGNOSIS, LOYOLA UNIVERSITY, CHICAGO, ILL.

Much controversy has surrounded the study of the internal secretion of the pancreas and its physiological action and therapeutic possibilities. Naturally this has made it difficult to establish the therapeutic application of pancreatic opotherapy upon as broad a basis as its well-known and favorable enzyme action upon digestion.

Almost all are now agreed that the "theory" of the dual capacity of the pancreas is a fact, but not all will admit that the term "Langerhansian hormone" is warranted by the findings, for it is still asserted that while the pancreas may produce an internal secretion we have no proof that its activities are due to a hormone, nor have we been able to isolate one, and not all are agreed that the islands of Langerhans are the seat of the elaboration of the internal secretion.

The writer, however, is convinced by personal experience and by a study of a large amount of literature—for the literature dealing with or related to this subject is extraordinarily voluminous—(1) that the term "Langerhansian hormone" is warranted; (2) that hormone-bearing extracts of the pancreas can be prepared and frequently applied with success in practical therapeutics; and (3) that the presumed pancreas hormone has little or no direct connection with the external digestive secretion of this organ and hence practically no influence upon alimentary disorders, or, more strictly, indigestion.

An attempt will be made to marshal a few of the essential facts which are the basis of the above conclusions and as the skein is unraveled it will appear that different extracts of the pancreas are very useful in the treatment of certain well-defined disorders of metabolism.

The internal secretory function of the pancreas does not seem to have been thought of until 1889, when the memorable work of von Mehring and Minkowski[1] showed that the removal of the pancreas was invariably followed by the symptom-complex which is called diabetes mellitus. Hence the study of the internal secretion of the pancreas is inseparably connected with the study of diabetes. This substantiated the theory put forward twelve years previously by Lancereaux,[2] which was based upon his clinical observations on several cases of severe diabetes in which degeneration of the pancreas was found at autopsy. He was the first to use the term "pancreatic diabetes," and, of course, he was severely criticised, for others promptly found indubitable cases of diabetes without evident lesions in the pancreas, and still others found grave pancreatic disease with no previous sign of diabetes. It is now known that Lancereaux's theory is well established and we are better able to explain its *raison d'être*.

While reference has repeatedly appeared in medical literature to von Mehring and Minkowski's experiments, it seems advisable briefly to outline their epoch-making results. They made many tests upon dogs, thereby establishing the fact that after complete removal of the pancreas, if the animal survives the operation, diabetes persisting until death never fails to appear. If one-fourth or one-fifth of the gland remains, diabetes does not follow; or if a portion of the pancreas containing the islands of Langerhans and still attached to its arterial supply is first transplanted under the skin and all the remainder of the pancreas is removed, no glycosuria is produced; but the removal of the transplanted portion is followed by glycosuria.

In this latter experiment, as the digestive secretions of the pancreas are not discharged into the intestinal tract, it seems to be proved that it is neither the digestion of the food in the intestines nor injury to nerve structures that is at fault, but that the cause is evidently lack of an internal secretion, presumably from the transplanted portion which contains the islands of Langerhans.

A number of years later Minkowski[3] was stimulated to repeat his experiments, modifying his technique by performing a two-step operation: He first removed, for later convenience, the splenic portion of the pancreas and did a gastrojejunostomy; from this operation the dog recovered and gained 1450 gm. in the following month. The second part of the operation was then performed, at which the pancreas was divided at a distance of two or three centimeters from its head. The duodenum, to which was attached the head of the pancreas, was then removed, and a cholecystenterostomy was performed. Recovery was complete and the dog remained in good health, showing sugar in the urine for only two days after the operation. At the end

of four weeks after the operation the dog's urine was still sugar free, even though fifty grams of sugar and fifty to one hundred grams of rice soup formed a part of the daily diet. The remainder of the pancreas was then extirpated, and within a few hours 100 c.c of urine containing 9 per cent. of sugar were excreted.

A similar experiment was performed upon another dog, but a small pancreatic graft was inserted under the skin of the abdomen, with the result that the onset of diabetic symptoms was postponed until the graft was removed.

It would be superfluous to relate the numerous confirmatory experiments or, for that matter, the inevitable dissenting voices. Biedl, with good authority, says:[4] "The results have since been confirmed by means of many hundreds of experiments undertaken by numerous authors, including Lépine, Hédon, Gley, Thiroloix, Caparelli, Harley, Schabad, Cavazzina, Landmeyer, Selig, and Rumboldt, among others." In the latest of his numerous communications on this subject Hédon[5] has conclusively shown that the blood passing from the pancreas has a decided antidiabetic influence. He removed the pancreas from a dog which he kept alive for a month. The graft was then removed and glycosuria quickly appeared. Transfusion from the inferior pancreatic vein of a healthy dog was arranged and by careful weighings the amount of blood transfused was known. For three hours transfusion was continued and 300 gm. of blood was passed. Laboratory estimations of the urine showed that at the commencement of the transfusion the sugar percentage was 6.5 per cent. and shortly reached 8.1 per cent. in spite of the transfusion, but that very soon the sugar disappeared and after three hours the urine barely reduced Fehling's solution.

The figures given prove that the pancreatic venous blood has a marked influence on the renal secretion, diminishing the amount of water and its concentration, slightly increasing the urea, and almost completely eliminating the sugar. These experiments confirm Hédon's previous work and are convincing evidence of the presence of an internal secretion of the pancreas and its influence upon glycosuria.

Von Noorden in his latest book[6] says: "I think I shall be voicing the opinion of all pathologists when I say that every individual who has a diminished tolerance for carbohydrates, either permanently or extending at least over a considerable period, and thus exhibits the most important clinical symptom of diabetes, must be considered as a subject of pancreatic insufficiency. We need not always expect to find perceptible anatomical evidence, for there may be functional impairment where no macroscopic or microscopic pathological appearances can be discovered."

The pancreas begins the elaboration of its internal secretion before its external secretion is needed. This has been shown by Carlson and Drennan and later by Lafon,[7] who, in a paper read before the Société de Biologie of Paris, reports having observed that in a pregnant dog, extirpation of the pancreas did not cause glycosuria until the uterine cavity was emptied. It may be reasonably supposed that the production of the internal secretion of the fetal pancreases was diffused into the blood of the mother and supplied the function of the removed pancreas.

Another most convincing experiment by Knowlton and Starling[8] justifies the idea that the pancreas influences carbohydrate metabolism by an internal secretion, rather than by any power which its cells might have of removing or neutralizing toxic substances while the blood is circulating through it. They made observations on the rate at which sugar disappeared from blood that was repeatedly perfused through an isolated mammalian heart preparation (dog), and found that the consumption of dextrose per hour and per gram of heart muscle was usually less than 1 milligram when the heart and blood were those of a depancreatized dog, as against 4 milligrams when the heart and blood were from a normal animal. When the heart was taken from a diabetic animal and the blood from a normal one the consumption of dextrose for the first hour was still low, but it increased steadily during the next two hours; conversely, when the blood of a diabetic animal was perfused through a normal heart, the dextrose consumption, although almost normal during the first hour, fell off markedly during the second and third.

These results may be interpreted as an indication that a hormone necessary for the utilization of sugar by the tissues is evidently absent in the diabetic blood. This idea is further supported by the observation that the addition of a boiled pancreas extract to the diabetic blood used in their experiments restores almost to normal its glycolytic power.

Being now convinced that the pancreas is concerned in sugar combustion it may be well to establish the fact that the islands of Langerhans are evidently the seat of the elaboration of the pancreatic internal secretion and thus explain the term "Langerhansian hormone."

It was in 1895 that Schäfer[9] first offered the suggestion that the seat of trouble in pancreatic diabetes was in the islands of Langerhans and the autopsy findings reported by a number of writers have confirmed this. One of the conclusions arrived at by Bosanquet[10] in his Gouldstonian lecture in 1905 is as follows: "Although it is not yet proved, yet it is becoming increasingly probable that the pancreas is diseased in all cases of diabetes mellitus. An increasing bulk of evidence is also accumulating to show that the function of the pancreas, which is in abeyance in diabetes, is normally performed by certain special groups of cells known as the islands of Langerhans, which are distinct from the ordinary secreting cells of the gland."

Thoinot and Delamarre[11] state that they "have now examined the closed intrapancreatic glands of 167 subjects and have been able in 130 cases to discover Langerhansian lesions. We are, therefore, logically led to regard these forms of diabetes as a clinical demonstration of Langerhansian insufficiency." Lazarus[12] has induced glycosuria and cachexia in guinea-pigs by administering adrenalin and phloridzin during a period of several months. At the autopsies the adrenals and pancreas were enlarged and the islands of Langerhans had increased both in number and size. He supposes that this Langerhansian hypertrophy is a result of the efforts of the organism to neutralize the excesses of adrenalin that were given. Lombroso could not duplicate these experiments and contradicts Lazarus's views.

Opie's[13] experiments at the Rockefeller Institute included a series of the most painstaking post-mortem and pathological examinations. As a result of it he states that: "The study of pancreatic diabetes has shown the relationship of diabetes to lesions of the pancreas and to its various histological structures. If the various lesions to which the pan-

creas is subject are reviewed, it will be found that those which destroy the islands of Langerhans are almost constantly accompanied by diabetes." At Opie's suggestion Cecil[14] made a series of examinations in the case of 90 patients who died of diabetes and concluded that: "Lesions of the pancreas occur in more than seven-eighths of all cases of diabetes mellitus, and in such cases the islands of Langerhans constantly appear changed, the lesions in some cases being limited to these structures. In half of those cases of diabetes, in which the pancreas shows no changes, the size of the pancreas or the number of islands is less than normal."

In this connection Cammidge[15] also writes: "It is highly probable that the islands of Langerhans are in some way intimately associated with sugar metabolism, and personally I have no doubt that, in at any rate the majority of cases of diabetes, lesions of the pancreas, and particularly the islands of Langerhans, are responsible for the disease." Further evidence is available in quantities and "the case in favor of the islet theory is steadily growing stronger." The most conclusive evidence has been adduced by Weichselbaum,[16] who, after many years of study, has made the most positive statement on this subject. He states that in *every one* of a series of 183 patients who died with diabetes, in his examination of the pancreas he found distinct and characteristic lesions in the islets, while in an even larger series of control cases representing many different diseases no corresponding changes were found. The slight discrepancy between the findings of Weichselbaum and those of Cecil referred to previously is probably due to the fact, mentioned by Weichselbaum, that when lesions of the islets occur in young persons hydropic degeneration is most frequent, and that lesions of this character are easily overlooked, especially if the tissue has not been properly preserved and prepared. This would account for the cases in which the islets have been said to be normal in fatal diabetes, and perhaps may explain why Cecil did not find lesions in the remaining one-eighth of his cases. Weichselbaum's work seems to establish conclusively that the majority of cases of diabetes mellitus are not only of pancreatic, but of Langerhansian origin. Heiberg[17] has also shown that there is always danger to the island tissue in the pancreas of diabetics. He has studied the islands quantitatively instead of in the usual purely qualitative way.

Morris[18] of New York believes that many cases of glycosuria are due to pancreatitis caused by the effects of bacteria escaping from the duodenum and consequent squeezing of the islands of Langerhans. As soon as the pancreatitis is relieved, the pressure is reduced and the islands are enabled to resume their functions and the glycosuria shortly disappears.

Tiberti[19] has shown that an artificially induced hyperplasia of connective tissue in the pancreas ultimately destroys the islands of Langerhans and so glycosuria results, and Lissauer[20] found in twenty-four subjects with gin-liver that the pancreas showed more or less similar changes. His findings confirm those of Weichselbaum in twenty-seven similar cases. The importance of this "gin-pancreas" is evident when one remembers the comparative frequency of the development of diabetes mellitus in persons addicted to liquor.

A report by S. A. Scott[20] of Oxford University is of particular interest. He tells of a case of cancer of the pancreas with no previous glycosuria or symptoms of pancreatic internal secretory loss. At autopsy it was seen that the growth had effectively obliterated the ducts and destroyed the glandular part of the organ, with the result that only the islands of Langerhans survived. Opie[21] in his book describes and illustrates a specimen in a less advanced stage than Scott's.

In the Section of Medicine of the XVII International Congress of Medicine, Dock[22] makes the following summary of the foregoing facts: "Now that the relation of the pancreas to diabetes has been carried far towards a conclusion, it is worth while remembering how long it has taken us to reach this stage. Bouchardat very early claimed a place for the pancreas in the pathology of diabetes. Lancereaux and his pupil, Lapierre, tried to show the relation more than thirty years ago, but sought it in the external secretion. Von Mehring and Minkowski looked for it in the internal secretions a decade later; Hansemann soon after insisted on a specific anatomical alteration. In 1895 Schäfer made the pregnant suggestion that the islands of Langerhans are at fault, and in a few years this was confirmed on a large scale by the work of Opie, Weichselbaum, Saltykoff, Hirschfield, Russell, Heiberg, and many others. There is no question now as to the existence of the insular lesions in most cases of diabetes. . . . It hardly seems necessary here to discuss the meaning of cases of pancreatic disease without diabetes, and of diabetes without pancreatic disease—at least disease we can recognize anatomically with our present methods."

A number of experiments have shown that the Langerhansian hormone antagonizes the power of the chromaffin hormone to "mobilize" sugar, or in von Noorden's words, "the pancreas acts as a brake upon the sugar factory."

Zuelzer[23] was among the first to discover the fact that adrenalin glycosuria could be suppressed by injections of an albumose-free pancreatic extract. Frugoni[24] then confirmed this by showing that pancreas extract had the power of destroying adrenalin *in vitro*. Ghedini[25] (and later other investigators) have shown that a fatal dose of adrenalin when mixed with pancreas extract does not cause death and is practicaly innocuous. Pick and Glaesner have also prevented adrenal glycosuria by adding to the adrenalin solution 4 to 20 c.c. of liquid pancreatic extract. The same result, obtained however by a totally different experiment, was secured by Frouin and André Mayer,[26] who have demonstrated a diminution of the manifestations of experimental pancreatic diabetes by partial or complete removal of the adrenals.

Since the use of hormone-bearing extracts of the pancreas in diabetes is frequently unsuccessful, it is desirable to be able to discern which cases are likely to benefit. Lépine believes that in many cases of glycosuria, and occasionally in non-diabetic disorders, there is a functional insufficiency of the pancreas, which is often very difficult to recognize. Sometimes this is possible only by making a therapeutic test. However, there are several subjective signs which are frequently seen in these cases: Marked loss of weight (the French call pancreatic diabetes *"le diabète maigre"*), serious digestive troubles with steatorrhea, and an infrequency of soaps in the feces.* These and other tests not

*The subject of "The Functional Diagnosis of Pancreatic Disease" is exhaustively studied by Pratt[27] in a paper bearing this name and which is amplified by no less than 96 bibliographic references (see also Leech's review).[28]

mentioned here are evidence of a general pancreatic disorder, but not necessarily of a deficiency of the pancreatic internal secretion, although it is likely that the manifestations of severe disease of the pancreas will not be confined to its external secretion alone. There is, however, another important procedure which appears to be of considerable promise.

The relation of the Langerhansian and chromaffin hormones to pancreatic insufficiency, and particularly to the so-called "pancreatic diabetes," led Loewi[29] to suggest a clinical test which gives fairly constant and useful results. He showed that the instillation of 3 or 4 drops of adrenalin (1:1000 solution) into the conjunctival sac causes mydriasis in patients suffering from pancreatic disease. Here it is presumed that, the Langerhansian hormone being diminished or absent, there is an increased excitability of the sympathetic system due to an excess of the antagonist adrenal hormone; and the minute amount of adrenalin is capable of influencing mydriasis. Where this does not take place following the instillation it is presumed that the pancreas hormone is present and that this is evidence that the disorder of the internal secretory function of the pancreas is negligible. This is not an infallible test, but as it is quite innocuous and so simple it is recommended in every suspicious case, and especially in all cases of diabetes. Gandola Quadrio[30] tried this procedure in twenty-five cases in his medical clinic in Rome. Twenty did not respond and no other sign of pancreatic disorder was apparent. Of the remaining five, four had definite pancreatic disease (two diabetes and two pancreatic tumors), while the remaining patient was an epileptic, who, however, showed no sign of alteration in the pancreatic function.

With the formidable amount of evidence to show that the pancreas, and more specifically the islands of Langerhans, are frequently at fault in diabetes it would seem proper to infer that just as the administration of thyroid extract enables one to replace the lost hormone in athyroidism, etc., so the deficiency of the Langerhansian hormone could be replaced by the administration of extracts of the Langerhansian islets. This is true in a degree; but the results are not so specific as those that follow thyroid medication in hypothyroidism for several reasons:

First, not in every case of diabetes is the pancreatic factor present or prominent. Second, very few preparations of pancreas are made with the object of specifically supplying as much as possible of the islet substance. Third, it is no easy matter to supply the lacking hormone for it is normally supplied continuously to the blood, and we have no means of knowing how much is elaborated or, in disease, how much is lacking in each case. Fourth, the antagonism of the chromaffin hormone must be considered, for the diabetes may be due, not simply to a deficiency of the pancreatic internal secretion, but to an exaggeration of that of the adrenals or a combination of both. Fifth, evidently several other factors are concerned and hence the hormone treatment of diabetes alone cannot be instituted with hopes of success.

The exciting cause of the disturbed hormone-balance is not to be neglected, and if it cannot definitely be found (and rarely can this be done, much less can it be controlled) all one can expect to accomplish in this direction is to favor the restoration of the hormone balance as much as possible. This is best accomplished by (1) the regulation of obvious elements of disturbance, such as indigestion, anemia, worry, etc., (2) the regulation of the dietary, so that a minimum of the deficient hormone will be required, (3) the sedation of adrenal overactivity if present, and (4) the exhibition of preparations containing a maximum of the Langerhansian hormone in doses graded to fit the condition present.

As an adjunct remedy in pancreatic diabetes this method is of encouraging utility. Frequently glycosuria is reduced to a minimum or disappears entirely, and after response to this treatment a wider dietetic range is made possible.

Therapeutic trials of feeding pancreas have been carried out by several writers. Combe[31] found it of good service in certain cases, although it did not suffice completely to cause the disappearance of glycosuria, save only in a few cases. He called special attention to the improvement in the nutrition and general condition which was also brought about.

Cowles[32] relates an interesting case in which the ingestion of from one to three calves' pancreases daily reduced the daily amount of urine from 7 to 10 to from 2 to 3 quarts; the specific gravity from 1,040 to 1,045 to 1,028 to 1,030; and the sugar, although the urine was never entirely sugar-free. The weight was materially increased, during one fortnight 161 lbs. being gained. Circumstances caused the patient to stop treatment and some time later he died from sepsis. The pancreas was found to be a mere fibrous cord. Cowles suggests that the numerous failures with this treatment are due to the administration of too little pancreatic substance as "few people would be able to eat, even if they could get, the amount of uncooked pancreas taken by my patient."

Zuelzer[33] has reported good results from his preparation and believes that it is possible to cause sugar, acetone, and diacetic acid to disappear from the urine of diabetic patients by the injection of a specially prepared pancreatic extract. In six cases, between six and sixty-five years of age, treated with subcutaneous injections of extracts of pancreas obtained from living animals at the height of digestion, he reports that the results were uniform and constant, the glucose, acetone, and diacetic acid being always diminished and usually entirely absent from the urine in two or three days after injection. In all these cases no change was made in the diet after administration.

It is evident that the pancreas-ferment preparations may have an excellent influence upon glycosuria. This is probably due to the restorative action on the pancreas caused by the reinforcement of digestion and the removal, in part or altogether, of the pancreatic disability which is reflected not alone upon its external but also on its internal secretion. Walko[34] noted a conspicuous effect upon the sugar content of the urine, which was seen in a case of glycosuria in chronic pancreatitis. Under pankreon medication the excretion of sugar ceased entirely after eleven days and did not return, although a gradual increase was made in the quantity of food containing carbohydrates.

Rennie and Fraser[34] prepared an extract of the islands of Langerhans of the *Teleostei* (a genus of fish in which Langerhansian islets are sufficiently large to be visible to the naked eye). It was used in five cases of diabetes with some improvement, but the experiments could not be continued owing to the limited supply of the extract and the difficulty of securing it.

Crofton[35] of Dublin reports good results in a child of thirteen following the administration of a total extract of the pancreas (holadin), and in a later paper[36] tells his further experiences. He begins treatment by giving a preparation of secretin;* if no marked improvement is noted he gives a pancreas extract from which all the coagulable proteins and ferments have been removed by heating to 80° for three hours. He frequently gives secretin and pancreatic extract together. As to his results Crofton writes: "I have seen a sufficient number which were going to the bad on the several lines of treatment improve and resume their usual mode of life, and this on an ordinary full diet. This encourages me in the idea that I am working on the right lines. The patients soon begin to lose their abnormal thirst and hunger, and the wretched feeling of weakness and illness. In some cases the amount of sugar and urine decreases rapidly, but I have never yet succeeded in entirely getting rid of the sugar, although the patient has frequently declared himself well and strong and able for his full quantum of arduous work."

The writer's experience has been limited to a preparation called trypsogen, said to contain the pancreatic internal secretion besides trypsin and amylopsin. In several cases of unmistakable diabetes mellitus (with several or all of the usual symptoms—glycosuria, polyuria, thirst, emaciation, and asthenia) the weight has been increased, polyuria quite controlled, and sugar reduced. Occasionally the sugar disappears entirely and, with no further treatment, does not return. A case has been seen in which sugar would return immediately the dosage of this preparation was stopped, and another in which glycosuria returned if the dose was reduced below what apparently was the minimum effective for that patient. No cases of gangrene have been met with personally, but several correspondents have reported encouraging experiences with this treatment, and in an excerpt from a paper published by Attix and Rommel[38] is an interesting record of the successful treatment of several severe cases of gangrene with trypsogen.

Certain cases have been found to respond to this treatment in a limited degree, and the sugar is reduced, but persists in small amounts; while again, not infrequently, the results are negative. Quite recently Wynter[39] reported in the discussion on glycosuria at the British Medical Association meeting at Brighton (1913) that he had seen very good results follow this remedy in a severe case of glycosuria.

The evidence is by no means unanimous, nor are the results constant, but it is proved beyond all question that such a condition as the "Langerhansian insufficiency" mentioned by Thoinot exists in many cases of diabetes and that a means of controlling this may be found in extracts of these islands. However, this is but one factor in the control of this complex disease. It seems that pancreas, or preferably Langerhansian preparations, should be added as a part of the routine treatment of all cases of diabetes not definitely known to be due to hepatic disorders as mentioned previously.

*Pochon[37] was probably the first to suggest the combination of secretin-bearing extracts (duodenal) and pancreas extract in diabetes. He believes that by combining these products one can stimulate both the internal and external secretory powers of the pancreas. He reports two cases in which the sugar fell sharply from 50 gm. to 3 gm. and from 70 gm. to 4.50 gm. per liter, and in other ways improvement was apparent.

## THE TREATMENT OF TRIFACIAL NEURALGIA BY THE INJECTION OF ALCOHOL INTO THE GASSERIAN GANGLION.

BY CARL D CAMP, M.D.,

ANN ARBOR, MICH.

It is well known that the best treatment for trifacial neuralgia is the removal of the cause, and there are many causes for this condition that are removable. In 1909 I published a paper on "The Cause and Treatment of Trifacial Neuralgia" (') in which I reported some cases which I considered interesting for the reason that in these cases a definite cause for the neuralgia was discovered and removed. If we apply to these cases the term symptomatic trifacial neuralgia, it makes but little practical difference, for the fact remains that, without a general and complete examination of the patient the cause would not have been found. The only real difference between those cases called symptomatic and others is the fact that in the latter the cause is not discovered. Pains in the face that are the direct result of local inflammatory conditions and certain psychalgias are, of course, excluded from any category of neuralgia. There are cases of so-called "idiopathic" trifacial neuralgia, in which the cause cannot, in the present state of our knowledge, be determined or removed; such cases usually occur

in persons well advanced in years and are supposed to be due to some change in the nerve itself or in the bony canal. Dana would limit the term tic douloureux to cases of this description. The treatment that we have used for these cases has always been more or less unsatisfactory. Medical treatment practically never cures and rarely benefits. Treatment by electricity is in about the same position. The surgical exsection of the nerve, superficially, frequently gives relief for a time, but the pain returns in spite of the elaborate precautions often taken to prevent the regeneration of the nerve—such as plugging the foramen of exit, twisting out the nerve, etc. The injection of alcohol or osmic acid into the nerve as it emerges on the face is easier than the surgical resection, and, in my experience accomplishes about the same result. The deep injection of the nerve trunks as they leave the foramina in the skull, Schlösser's method, which has been frequently done in this country by Kiliani, H. Patrick, and others, although at first considered curative, is now known to be frequently followed by recurrences. The Hartly-Krause operation, excision of the Gasserian ganglion, is usually curative but is a dangerous and difficult operation and frequently leaves a bad deformity. These objections are not overcome by Spiller and Frazier's modification—the section of the sensory root of the ganglion, nor by the suggestion that is made by Alexander and Unger[2] that the ganglion be exposed as by the Krause operation and then destroyed by the injection of alcohol. Practically the same objections apply to the operation done by Wright[3] and also suggested by Sicard, *i.e.* under general anesthesia, dividing the zygoma and the coronoid process and reflecting them upward and then dissecting back to the foramen ovale and, with a curved syringe, injecting alcohol or osmic acid into the ganglion.

In May, 1909, W. Harris[4] stated that the ganglion could be injected with alcohol by passing a needle through the cheek in much the same way that the third division of the trigeminal nerve was injected as it left the foramen ovale. He demonstrated this possibility on a cadaver. January 27, 1912, he published[5] details of three cases in which he had done this operation with good results in patients with neuralgia and also published his technique. His paper was published thirteen months after he had injected the first case and there had been no return of the pain. Shortly after this Härtel[6] published an elaborate paper in which he advocated the injection of the Gasserian ganglion in a somewhat different way—the needle was inserted in the mouth just outside the alveolar process above the second molar tooth and was directed upward and backward. He claimed that this way was easier because it furnished more bony points to guide the operator and because the long axis of the foramen ovale was anteroposterior. He also claimed that there was less danger of accident by this method. He reports a number of successful injections. Alexander and Unger[2] tried the Härtel method and failed because they could not enter the foramen. A. Simons[7] also tried this method and had a fatal meningitis follow. So far as I know the only man in America who has published anything along this line is Grinker.[8] Grinker reports that his first attempt was unsuccessful. Of his second attempt he simply says, "I made a successful injection into the Gasserian ganglion according to the technique as described in the previous portion of this paper. The two lower branches of the trigeminus had become completely anesthetic and the patient left the hospital free from pain." I should doubt that the ganglion was injected if the first division was not affected.

The Harris method has been used by Tapetas,[9] who reported two cases so treated with good results. While the publication of his paper preceded that of Harris by several months, Harris probably deserves credit for priority for he demonstrated the possibility of the operation, in 1909, on the cadaver and performed it on a patient thirteen months before he published his paper.

My attention was first attracted to the paper by Harris and I practised this operation on a number of cadavers in the anatomical laboratory of the University of Michigan. I found that on the cadavers used there was little difficulty in making the needle pass through the foramen ovale and penetrate the Gasserian ganglion. Necessarily it passes very near to important blood-vessels and they are liable to injury. If the needle points too far back it enters the jugular foramen or the foramen spinosum, if it passes too far through the foramen it will wound the cavernous sinus. As Offerhous[10] says of Schlösser's operation, "it is millimeter surgery," and the same author, in 1910, referred to Harris' suggestion as "improbable."

Case I.—April 19, 1912, I injected a patient with trifacial neuralgia, using the technique suggested by Harris. The patient was fifty-six years old and had had neuralgia for fourteen years. He had been extensively treated and had an operation on the nerve with temporary relief. After the injection it was noted that there was analgesia in the distribution of all three branches of the nerve and he had no attacks. He was discharged from my service in the hospital six days later, and I have heard that his neuralgia is cured but have had no opportunity to reexamine him.

Case II.—The second patient was a woman, age forty-six, with severe trifacial neuralgia, of two years duration. She was admitted to the hospital, December, 1912, and on January 6, 1913, had an injection of alcohol into the peripheral nerves at their exit points on the face, with complete relief. On February 17, the patient came back to the hospital, the pain having returned two days before. The Gasserian ganglion was injected, Harris' method, on February 24, 1913. In less than ten minutes after the injection there was complete analgesia of the right side of the face in the distribution of all three branches of the fifth nerve, and the right side of the tongue. The corneal reflex was lost on that side. Sensation to pressure was preserved. On February 27 it was noted that she had a vesicular eruption about the right corner of the mouth resembling a herpes zoster. March 2 she had no pain and the area of analgesia was the same as before. A steel pin was thrust through the right side of the tongue without causing pain though the patient said that she felt it going through. The corneal reflex was lost but there was no keratitis. An examination made December 11, 1913, showed the area of analgesia slightly less extensive but otherwise the same as at the previous examinations.

Case III.—The third patient was a man, aged sixty-eight years, with typical and very severe neuralgia in the left side of the face, duration four years. His blood pressure was 200 mm. Hg. but, except for the manifestation of the neuralgia, his neurological and physical examination was negative. He was given an injection of 1 c.c. of 1 per cent. cocaine in 80 per cent. alcohol into the Gasserian ganglion, July 24, 1913. Analgesia of the left side of the face was complete inside of a few minutes. After the withdrawal of the needle he said that he felt dizzy and nauseated and there was noticed a weakness in the muscles of expression on the left side of the face and a paralysis of the left external rectus muscle but this paralysis was transient and there was no trace of it the following day. There remained a permanent analgesia of the left half of the face in the distribution of the fifth craniel nerve also analgesia of the left half of the tongue, and of the mouth as far back as the middle of the tonsil. The left cornea was anesthetic and the

reflex abolished. It was also noted that the temporal and masseter muscles on the left side did not contract on mastication. The sense of taste was preserved. Some interesting physiological studies made on this patient relative to the functions of the Gasserian ganglion are not recorded here. Dr. R. B. Canfield reported that the tympanitic membrane was anesthetic, the only response to the probe being a ringing tinnitus. On January 12, 1914, the patient returned to the hospital at my request for reexamination and for demonstration at the January meeting of the Clinical Society of the University of Michigan.[11] He said that he felt well and had had no pain. He felt light touches with the finger on both sides of the face but those on the right side were more "distinct" than those on the left. Light touches with cotton were not felt on the left side of the face. He had analgesia to pinpoint on the left side of the face in the distribution of all three branches of the fifth nerve. He felt pinpoint as such on both sides of the tongue but less distinctly on the left side. The conjunctiva on the left side was anesthetic and the corneal reflex lost; it was very prompt on the right side. The hard palate and gums were analgesic on the left side. He had had no inflammatory trouble with the left eye though there seemed to be more lacrymation than on the right side. The pharyngeal reflex was active on both sides and the masseter and temporal muscles contracted on both sides though somewhat better on the right side than on the left.

It is a fair inference that the Gasserian ganglion has been destroyed in this patient since the extent and character of the sensory changes six months after the injection are practically the same as those noted after the surgical removal of the ganglion or the section of its sensory root and, if this is the case, there will probably be no recurrence of the neuralgia.

*Indications and Contraindications.*—The indications for the injection of the Gasserian ganglion are the same as those for Gasserectomy, namely, severe trifacial neuralgia for which the cause cannot be discovered or, if discovered, removed, *i.e.* those cases called idiopathic or tic douloureux. It would no doubt be desirable to try the effect of peripheral injections into the nerve trunks first and if relief is obtained in that way the more serious procedure may be avoided. There are no serious contraindications except the non-fulfillment of the above indications. Heart disease or high blood pressure while increasing the seriousness of the situation are no contraindications; some measure for relief is a necessity and the injection is less dangerous than Gasserectomy.

*Technique.*—The technique used is essentially that described by Harris.[5] No general anesthetic is used but the patient may be given a dose of morphine hypodermically about fifteen minutes before the injection or bromide, as thought desirable, and the skin of the cheek may be frozen. I have not used these measures in the cases above recorded. The patient sits in a chair, preferably with a head rest. His mouth is held open about ½ inch with a piece of cork or mouth gag. He is requested not to attempt to talk but to answer by gestures or arranged signals, such as: raising the right hand, "yes"; left hand, "no," etc. The skin of the cheek is made aseptic with benzine and iodine and under aseptic precautions a sharp needle or trocar is inserted through the skin opposite the lower border of the sigmoid notch and pushed inward and slightly upward and backward through the fascia and muscle. This is then withdrawn and a hollow needle about 1.2 mm. in diameter and 10 cm. long takes its place. This needle is marked in centimeters; it is sharp pointed but has an accurately fitted trocar, a little longer than the needle, with a rounded end. With the trocar in place the point of the needle is less likely to injure the blood vessels. The needle is gradually pushed through the sphenomaxillary fossa to the foramen ovale. Contact with the inferior maxillary division in the neighborhood of the foramen ovale causes sharp neuralgic pain in the distribution of that nerve and as soon as one is satisfied that the needle point is in this situation a few drops of 1 per cent. solution of cocaine in alcohol are injected through the needle and an interval allowed for it to take effect. There should be then an analgesia of the skin in the distribution of the inferior maxillary nerve and also an analgesia of the parts at the needle point. Several trials may be required to produce this anesthesia. After this has occurred the outline of the foramen ovale is made out with the needle point and the needle pushed through the foramen (not over one centimeter) until the patient complains of a sharp neuralgic pain over the orbit. One cubic centimeter of the alcoholic solution of cocaine is slowly injected at this point. The needle is left in place until tests show an analgesia of the entire distribution of the trifacial nerve which, in my cases, has occurred in less than ten minutes. The needle is then withdrawn. The appearance of analgesia in the supraorbital region is necessary to give assurance that the needle has actually passed through the foramen, for the proximity of the foramen rotundum to the foramen ovale makes it possible that alcohol simply injected into the sphenomaxillary fossa would cause analgesia in the two lower divisions of the fifth nerve. The great variations in the size and shape of the skull in different individuals makes it impossible to give more definite directions for reaching the foramen ovale but I am convinced that he who trusts to measurements of the skull and theoretical angles will be less successful than he who first practises extensively on various cadavers and then trusts to his sense of direction and the correct interpretation of the physiological phenomena caused by the passage of the needle point.

The Härtel method differs from the Harris method and the one described here in that he starts from the mouth and passes the needle upward and backward outside the alveolar process. The only argument in favor of this method is the fact that the long axis of the oval foramen lies anteroposterior but this advantage is largely illusory. I have never tried this method but I have seen it tried unsuccessfully and there have been reports of its trial by Alexander and Unger[2] and others in which they were also unsuccessful in passing the needle through the foramen ovale. The foramen ovale is frequently quite round and passing the needle through the cheek allows a better sense of its direction. There is certainly more danger of infection by the Härtel method and A. Simons[7] records a fatal meningitis in a patient injected by this method.

*Untoward Effects.*—In attaining the object of complete destruction of the ganglion of Gasser certain phenomena may occur which are not intended. Harris does not report any untoward effects except faintness and retching in one case. Taptas reports two cases and in one of them there was complete oculomotor palsy lasting two hours. In my third case there was transient paralysis of the sixth and seventh cranial nerves on the same side, with some dizziness and nausea. Somewhat similar phenomena have been observed after injection of the nerve trunks by Schlösser's method and paral-

ysis in other cranial nerves than the fifth may occur after Gasserectomy. Unilateral weakness in the muscles of mastication may also be regarded as an undesired effect and has occurred in one case reported by Harris and in my third case. Its effects are transient and not serious; there is no interference with eating. A neuro-paralytic keratitis, so common after Gasserectomy, has not occurred after the destruction of the ganglion by injection methods even though the cornea is anesthetic. There has been no keratitis even when the ganglion has been exposed by the Krause method and alcohol injected directly into it (Alexander and Unger). It would seem from this that the keratitis which follows, in some cases, the Hartly-Krause operations may have the effect of ether on the cornea as one of the factors of its production.

*Physiological Effects.*—The physiological effects observed after the injection of the Gasserian ganglion are very similar to those after surgical extirpation of the ganglion. The area of disturbed sensation is the same in both cases. The character of the sensory change seems rather more constant in the injected cases than those in which the ganglion is extirpated surgically. There is complete analgesia in the distribution of the fifth nerve including the mucous membranes and cornea. There is anesthesia to cotton or hair but not to touches which include pressure. There is loss of temperature sense in the same area. The preservation of pressure sense in the face after surgical extirpation has been noted by several observers: Cushing,[12] Spiller, *et al.* and was also noted by Alexander and Unger[2] after they exposed the ganglion and injected alcohol directly into it. Cushing[13] has also noted the independence of the taste-fibers from the trigeminus after removal of the Gasserian ganglion. After the surgical operations the disturbance in sensation may apparently be slight, in some cases "hypalgesia" (Spiller, Dercum, Keen[14]), "warm sensation diminished" (Krause[15]). Dollinger[16] has noted an increased lacrymation on the affected side after surgical removal of the glanglion similar to that observed in my third case.

*Pathological Changes.*—Since the ganglion is not removed the permanence of the result will depend largely on the pathological changes induced by the injection. Perhaps the most light is thrown on this subject by the researches of May[17] who injected alcohol directly into the ganglia of cats. A histological study showed but little degeneration of the cells of the ganglia but degeneration of the peripheral nerves and also a marked degeneration of the sensory root of the ganglion which could be traced through the medulla to the spinal cord. These findings perhaps help to explain the absence of keratitis in these cases in spite of the corneal anesthesia and make it seem that the injection is in effect a section of the sensory root of the ganglion similar to that advised and carried out surgically by Spiller and Frazier.[18] The sensory root of the ganglion will not regenerate (Spiller[19]) so that the results will be quite as permanent as from ganglion removal, indeed, they may be even more so. In 1900, Spiller[20] examined two Gasserian ganglia removed by Cushing and found that in one of them the sensory root was diseased. He says that Krause had also observed a disease of the sensory root in a ganglion removed on account of trifacial neuralgia and in that case the neuralgia returned. Spiller ventures the prediction that the pain may return in Cushing's case unless all of the sensory root was removed or destroyed. Cases in which neuralgia has recurred on the same side of the face after removal of the Gasserian ganglion are very rare but such cases have been reported by Friedreich,[21] Garre,[22] Lexer,[23] Schwartz,[24] and Ssapegko.[25] In these cases the skin remains anesthetic and the pain is referred to the face apparently because of some lesion irritating the sensory root of the ganglion which was not destroyed. If we may rely on May's observations it would seem as though recurrences of pain from this source would not occur after the ganglion injections.

In conclusion it is safe to say that the injection of alcohol into the Gasserian ganglion by putting a needle through the foramen ovale is possible in many cases; the physiological effects are similar to those from removal of the ganglion; the pain of trifacial neuralgia is relieved and there is good ground for believing that the relief is permanent.

**Typhoid Bacilli in the Mouth of the Typhoid Patient.**—E. Mondolfo has found that in the majority of cases of typhoid fever it is possible to isolate the typhoid bacillus from the mouth of the patient. The typhoid bacillus is more frequently found in the mouth than in the circulating blood. The presence of this organism in the mouth may be detected as early as the end of the first week of the disease. The discovery of the typhoid bacillus in the mouth, Mondolfo says, is a valuable diagnostic measure in the early stages of the disease.—*La Riforma Medica.*

# SOME INJURIES OF THE INNER EAR.*

By EMIL AMBERG, M.D.,

DETROIT, MICH.

Case I.—Mr. F. G. R., 45 years old, was seen by me on May 2, 1913. He said that he heard well until three weeks ago, when he was hit in the right occipital region by a golf ball weighing 1½ ounces. The patient was twenty-five feet from the place where the ball was played. He was "terribly" hit. The ball bounced back 75-100 feet. Everything became dark, his knees gave way, and he was dizzy for a few minutes. He noticed about three or four hours later that evening, at home, a ringing noise in the right ear. He said that he had a bump on his head half as big as a fist. The ringing in the right ear disappeared within a week. The patient had also a ringing in his left ear. Now only the left ear rings when the patient comes home after playing three or four hours golf. Dizziness: He was dizzy only about ten minutes. Nausea: Felt nauseated after playing 1½ hours but did not vomit. He never complained in any way of his ears before the accident. Examination: Both drum membranes show a somewhat retracted hammer handle and an interrupted light reflex. Low fork 20. Low fork 40. a'; Vienna; fork and fork 4096 heard in both ears. Weber 128 = 36/100 i W, 19/100 i. After catheter: 41 100 i. W. 27/100 i. 0.5 Galton 0.0.

Iodide of potassium, gr. v, t. i. d. Patient improved. Was seen in my office March 26, 1914. 40/100 i W, 30 25 100 i.

Case II.—Mr. A. F., 40 years old, was seen by me March 4, 1913, and subsequently. He had, in July, 1908, suffered an injury to his head while riding in a vehicle which was hit by a street car. There was retraction of the hammer and interrupted light reflex in both ears. He did not hear in his left ear, and his hearing in the right ear was diminished. He said that he had heard well before the accident, but that he could not hear in either ear immediately after injury. Politzer's acoumeter was not heard in his left ear, and only 1.5 in. in his right ear. Tuning forks a', 4096, were not heard in his left ear. On March 5, 1913, forks 20 and 40 heard in right but not in left. He complains of noises in left ear since the accident.

He could not stand on one leg with his eyes closed. I saw the patient frequently. The Eustachian tubes were free. Romberg and Hinsberg impossible. When I tried to turn him in the turning chair used for labyrinthian tests I had to stop after the second time, as he showed such an amount of dizziness that I became alarmed. Since then he feared the turning chair. I tried this at a court trial, and he told me afterwards that he felt bad for about three days afterwards. III/24/13. He reported that when he sneezed he had a sensation as of being pricked by a needle in the occipital region. He had been working on a scaffold before the accident without becoming dizzy, but he could not do that any longer. There is a scar on the back of his head.

When seen again in September, 1913, the dizziness seemed to be somewhat less pronounced but the hearing in his left ear was unchanged. The noises "singing" or "like bees" which he had before, are not noticed the last two or three months. When he works hard he can not sleep and has to get up during the night sometimes repeatedly.

September 17, 1913. He says that in bad weather the whole left side of his head feels devoid of feeling.

Was seen January, 1914, and there was no change in hearing. He also stated that he could not work on high places as he could before the accident, *e. g.* not on a scaffold, although he often tried to do it.

Case III.—Mr. J. B., 27 years of age, was seen by me Dec. 16, in the office. Patient is a welder and uses an oxygen tank. On Dec. 11, at 3 P. M., the cap of an oxygen tank blew off (pressure from 1500-2150 pounds to the square inch, he says) and hit the patient slantingly on the left frontal region from the front, where a scar is still visible. Patient was unconscious for two hours and dull until about 9 A. M. the next day. The left ear was clogged up with blood, he says, and he was very dizzy for four weeks. Dizziness was very pronounced for two weeks. Even now he is dizzy when he bends over. Patient has had strabismus, but he says it is worse since the accident. To me it seems to change. Unadvised, the patient had syringed his left ear on December 26th.

He developed also some tenderness over the mastoid and discharge from his left ear. The whole left side of the head from the frontal bone to the mastoid is sore. There was a kidney shaped perforation of the left drum membrane. The patient claimed that the ear had been dry before the accident. The tenderness over the mastoid on pressure varied. On Jan. 2 he reported that he had pain in his left ear when his head was lying low. In the first week of January he also complained of a sensation of thumping and of pain, also that the left eye quivers after the thumping stops. January 8, reported that he had earache the night before, from 9 P. M. on, also pain from wound in frontal region back to the ear, and that the thumping kept working. Jan. 9, felt better.

Jan. 10, did not sleep last night. Mastoid tender on pressure, dull pain in head, restless. Feels better on the 13th. On the 17th reports that ear discharged freely last night, and the tenderness over the mastoid seems gone.

On January 19 he went to work at 6:20 A. M. but noticed a dragging headache at 7. This became worse all the time. At 1 P. M. he had to leave work. On the 20th he remained in bed all day. On the 24th he reports that the pain disappears every time the left ear discharges. *X*-ray report "sclerosed mastoid with small fractures in the region of the attic." On Feb. 10, after about a week's observation in Harper Hospital, I reluctantly decided to explore the mastoid. The antrum was deeply seated in the sclerosed mastoid and not opened. The canal was removed almost to the tympanic ring. The tympanic cavity was filled with granulations which were curetted. Since that time the head symptoms improved. The hearing is practically gone since the accident. When spoken to loudly from a distance of about one foot while the noise apparatus is in the right ear, nothing can be made out by patient. On March 11, 1914, the following tests were recorded: Forks 20.40, a', 4096 not heard in left ear. The a' fork placed on left mastoid process was heard in right ear. When turned 10 times to right nystagmus position: 25 seconds to left side, when turned 10 times to left nystagmus in about 20 seconds to right side. He says that the turning caused his head to ache. On March 13, he reported that he had headache after he left my office on the eleventh and that he was nauseated, also that he was dizzy until yesterday morning. Not all nausea had disappeared on the 13th. On the way home, he says, the discharge started again more freely. It is mucopurulent.

Patient started to work on the 16th of March but the work proved too strenuous for him, the headache became violent, especially across forehead. When he does light work he is not annoyed so much. At times the spot in the frontal temporal region was "as sore as a boil." March 20, 1914. Feels much better. Pain in a spot 2½ inches behind top of auricle. March 22, felt better, pain about one inch behind auricle. March 24, pain behind ear better. March 29, when bends forward still gets dizzy. Last night pain again 2½ inches behind top of auricle.

I have selected these three cases, among others, because they show certain characteristic points. There is some probability that in patient No. 1 an outspoken chronic condition existed before the accident, whereas the patients 2 and 3 exhibit more clearly the consequence of the accident.

In a previous introductory article on the subject-matter I referred to the text-books of Politzer and Urbantschitsch, in which the subject is treated.

Dr. D. B. St. John Roosa in his text-book (Sixth Edition, 1885), speaking of injuries of the osseous labyrinth, says: "In the chapter upon fractures of the temporal bone it was seen that there were such injuries in which the tympanum only was involved, but there are also cases in which both the osseous and the membranous labyrinth are injured and absolute deafness results." He quotes:

Case 1.—Severe fall, complete deafness on one side, normal drum membrane. Sept. 14, 1865. E. M., aged eleven. Five years ago, or when six years old, had a severe fall down stairs, striking his head, and he has

*Read before the Detroit Society of Neurology and Psychiatry, April 2, 1914.

been totally deaf on the right side ever since. The drum heads of both sides are normal. He cannot hear the ticking of the watch on the right side, except when upon the mastoid region, the meatus being closed. The air is easily forced through both tubes by Politzer's method and by the experiment of Valsalva, but no improvement to hearing results.

CASE II.—(Abridged). Profound deafness from blows on head. A man 45 years old, beaten in a fight a few months ago, was unconscious for four days. Gait irregular, great difficulty in keeping his head in an erect position, even when supporting it with his hand. Marks of blows still traceable over one eye and the right mastoid. Apparently an entire absence of hearing power.

Roosa describes a case in which the inner ear was permanently injured by a kiss. The boilermakers', etc., ears are well known, also injuries caused by whistles, etc.

It is very important to remember that Politzer remarks that in luetic patients even a slight injury may cause complete deafness.

A case reported by Harry Friedenwald before the Ninth International Otological Congress belongs to the class of commotion or concussion of the internal ear. He quotes: "Barnick, who found labyrinthine hemorrhages in several cases in those killed by severe cerebral trauma, with fracture of base of the skull but not of the bony capsule of the internal ear. The hemorrhages were found in the perilymphatic spaces and in the auditory nerve, and its divisions, and he continues that Strenger's experimental injuries in rats without fracture of the skull likewise revealed labyrinthine hemorrhages, similar to those found by Barnick; that these hemorrhages may become absorbed with partial or total restoration of the organ or they may produce permanent changes by the direct injury they cause or by the subsequent changes, connective tissue formations, etc., which result."

Ostmann is quoted, stating that the "complete recovery may occur after days or weeks, or the hearing may return to its previous condition, but tinnitus remains, or deafness, tinnitus, vertigo and disturbances of equilibrium may persist for a variable period; or improvement may occur which later disappears and a steady drop of hearing follows."

Siebenmann remarks that there are postmortem findings which show that sometimes a simple fall, striking the head on a flat ground, may prove sufficient to cause a fracture through both labyrinths and total deafness. Large statistical investigations (in the Clinic in Zuerich) shows that the labyrinth participates in one-fourth of all fractures of the base of the skull. It is rare that a fracture is exclusively confined to the pyramid. Both labyrinths are concerned in one-seventh of the cases which survive. They continue, that a subdural hemorrhage occurring in another place may produce the symptoms of a laceration of vessels in the labyrinth, even though there is no fracture of the pyramid, the blood running along the perineural lymph spaces and through the aquaeductus cochleæ into the labyrinth. Paralysis of the facial nerve shows in half the cases, and discharge of cerebrospinal fluid in about one-fifth. Lesions of other nerves besides the facial are observed less frequently, and concern the abducens oculomotor, trochlear, glosso-pharyngeal and the vagus nerves.

"Subjective noises usually remain, while dizziness as a rule is annoying in the beginning only. It disappears completely later on, or is noticeable only occasionally, for example in stooping or in looking in different directions."

Boenninghaus, in speaking of commotio labyrinthi, remarks that also slight changes of the end apparatus may lead to a commotion of the labyrinth, which are, however, unknown so far but are probably a degenerative neuritis. Vertigo, he says, may be very slight and of short duration, the cochlearis being the by far more vulnerable part of the acusticus. According to the experience of Boenninghaus in the Sanitarium for Accident Cases in Breslau, vertigo and nystagmus disappear soon. After a year nystagmus could be shown by him only in one-fourth of the patients, although Rheses in 1906 found a much higher percentage. The decrease of hearing for speech and especially for high-pitched noises (watch) exists longer and a slight diminution for bone conduct exists the longest.

Boenninghaus also states that the vasomotor complex of symptoms after a concussion of the skull is generally well differentiated from a traumatic neurosis. He quotes Freund (1904), who says that in plain cases the patients complain of constant or occasional headache, feeling of dizziness, intolerance toward alcohol, inability to work in a bent position and to remain bent for a while and to lift heavy objects. Scintillating before the eyes, buzzing in the ears and sometimes a strange sensitiveness for noises and light exist. Dizziness is present when the patient bends over, whereas it is absent as a rule when the eyes are closed."

Camp, in an article, "The Differential Diagnosis of Conditions Causing Increased Intracranial Pressure," (*The Cleveland Medical Journal*, January, 1912), says that it should be remembered that the intracranial pressure varies somewhat with the position of the body. It is also influenced directly by the blood pressure; if the blood pressure is very high the intracranial pressure will also be high, and the blood pressure may be reduced by the drawing off of cerebrospinal fluid sufficient in amount to reduce the intracranial pressure, as shown by the observations of Parisot and himself. He continues that traumatism to the skull frequently results in a marked increase in intracranial pressure as shown in the cases reported by Weitz, when the pressure, by lumbar puncture, was found to be from 200 to 300 mm. of water. The reason for the increased pressure found in these cases is not clear; there was no fracture of the skull and the negative findings in the cerebrospinal fluid withdrawn would apparently exclude hemorrhage or inflammatory change. Apparently the increased pressure is due to a simple transudation of serum. It may persist for months after traumatism and explain the continued headache, epileptic attacks, etc., sometimes seen in these cases, and which may cause worry for fear a fracture of the skull or hemorrhage has been overlooked. De Schweinitz (*Annals of Ophthalmology*, April, 1911) has called attention to the fact that choked disc can occur under these circumstances and that, while it is sometimes an indication for operation, it frequently disappears without treatment."

Siegmund Erben, in an article, "Diagnostic Considerations of Vertigo" (*Medizinische Klinik*, Nov. 26, 1912), says: "After injuries to the skull, with and without commotion, the list of complaints almost constantly contains that of vertigo. The labyrinth can be affected even in slight injuries to the skull. This shows itself already in the first days after the accident by disturbances of hearing. The hearing test furnishes the symptoms spoken of and the vestibular irritations show lack of reactions.

Vertigo after those lesions is never lasting. After a few weeks it has disappeared, even if the injuries to the acoustic nerve or vestibularis can still be shown. The vertigo persisting after months has the character of the neurasthenic vertigo. If the injury to the head resulted immediately in syncope, vomiting and slowing of the pulse, we must admit for the first half year the possibility of moderate attacks of vertigo (the vertigo appearing suddenly in caisson workers is of labyrinthian origin). This vertigo can be explained by disturbances of the regulation of the arteries of the brain or by a chronic inflammatory condition of the coverings of the brain emanating from the seat of injury. The latter can be assumed if the region of the injury remains sensitive to tapping, and if besides a psychical irritation exists. In a small percentage of injuries to the head this vertigo is the beginning of a psychosis."

In the *Wiener Klinik*, 1880, Urbantschitsch, speaking of forensic considerations of the hearing organ, says that concussion of the head or a blow on the top of the skull can affect such parts of the central nervous system which are of greatest importance for hearing, because they are the acoustic centers. While Urbantschitsch is aware of the fact that this is a hypothesis, he refers to the beautiful experiments of Duret concerning the hemorrhages in the central nervous system (especially on the base of the brain and the medulla) in consequence of concussions. "A blow on the head," he continues, "with apparently no effects whatever, must perhaps be considered a few days later as the cause of a lasting deafness."

*Conclusions.*—1. It is essential that in any case of injury to the head, be it direct or indirect, an inquiry should be made concerning the hearing before the accident.

2. As soon as possible after the accident the condition of the middle ear and the inner ear, the blood pressure, also the absence or presence of syphilis, should be established.

3. The patient should be under constant supervision, at necessary intervals, in order to watch the functional disturbances on the part of the ear, besides other complications, *i.e.*, mastoiditis, etc.

4. The prognosis concerning the restitution of hearing should be very guarded.

5. The convalescence after some injuries of the head is often very protracted.

## THE MEDICAL MANAGEMENT OF EXOPHTHALMIC GOITER.*

By ROBERT ABRAHAMS, M.D.,

NEW YORK.

ADJUNCT PROFESSOR IN MEDICINE AND ADJUNCT ATTENDING PHYSICIAN IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, CONSULTING PHYSICIAN TO THE HOME OF THE DAUGHTERS OF JACOB AND MANHATTAN STATE HOSPITAL.

A DISEASE which has no definite etiology nor specific therapy must of necessity be a football of empiricism. This is the history and experience of exophthalmic goiter from the time Parr, Basedow and Graves introduced it to the medical world.

The etiology of exophthalmic goiter was, and still is, a prolific source of investigation, speculation, theory and dogma. To mention but a few, the medulla was blamed for the disease; then the cervical sympathetic; then the pneumogastric; then the cerebrospinal system; then "some specific muscle poison"; then autointoxication of intestinal origin; then the thyroid gland itself. Among the less important but yet responsible etiological factors may be mentioned influenza, scarlet fever, pregnancy, disappointment in love, other psychical shocks and that impalpable influence, heredity.

Hand in hand with these causative factors were linked what appeared to be, for the time being, logical, rational, and appropriate remedies. Thus the medulla was soothed by sedatives; the cervical sympathetic was resected; the pneumogastric was stretched; the cerebral spinal system was humored with static, galvanic, and faradic electricity; the intestinal tract was cleaned and disinfected; the thyroid gland operated on; love affairs adjusted, etc. Yet, after all these varied measures, we still have the problem of treating Graves' disease on hand.

Some observers did not worry about the etiology of the disease, their study was the symptomatology, and thus we are confronted by a list of drugs imposing in length and variety, some good, some bad, and some indifferent—most of them at present are forgotten. The most astonishing thing in the medicinal treatment of exophthalmic goiter is that drugs were employed with alleged good results which are considered to-day not only contraindicated but actually fatal. I refer to the thyroid extract. To treat exophthalmic goiter with thyroid extract is like adding fuel to the flame. In my early experience with that extract, just about the time that it was put on the market, I came perilously near sending patients with Graves' disease to actual graves by feeding them on thyroid. As a matter of fact, continuous taking of thyroid extract may be responsible for serious forms of Graves' disease. Yet, as stated above, the drug was given freely and "favorably"; for aught I know to the contrary some may still give it.

The tendency to-day is to think of exophthalmic goiter in terms of hyperthyroidism, a condition resulting from hyperplasia and hypertrophy of the thyroid gland. An enlarged gland means an increased secretion, perhaps a perverted secretion; the increase or surplus secretion is apparently responsible for all the mischief.

As this is a medical paper, it can only be mentioned parenthetically that surgeons are taking advantage of this conception of exophthalmic goiter and resect a good part of the thyroid body, leaving just enough glandular substance to produce a normal amount of secretion. The results are claimed to be excellent. Now, what causes the hyperplasia and the hypertrophy? There is the rub and the crux and the mystery of the situation.

As often as I have studied exophthalmic goiter, just as often have I wondered that so very little, if anything at all, is said about the means of preventing the disease. Observers, writers, clinicians, all are busy with the full-fledged affection, but not with its beginnings. Now, as with all ills that human flesh is heir to, prevention in this disease is superior to cure. Prevention may not succeed in every case, but our efforts are rewarded in some. Graves' disease is far and away more common in women than in men. I believe that the foundation of the trouble is laid in the turbulent days of budding womanhood, the period of puberty. It must be your observation, as it certainly is mine, that the thyroid gland in young girls swells and puffs before and

*Read before the New York Physicians' Association, March 26, 1914.

partly during menstruation to return again to normal size when that period is over. In these modern days of the "Culebra cut" in the sternal region of woman's apparel, one can pick out on public thoroughfares and conveyances the menstruating girl by the size of her conspicuous thyroid gland. The disturbance of the nervous system before and during menstruation manifests itself in many ways. These manifestations are apparently physiological, but their frequent repetition concurrently with added work, excitement, worry, or disappointment, increases and aggravates the normal manifestations and the nervousness becomes pathological. Under such circumstances, it will be found that at every returning menstrual period the thyroid gland will be larger and larger until the increase in size becomes permanent. Then, if not before, the heart action grows rapid, the tremor of the hands is rendered visible, and one or two of the many eyelid signs will appear if not the exophthalmos itself.

The prophylaxis is plain and simple, namely, noticing these nervous disturbances and enlargement of the thyroid, let us insist on absolute rest both of body and mind before and during menstruation. And if there be any elements of disquiet they should be promptly and radically removed.

I never heard it mentioned, but I know it to be a fact, that persistent polyuria in a young woman is a forerunner of Basedow's disease. Frequent and excessive micturition is occasionally associated with exophthalmic goiter, but he who interprets this sign properly, long before serious clinical symptoms appear, may prevent the occurrence of the disease and be blessed by the patient for evermore. Polyuria minus glycosuria is frequently diagnosed as diabetes insipidus, but in reality it may presage Graves' disease. I have at present a young woman with exophthalmic goiter under treatment, who gives a history of polyuria which preceded the goiter, exophthalmos, and rapid heart by fully six months.

Another suggestive sign of the approach of exophthalmic goiter is unaccountable and persistent night-sweats occurring in young women without any discoverable organic lesion. These patients frequently have also palpitation of the heart.

Still another sign which occasionally heralds the onset of exophthalmic goiter in young and middle-aged women is paroxysmal tachycardia. By and by the paroxysmal attacks become continuous, constituting one of the four cardinal signs of Morbus Basdowii.

Yet one more sign which I noted in one case and which preceded the disease by many months, occurring in a young anemic girl, was uncontrollable diarrhea, without a discoverable cause.

All these signs are danger signals, pointing to the road of prevention. A quiet mode of living, digestible and nutritious food, suitable tonics, and a change of climate will prevent the occurrence of the disease. Parallel to these border-line cases of exophthalmic goiter are border-line cases of insanity. In many instances both types of perversion can be prevented by correct interpretation of warning signs and timely interference.

The treatment of a full-fledged case of exophthalmic goiter is difficult but not hopeless. One grand and encouraging feature about the disease is the readiness with which patients lend themselves to every new form of treatment, and are confident that the new remedy will surely cure them. This is not bad, because hope and cheer will favorably affect a psychically disturbed patient, and besides, until the new remedy has grown old and impotent, the physician has ample time to arm himself with another one. .This favorable influence of new drugs may account for the great variety of organic and inorganic substances, from extract of spleen to sodium phosphate, which are credited with the cure or improvement of goiter.

The ideal treatment of exophthalmic goiter is found in complete isolation, rest, and freedom from every conceivable care and worry. With this treatment, no medicinal agents need be associated. Yet many of us have seen classical Basedow's disease in jaded and careworn housewives who did as well as their more favored sisters of leisure, with only the ordinary remedies.

One should never grow weary of looking for a cause in every case. If, however, diligent efforts in that direction are not crowned with success, may I suggest syphilis as a cause? In 1901 (*Phil. Med. Journ.*, February, 1901) I correctly diagnosed and successfully treated three pronounced cases of exophthalmic goiter of syphilitic origin. In those days there was no Wassermann to help along, but now I would advise that a Wassermann be made in every case to make sure that ubiquitous syphilis is not the underlying cause. A case of this kind was recently reported by Dr. Harold J. Lewis of Rochester, N. Y. (*Journ. Am. Med. Assn.*, Nov. 1, 1913). The late Dr. Leonard Weber of this city, reported a few years ago a goodly number of cases of Graves' disease treated with arsenic and bichloride of mercury internally and cured. Those cases were undoubtedly of syphilitic origin, although Dr. Weber refused to accept a luetic origin for them. Similarly, the literature of the disease abounds in instances where the external application of a mercurial ointment or plaster to the thyroid gland and the internal use of iodides resulted in either complete cure or very marked improvement. If a Wassermann is not available, one should resort to the therapeutic test: let the patient take potassium iodide for a week or so added to or coupled with corrosive sublimate. If the patient shows signs of improvement the goiter may be assumed to be of syphilitic origin; if on the other hand the patient gets worse, the origin of the disease is not luetic. The same thing is done in aortic disease. Long before the Wassermann test was discovered, our aortic patients were given iodide of potassium. A good many of them wonderfully improved under this form of treatment; nobody, however, suspected the particular reason for the improvement; the Wassermann test came and shed light on our Egyptian darkness. We were shown that 80 per cent of aortic lesions are of syphilitic origin and this accounted for the improvement under iodides and mercury. The same may hold good for those forms of exophthalmic goiter which do so well under the same drugs. At any rate this reasoning has the merit of plausibility. However, while the treatment of some cases of exophthalmic goiter can be specific, yet most of the time and most of the cases the treatment must be shaped according to signs and symptoms.

The most distressing sign of the disease is the rapidity of the heart action. I find, in my experience, that the tincture of strophanthus given in 5 or 10 minim doses, three times a day, is most useful to steady the heart. This drug has been my standby in a practice covering a period of twenty-three years. For a long time strophanthus was dis-

credited in Graves' disease for the reason that it produced diarrhea. At present the tincture of strophanthus is free from that drawback and can therefore be given with the same safety, security, and confidence as any other tincture without running the risk of undesirable side effects. If, however, strophanthus fails, the tincture of belladonna in the same dose is a good second best. Strange to observe, digitalis, the sheet anchor in many a form of cardiac disease, acts badly on the heart in Basedow's disease, although there is noted a strong functional similarity between the heart of Basedow's and some types of rheumatic cardiac lesions.

The other distressing conditions in exophthalmic goiter are tremor and nervousness. These are very well controlled by ammonium bromide in doses of twenty grains three times a day; this need be given for a short time only, because when the strophanthus begins to act the nervousness subsides, as a good share of it results from the consciousness of a rapid and pounding heart.

The lukewarm shower-bath is another means to allay tremor and nervousness. The bath also works well as a hypnotic. Iron is rarely indicated, an opiate never. Once in a great while, when the patient is much disturbed at night with frequent urination, one-quarter grain of codeine taken at bedtime will mitigate that evil.

There is no direct means of reducing the size of the thyroid except by the method of treatment thus far and further indicated. Yet plaster of any kind, belladonna, zinc, or adhesive, seems to reduce the size of the gland; the reduction is apparently affected by pressure of the plaster. I have seen a fair degree of diminution of the thyroid body obtained by repeated application of flexible collodion. The patients instinctively know the value of external pressure as they learn to put ribbons tightly around their necks, although in the beginning the ribbons are employed to hide the deformity.

The eyes rarely need attention, although in one case the eyelids were partially sewed up to keep the eyeballs from falling out. That was the severest case that I ever saw.

The diet should be of the simplest kind; some of these afflicted individuals have ravenous appetites for a time. I indulge them until they are satisfied; after they are surfeited they become docile and are willing to take advice. Tea and coffee are the bane of exophthalmic goiter. These beverages should be forbidden if necessary at the point of the bayonet.

I have used serums in the treatment of this disease. As Dr. Beebe* is here to speak, he can tell you more than I can about the serum with which his name is honorably associated. I have used his serum and also another one, the antithyroidin of Mobius. Unlike Beebe's serum, this one is given by the mouth. The dose ranges from ten to thirty drops three times a day. I can report a complete cure in one case. Another, which is at present under treatment, and is as typical a case of Graves' disease as ever I saw, is doing remarkably well under this serum. This case failed to respond to complete rest in bed, strophanthus, belladonna, and Beebe's serum. After taking the antithyroidin the young woman goes to work, climbs five flights of stairs several times a day without dyspnea, and remains free from nervousness.

I propose to treat a patient in the near future with her own serum and will report the result.

*Dr. Beebe discussed the serological treatment of Graves' disease at this meeting.

It is not the province of this paper to discuss the surgical treatment, except to state that exophthalmic goiter once in a while gets well without treatment; more often its symptoms are held in abeyance by medicinal measures; occasionally ordinary remedies cure it; now in view of all these considerations surgery should be the very very last resort. None of my patients were operated on.

I wish to state that the conclusions in this paper are drawn from my own personal experience. The experience of others may be better but my object here is to record and to report, not to classify and to compile.

257 West Eighty-eighth Street.

## WRIGHT'S SOLUTION: A SUBSTITUTE FOR ANTISEPTIC SOLUTIONS

By G. K. DICKINSON, M.D.,

Jersey City, N. J.

The recent epidemic of suicide and disaster with bichloride tablets makes a statement as to the excellent properties of Wright's solution timely.

The medical profession as well as the public have long been employing washes for wounds, sinuses, and running sores of all kinds, so it will be impossible to prevent this type of domestic treatment, for that which is customary in clinics and at hospitals will become popular with the public.

In the preantiseptic days balsam of Peru and balsam of fir were used for wounds. They had stimulating properties and in a mild degree produced a hyperemia, but did not aid the serum and were dirty and ineffective.

Lister introduced carbolic acid to the profession and it reached the public mind. By it bacteria were killed, but chemical pus was formed. Local irritation, disturbed healing and its absorption frequently resulted in irritation of the kidneys.

Then came bichloride of mercury and its allied compounds. These could be easily compressed into tablets and were kept in the hospitals and clinics for immediate use and also in the home on the closet shelf alongside other tablets of similar appearance.

Bichloride is not an ideal. It coagulates albumen. It is destructive to tissue as well as to microbes. It does not assist Nature in producing local hyperemia and bringing out the serums for wound healing. To be potent in a reasonable time, it must be made in strong solution.

Practically the majority of solutions used in surgery have not been potent because of the time required for antibacterial effect and the little time given for this purpose.

At our clinic in Christ Hospital carbolic was discontinued years ago because of dermatitis, bloody urine, and other disturbances following its use. Bichloride has not been used for over two years, nor has any other antiseptic been employed in the treatment of wounds.

The delightful effects of the Wright's citrated isotonic solution* came to our attention and for the last two years nothing but it has been used. In all the thirty-seven years we have been attending surgical cases never have we noted such prompt results and such beneficent effect as obtained by the *proper* application of this solution. We have practised

*Formula: Sodium citrate, 0.5; sodium chloride, 3.0; distilled water, 100. From Wright's "Studies on Immunization," p. 464.

long enough to be accustomed to the novel and the specific in action, but nothing in the surgical treatment of wounds has pleased as much as has it.

It is helping Nature on her own lines. Nature heals through hyperemia. The salt in the solution produces a mild hyperemia. Nature sends the phagocytes and opsonins into the wound. The citrate of sodium keeps the wound itself free from deposit and allows of the permeation of the healing serum. Wounds are embarrassed by the accumulation of dead leucocytes and decomposing serum, and the presence of microbes in this accumulation, which neither the mercury salts nor the phenols efficiently controlled.

Wright's solution keeps the wound clean, favors proper granulation, and hastens the separation of small sloughings. To be properly applied there should be sufficient gauze kept *well-sopped*. If hospitals and clinics would but thoroughly try out this simple, cheap, and physiologically effective method, the public would soon follow suit and the bichloride tablet and its dangers would disappear.

During the two years in which it has been in constant employment in Christ Hospital it was used at first only for wounds that failed to heal (such as after appendicitis operations), and those that had become infected. The more it was used the more confidence we had in its ability to cleanse and promote the healing processes à la Nature. Boils were effectively treated by it. A huge carbuncle on a big neck was incised, then gauze applied and kept sopped with Wright's solution, the gauze being changed frequently. There was an improvement in conditions and a cleansing and recuperation beyond that ordinarily expected. In erysipelas and lymphangitis gauze kept sopped added to the comfort of the patient and controlled extension. The solution as an irrigant at a temperature of 110° plus, is also used with great success in vaginitis, septic endometritis, and in infected wounds following gall-bladder surgery.

One should not be too enthusiastic in the estimation of the value of therapy, but it has long been recognized that the truth is always simple, and that the things that cure are seldom complicated. One cannot controvert the idea that when a physician is curing a patient he is aiding Nature. If the patient recovers in spite of the treatment, however, the treatment cannot be said to be not on a line with Nature's method.

According to the experience gained at Christ Hospital the sooner the profession relegates the chemical antiseptics to the background and follows out the ideas promulgated by Wright, the more sensible and the more successful the treatment will become.

280 Montgomery Street.

## Medicolegal Notes.

**What Constitutes Employment—Is a Physician Giving Services Gratuitously Liable for Malpractice?**—In an action for malpractice in diagnosing and treating a felon on the plaintiffs finger, the close question of fact was the defendant's employment. There was no direct request to treat the finger, no promise of payment for services, and apparently no expectation thereof on the part of the defendant. As he was leaving a patient's house, having attended to his patient, he found this plaintiff near the door where she and her employer had been discussing her aching finger, and one of them asked the defendant if he thought the trouble was a felon. After looking at it he gave his opinion that it was not, and suggested salt pork as an application. The next time he visited the house he examined the finger, opened it with a needle, and gave directions to continue with the use of salt pork. The last time, after attending to the patient on whose account he made these three visits, he again inquired about the finger, was informed that it felt worse, examined it, and advised that some one open it up with a needle.

This version of the facts, given by the plaintiff, was denied by the defendant, who stated that he merely gave the finger a look on the first visit; but the jury adopted the plaintiff's version. It was held that if the defendant undertook to diagnose, treat, or prescribe for the ailment, his responsibility for failure to possess and use the skill and care of the ordinary physician was not dependent upon an express agreement of employment or promise to pay for the services. If the defendant undertook to render services, the law implies an agreement to pay therefor. It has also been held that even as to charity patients and those whose treatment is undertaken without the expectation of pay the physician must possess the skill and use the care of the ordinary practitioner. The defendant was on a professional visit in the home where the plaintiff was one of the household. She was suffering; the pain interfered with her employment. The head of the house directly or impliedly asked the defendant to examine the finger. Under these conditions his acts in attending to the plaintiff's suffering were held to be quite persuasive of the relation of physician and patient between the two.—Peterson v. Phelps, Minnesota Supreme Court, 143 N. W. 793.

*Note.*—In support of its statement as to the liability of a physician who undertakes gratuitous treatment, which, it is to be noted, is mere obiter, and not necessary to the decision of the case, the court in the above case cited McNevins v. Lowe, 40 Ill., 209; Du Bois v. Decker, 130 N. Y. 329, and Peck v. Hutchinson, 88 Iowa 320. The two last named cases are also merely obiter on the point. In McNevins v. Lowe it is said: "If a person holds himself out to the public as a physician he must be held to ordinary care and skill in every case of which he assumes the charge, whether in the particular case he receives fees or not. But if he does not profess to be a physician or practise as such, and is merely asked his advice as a friend or neighbor, he does not incur any professional responsibility."—J. S.

**Malpractice — Evidence — Nonliability of Charitable Hospital.**—Action was brought against a surgeon and his employer, a charitable hospital, for alleged malpractice of the surgeon in performing an operation. While using a uterine packer, the surgeon lost the spring out of the machine, which became imbedded in the uterus of the patient. The spring was about 12 inches long, and remained some fifteen days after the operation, when it was discovered by another physician, who removed it. One end he found in the neck of the uterus; the other had pierced the posterior vaginal wall, and passed into the rectum. It appeared that the packer used by the surgeon was not then used by those possessing average learning and skill in the locality. It was held that the surgeon was negligent in leaving the spring in the cavity, in failing to discover and remove it, and in using a packer that was unsafe. In the circumstances the jury were held to be authorized to infer negligence without the aid of expert evidence. The surgeon was held liable.

The hospital, however, was held not liable. The rule was stated to be that where a hospital is incorporated for charitable purposes only to found a medical and charitable sanatorium, hospital, and asylum for the care of indigent or other sick persons, the property acquired being devoted exclusively to the maintenance of the institution, such hospital, having exercised reasonable care in selecting a surgeon, is not liable for his negligence or malpractice. The rule applies where the plaintiff has paid for the services rendered, where the amount received was not for private gain, but more effectually to accomplish the purpose for which the charity was founded. Some of the cases hold that a corporation conducting a charitable institution is not liable for the negligence of an employee even where it had failed to exercise reasonable care in selecting him. This is upon the ground that all the institution's property is a trust fund, and that that fund cannot be diverted to extraneous objects. In the present case the court was not required to go to that extent.—Wharton v. Warner, Washington Supreme Court, 135 Pac. 235.

## RECENT INVESTIGATIONS ON ACIDOSIS.

THE subject of acidosis is one that has awakened considerable interest within recent years. One of the newest investigations along this line is the determination of acidosis in diabetes by means of the measurement of the carbon dioxide pressure in the respiratory air. This investigation was made by L. S. Fridericia, who reports his results in the *Zeitschrift für klinische Medizin*, Vol. 80, Nos. 1 and 2. He finds that in the case of diabetics the determination of the carbon dioxide pressure yields results that are fully in agreement with those obtained by the measurement of the ammonia excretion in twenty-four hours specimens of urine, as obtained by the methods of Björn Anderson and Lauritzen. The author notes that in the case of diabetics the abnormally large amount of acetonebodies that accumulates in the blood results in an increased elimination of acids by way of the urine and an increased formation of ammonia in the intermediate metabolism. In addition, by means of an increased respiratory activity, the carbon dioxide content of the arterial blood is diminished. Beddard, Pembrey, and Spriggs were the first to note that in diabetic coma the carbon dioxide pressure in the respiratory air is reduced to one-half the normal amount. Other observers have recorded that in untreated diabetic acidosis the carbon dioxide pressure in the respiratory air is always reduced and is most pronounced in cases of threatening acidosis. Fridericia investigated the carbon dioxide content of the respiratory air in eight diabetic patients who also gave evidence of acidosis. The method employed was that devised by Haldane. At the same time the urinary ammonia was measured. The estimations were made twice daily. The results were recorded by means of graphic curves, which showed that coincident with an increased ammonia excretion there is an abnormally low carbon dioxide pressure in the respiratory air. The author believes that the measurement of the carbon dioxide pressure of the respiratory air should be employed as a routine clinical method by means of which diabetic acidosis may be determined and its variations closely followed. The method has a number of advantages over the one commonly employed. Thus the former requires no accumulation of a twenty-four hour specimen of urine. The only drawback is the fact that the average clinical laboratory does not possess an apparatus for the analysis of air, but Fridericia has devised a simple apparatus of this kind, which he promises to describe in the near future.

In the same numbers of the *Zeitschrift für klinische Medizin* Marius Lauritzen discusses the clinical value of the determination of acidosis in diabetes mellitus and extols the practical value of Fridericia's method. He finds that it is possible to follow with great ease the variations in acidosis that are evoked in response to dietetic and medicinal measures. His investigations have shown that moderate grades of acidosis accompanied by the excretion of two to three grams of ammonia may be overcome solely by dietetic measures. Only in advanced cases is it necessary to employ for some time increasing doses of alkalies.

A most important clinical study of the essential features of acidosis and of its occurrence in chronic renal disease has been made by A. W. Sellards, who reports his results in the *Johns Hopkins Hospital Bulletin*, May, 1914. He finds that the essential feature is a dearth of the body in bases or in substances such as sodium carbonate that readily give rise to bases. The fundamental features of acidosis are an increased intolerance of the body to fixed bases, a diminution in the titratable alkalinity of the blood serum, and a diminution in the carbon dioxide of the blood. Of eminent clinical importance is the fact that an acidosis of high degree occurs in certain diseases of the kidney. This acidosis reaches its maximum in the uremia of acute and of chronic diffuse nephritis. It is often present many months before the development of uremia. It represents the effect rather than the cause of the renal lesions and is only of secondary importance.

Sellards points out that some of the toxic symptoms of uremia are due, not to the presence of a toxin, but to the absence of a normal constituent of the blood, namely, the carbonates. Therefore, the therapeutic bleeding for the removal of any toxins that may be circulating causes at the same time a still further diminution in a substance in which the blood is already seriously depleted. This disadvantage could be readily obviated by the injection of bicarbonate of sodium at the time of bleeding. This acidosis is perhaps the result of a defective function of the kidney in the normal separation and excretion of acid salts. If this supposition is correct, the acidosis would be an indirect expression of renal retention. In support of this it has been found that the acidosis is in general parallel to the ordinary signs of renal retention, such as the suppression of the excretion of dyes and sugars and the accumulation of non-protein nitrogen in the blood. Some of the clinical symptoms of uremia are attributed to an impoverishment of the body in bases and are found to be partially relieved by the injection of sodium bicarbonate. In uncomplicated cases the typical air hunger which sometimes develops and the accompanying bright color of the mucous membranes are further expressions of acidosis. In the acute nephritis of Asiatic cholera, the early injection of massive doses of so-

dium bicarbonate results in permanent benefit. Chronic diffuse lesions of the kidney lead eventually to the development of acidosis, which, if not treated, will progress to such an extent as to produce the clinical picture of air hunger. In the stage of uremia acidosis sometimes constitutes the immediate cause of death. In the selection of the proper alkali for administration the bicarbonate of sodium meets the essential requirements. The administration of the normal sodium carbonate is regarded by Sellards as unnecessary and inadvisable. In any case of acidosis the administration of bicarbonate of sodium may be continued until the urine becomes alkaline, even though extensive renal lesions are present.

One of the principal points brought out by Sellard's study is that an acidosis of high grade may occur in the absence of any disturbance in the carbohydrate metabolism and without producing an increase in the excretion of ammonia.

## SANITATION MISAPPLIED.

It affords striking evidence of the value placed on sanitation by the general public, that commercial concerns make a feature of their advertising in the statement that their business is conducted on sanitary lines. Naturally this is especially the case with groceries, bakeries, barber shops, etc., and in establishments in which food and clothing are sold. This is a healthy sign and up to a certain point can do nothing but good, but it is evident that in order to do the most good it is necessary that all those who thus advertise should live strictly up to their professions. If they do not, more harm than good will be effected. In *Public Health Reports*, May 5, 1914, attention is drawn to this fact and it is pointed out that where the sanitary influence exists in name only or by implication in the presence of some "sanitary-looking" mysterious apparatus or exterior it frequently occurs that a false sense of security is indulged in by the user, and quite possibly to his detriment. For instance, the public is often gulled by the ignorant use or misuse of disinfectants and deodorants. Of course disinfectants are valuable, indispensable in fact in cases in which their employment is indicated, but although good in themselves when misapplied their use is a farce and they lead to a fake sense of security. Deodorants again, are of questionable value and may even become a menace, since at the best they absorb or neutralize an odor which may indicate the presence of some harmful substance which ought to be disposed of, and at the worst merely substitute a stronger and perhaps less disagreeable odor, without in either case having destroyed the dangerous substance whose presence they only mask.

The advertising of sanitary measures by commercial concerns is too frequently glaringly manifested in the case of so-called pasteurized milk. Pasteurization conducted in the manner it is conducted frequently by milk dealers is a very harmful practice. It induces a feeling of security, whereas in reality milk so treated is more dangerous than if it had been left in its raw state. Pasteurization, properly done, is essential, and so also other sanitary measures properly carried out are in the best interests of public health; improperly or ignorantly carried out they are a menace to the health of the community.

## FULMINATING GANGRENE OF THE GENITALS.

This mysterious affection is usually regarded as a composite of various clinical entities which pursue analogous or identical courses. Now and then we can hardly avoid the conclusion that a true venereal propagation has occurred, while in other cases a simple injury from coitus has become inoculated with a germ of great virulence. The fact that in a recent case of this sort a salvarsan injection terminated the condition suggests that the spirochete of syphilis, or at least some spirochete was the pathogenic agent.

This affection has received a great deal of study at the hands of French writers, and is in fact known by Fournier's name. A very large morbid material has been collected and analyzed. It is therefore of interest to mention a case recently reported by Löhe before the Society of Physicians of Charité Hospital, Berlin (*Berliner klinische Wochenschrift*, May 4). The patient, a man of 61, under treatment for a genital affection not named, suddenly developed an enormous swelling of the penis which extended centralwards. The organ was of the size of a man's forearm, while the scrotum swelled to the dimensions of a child's head. Only at a later period did blebs develop, giving exit to a gangrenous fluid. The patient was anesthetized, and free incisions made, the prepuce being split. In this manner 100 c.c. of the same fluid was evacuated. The patient recovered under a combined surgical and supporting plan of treatment.

The author, like others in the past, seems to regard this affection as practically an erysipelas, in which intense inflammation brings about lymphatic stasis and gangrene. Such a theory hardly accounts for the majority of these cases, for the initial lesions may be gangrenous vesicles. In the present case constitutional disease (diabetes) and urinary infection could be excluded despite the coincidence of enlarged prostate.

## Some Reactions of the Blood After Cancer Inoculation.

A physician of Grahamstown, South Africa, Dr. G. Carrington Purvis, for some time past has been pursuing experiments with the view to preparing a cytolytic serum, or a serum which would kill the cells of cancer occurring in a human being. The results of these experiments were described in the *Lancet*, 1912, Vol. 2, page 438. More recently Dr. J. A. Shaw Mackenzie has been investigating the blood conditions in carcinoma, and on the chemical side of the cancer problem, and published a paper on the subject in the *Medical Press and Circular*, May 13, 1914. Experiments on goats, sheep, rats, and mice, and by repeated inoculation with fresh cancerous material showed that a certain degree of reaction was produced. Remarking on the results of his investigations Mackenzie said that such re-

actions of the blood after cancer inoculation in animals, so far as they went, seemed to show an analogy with other forms of immunity. The reactions of the blood after repeated inoculation ran parallel with the reactions in anti-diphtheritic serum and other antitoxic sera and vaccines. It was pointed out that in the present stage of inquiry definite conclusions were obviously impossible. If, however, the analogy of the reactions described following inoculation with fresh cancerous material was admitted, this did not necessarily commit one to a parasitic theory. Mackenzie had regarded the reactions as tissue or chemical reactions, supported as this view was by similar initial reactions in mice and rats after one inoculation of fresh normal tissues, tissue extracts and substances. The more immediate point was whether serum obtained by the method of Purvis or by repeated inoculations of fresh human cancer tissue or serum in animals possessed any therapeutic value. Purvis thinks that he has obtained some improvement by these methods in two or three cases of malignant growth.

### Glaucoma.

Our knowledge of the mysterious and much dreaded "green cataract" of ancient practitioners advances but slowly. Quite recently, however, certain evidences of an increase along this line were collated by Fleischer in a paper read during the year before a Tübingen medicoscientific body (*Münchener medizinische Wochenschrift*, April 14). Schur followed with advances in glaucoma therapy. The normal tension of the eye as determined by Schlötz's tonometer is from 15 to 27 mm. of mercury. We know that most of the alkaloids used in eye practice (cocaine, atropine, etc.) elevate the tension. In simple glaucoma increased tension is not always present, which fact adds much to the obscurity of this affection. Important are the results of study of the visual field by Bjerrum's procedure. It appears from an analysis of these complex finds that certain individual nerve bundles are affected. The cavernous atrophy of the optic nerve seen in simple glaucoma has also been noted in myopia. Schur divides all glaucome cases into operable and practically non-operable, although the distinction is not arbitrary. In the operable type vision is preserved or may be normalized by reduction of intraocular pressure. Fortunately, non-operable cases are in the great majority. Under favorable conditions they need not exceed 14 per cent., and modern knowledge and technique will surely reduce this figure. In from 3 to 4 per cent. of all cases of glaucoma the prognosis of operative intervention cannot be determined in advance.

### Permanent Drainage in Ascites.

This principle of treatment has now been applied in a great variety of resources. The oldest of these is the establishment of an "Eckfistula," so called, in which the portal vein is implanted into the vena cava; and of the corresponding lateral anastomosis between these vessels. The last named operation has been done successfully in mankind. The Talma-Drummond operation, through which the portal vein is drained into the systemic circulation, has been widely practiced with a record of from 30 to 50 per cent. of favorable results. Ruotte has made a communication between the great saphenous vein and peritoneal cavity. In at least one case the result was a success. Others have simply allowed the ascitic fluid to seep into the subcutaneous tissues of the thigh. Rosenstein has established a valvular opening between the peritoneal cavity and bladder, with partial success. At a meeting of the Freiburg Medical Society, held last February (*Münchener medizinische Wochenschrift*, April 21), Oberst describes a simple modification of the direct drainage of ascitic fluid into the subcutaneous tissues. Instead of the crude methods of his predecessors, he formed by plastic work a tubular structure narrow at its peritoneal end and spread out at its lower extremity beneath the skin of the thigh.

## News of the Week.

**Public Health Education.**—President Butler of Columbia University, New York, recently appointed a committee composed of members of the Faculties of the University, to study the question of work in public health, sanitary science, and preventive medicine, and report to the University what courses should be given in these subjects in the College of Physicians and Surgeons and other departments of the University. The committee includes Prof. R. A. Seligman, Chairman; Dr. Frederic S. Lee, professor of physiology; Prof. James C. Egbert, director of the summer session and of extension teaching; Dean Samuel W. Lambert, of the Medical Faculty; Prof. Henry C. Sherman; Miss Mary A. Nutting, professor of nursing in Teachers College; Dr. Robert E. Chaddock, associate professor of statistics; Prof. Alexander Smith; Daniel D. Jackson, associate professor of civil engineering; Dr. Hans Zinsser, professor of bacteriology; Dr. Walter Bensel, and Dr. Haven Emerson.

**Long Island College Hospital.**—At the meeting of the Alumni Association of the Long Island College Hospital, Brooklyn, on June 9, announcement was made of the adoption by the college of a five years' course, and of various changes in the curriculum as a result of this departure. Candidates from the high schools, possessing a full medical student's certificate, will be admitted to the subfreshman class of the college, and will take up chemistry, biology, physiology, embryology, physics, and French or German. The freshman and sophomore years will be spent entirely in the various laboratories, which have been fully equipped. Clinical work in medicine and surgery and daily dispensary attendance will occupy the fourth year, and the fifth or senior year will be given over to hospital bedside work. The Long Island College Hospital, when its new wing is completed this summer, will contain 450 beds, to which the students will have free access, and as all the clinical branches will have full time resident instructors ample opportunities in clinical instruction will be afforded. Some changes have also been made in the personnel of the Faculty, which is at present as follows: Archibald Murray, M.D., professor of pathology; William Lintz, M.D., professor of bacteriology; John C. Cardwell, M.D., professor of physiology and pharmacology; Matthew Steele, M.S., Ph.D., professor chemistry; William Francis Campbell, M.D., professor of surgery; William B. Brinsmade, M.D., professor of clinical surgery; Joshua M. Van Cott, M.D., professor of clinical medicine; E. H. Bartley, M.D., professor of pediatrics. The chair of anatomy, histology, and em-

bryology has not yet been filled, but Thomas H. Evans, M.D., has been appointed a full time assistant professor in this department.

**The Yale Medical School.**—Yale University has received the sum of $125,000 for the erection and equipment of a clinical and pathological laboratory to be known as the Anthony N. Brady memorial laboratory. The announcement is made also that members of the Brady family will establish the Anthony N. Brady memorial foundation of $500,000, the income from which is to be given annually to the university for a term of ten years in order to enable the university to declare operative at this time the agreement with the General Hospital Society of Connecticut and to conclude the alliance between the New Haven Hospital and the Yale medical school. If within the ten-year period the university receives a total of $2,000,000 additional for medical school endowment and building funds the $500,000 will become the absolute property of the university. Over $1,110,000 has already been pledged, and if $390,000 more is obtained before January 1, 1916, the General Education Board will give the $500,000 necessary to complete the $2,000,000.

**Changes in Medical Faculty.**—The Board of Trustees of the Medical College of the State of South Carolina have announced the resignation of Dr. Joseph Maybank as professor of clinical medicine, and the appointment of W. H. Ziegler, Ph.D., as professor of pharmacology, and of Joseph B. Hyde, Jr., Ph.G., as full professor of theoretical pharmacy.

**Dr. Sturm Fined.**—Dr. Maurice Sturm, who was associated with Dr. F. F. Friedmann in the introduction of the latter's turtle serum in this country, was fined $1,639 by Supreme Court Justice Blanchard on June 11, for failing to obey an injunction order. The injunction was obtained by the Standard Distributing Company, after it had bought the rights to the turtle serum in this country, to restrain Dr. Sturm from offering the treatment. It was shown that Dr. Sturm, subsequent to the issuance of the injunction, had treated patients here and had contracted for the sale of the North Dakota rights to the serum. The amount of the fine imposed was the cost of the contempt proceedings.

**Proposed New Hospital Site.**—The New York State Hospital Commissioners, it is reported, are considering the purchase of a site at Oakside, Long Island, on which to erect a new State Hospital for the Insane. The site consists of 162 acres of meadow land fronting on Great South Bay. It is feared that some opposition to the plan may develop among the wealthy summer residents of the neighborhood.

**Doctors Sail.**—The White Star liner *Oceanic*, which sailed from New York on June 13, carried 140 physicians, the first official delegation to the International Congress of Surgeons which will be held in London early next month.

**To Investigate Coroners.**—The recent trial of Coroner's Physician Otto H. Schultze on charges of neglect of duty may lead to the abolition of the ancient officer of coroner in New York. The long threatened investigation of the department by the Commissioner of Accounts was ordered by Mayor Mitchel on June 12, at the request of the City Club, which, because of the serious charges made during the trial affecting the efficiency and integrity of the performance of the Coroner's function in this city, urges the importance of an independent official investigation.

**Hospital Controversy.**—The trouble between Commissioner Kingsbury of the Department of Charities, New York, and the private hospitals of the city because of the Commissioner's refusal to approve some of the bills of the hospitals for the treatment of ambulance cases, was partly removed when ten members of the Hospital Alliance met the Commissioner on June 11. Mr. Kingsbury requested that the Alliance appoint a committee to confer with him regarding the needs and desires of the hospitals, and assured the members of the Alliance that his department desired to cooperate with the private hospitals and that all complaints would be received and carefully considered. The following committee was appointed: Dr. A. J. Rongy, Lebanon Hospital; E. M. Gattle, Hospital for Deformities and Joint Diseases; Dr. Royal S. Copeland, Flower Hospital; Edward I. Lazansky; Tobias A. Keppler; Frank Moss; and the Rev. William Farrell, Williamsburg.

**Ambulance Head to Go.**—At a meeting of the Board of Ambulance Service of New York, held on June 10, it was decided to abolish the office of Director of the Ambulance Service of New York City, which is at present held by the Rev. Dr. Daniel C. Potter. The position, which has carried a salary of $5,000, will be abolished on June 30, 1914. The Board will ask for a revision of the city's charter so that the ambulance service can be transferred to one of the departments in charge of the public hospitals or to the Welfare Department which has been proposed to consolidate all the hospital work of the city. In the meantime the work of the ambulance service will be under the direction of Commissioner Kingsbury.

**Charitable Bequests.**—By the will of the late Dr. Everett Herrick of New York, the sum of $25,000 is left to the New York Skin and Cancer Hospital; $10,000 to the Society for the Relief of Wives and Children of Medical Men; $10,000 each to the Association for Improving the Condition of the Poor and the Children's Aid Society; $25,000 to the Academy of Medicine to establish the Everett Herrick Library Fund; and $25,000 to the same institution to establish the Everett Herrick General Fund.

Bequests of $100,000 each are made to the Presbyterian Hospital, St. Luke's Hospital, and the New York Post-Graduate Medical School and Hospital, by the will of the late Mr. Harris C. Fahnestock of this city.

**Smallpox in Passaic.**—The occurrence of one death from smallpox, the first in the town from this disease since 1893, has been reported. No fear of an epidemic is felt.

**Diagnosis of Cancer.**—At a recent meeting of the executive committee of the American Society for the Control of Cancer, the following resolution was adopted: "That it is the sense of the executive committee that the City of New York should undertake free diagnosis of specimens of tissue suspected of being cancerous." The Department of Health now has the matter under advisement and will consult with its Medical Advisory Board before taking action. In the meantime, the Commissioner of Health would be glad to learn whether the cooperation of the Department is desired by medical practitioners who do not command laboratory facilities in hospitals or elsewhere.

**Medical Degrees Conferred.**—At the commence-

ment exercises of the Fordham University College of Medicine, New York, on June 9, the degree of Doctor of Medicine was conferred by the Rector of the University on twenty-nine graduates in medicine, and the following award of prizes was announced: To Eugene T. O'Connor, the prize given by Prof. Justin Herold for the best thesis by a senior on medical jurisprudence, and the first prize offered by Prof. R. C. Kemp for a thesis in gastrointestinal diseases; to Thomas K. Ryan, the second Kemp prize; to Edmund B. Sullivan, the prize in dermatology offered by Prof. W. S. Gottheil; to Francis Treiber, Thomas K. Ryan, and Bernard O'Connor, the prizes given by Professor Coughlin to the three men most proficient in clinical work at Gouverneur Hospital; to Maurice Lyons and Maurice Pollock, the junior prizes for work in gastrointestinal diseases; and to J. O'Connor, the sophomore prize given by Dr. M. C. O'Brien for work in physical diagnosis.

At the commencement eyercises of the Cornell University Medical College, held June 11, twenty graduates received the medical degree from the hands of President Schurman. The prizes awarded were as follows: The John Metcalfe Polk Memorial Prizes for general efficiency to Helen Letitia Palliser, Philip Moen Stimson, and Robert Joseph Shea; Prizes for Efficiency in Otology, presented by Professor Whiting, to Philip Moen Stimson and Robert Joseph Shea.

Eighty-three graduates of the University and Bellevue Hospital Medical College, New York, received their degrees from the Chancellor of the University on June 10. The announcement of the award of prizes was made by Dr. William Hallock Park, Dean of the College, as follows: The Valentine Mott Medal, to George J. Geisler; the Glover C. Arnold Surgical Prize of $100, to Charles M. Robbins. Hospital appointments have been given to all the members of the graduating class.

The sixty-second annual commencement of the Woman's Medical College of Pennsylvania was held on June 3, when the medical degree was conferred on eighteen graduates.

At the annual commencement of Temple University, Philadelphia, on June 4, eighteen graduates of the Medical Department received degrees.

Fourteen students were graduated from the Hahnemann Medical College and Hospital, Philadelphia, on June 4.

The medical degree was conferred on seventy-six graduates of the Medico-Chirurgical College of Philadelphia on June 5, when Dr. John Grier Hibben, President of Princeton University, spoke on, "The Physician's Philosophy of Life."

**City Death Rate.**—During the week ending June 6, there occurred in New York City a total of 1,291 deaths, giving a death rate of 12.06 per 1,000 of population, as against 1,447 deaths and a rate of 14.05 for the corresponding week of 1913. This makes an absolute decrease of 156 deaths, equivalent to a relative decrease of 213. The decrease occurred chiefly among infants under one year, ninety-one less deaths being reported in this age group. The death rate for the first twenty-three weeks of 1914 was 15.15 per 1,000, a decrease of 0.21 compared with the same period of last year.

**Immigration Records.**—During the first ten months of the present fiscal year, which ends on June 30, immigrants have been arriving at American ports at the rate of nearly 3,000 a day, and the indications are that by the end of the year all records will be broken. During April 119,885 were admitted, and the total for the ten months was 1,038,956. In 1907, 1,285,349 immigrants reached here, and this has been the record for a single year. The 1914 total is estimated now at 1,351,000 immigrants.

**Personals.**—Dr. J. Howard Agnew, formerly first assistant in the department of medicine, University of Michigan, has accepted the full time Professorship in Medicine in the University of Alabama, School of Medicine, at Mobile.

Surgeon-General William C. Gorgas, U. S. A., received the honorary degree of D.Sc. from Princeton University at the commencement exercises on Tuesday of this week. On the following day Yale University conferred upon him the honorary degree of doctor of laws.

Dr. Parker Syms announces his removal to 361 Park Avenue, New York.

Dr. Henry W. Rihl of Philadelphia, who was graduated from the Jefferson Medical College in 1849, celebrated his ninety-first birthday on June 2.

**The American Association of Immunologists.**—The first annual meeting of this association will be held at the Hotel Chelsea, Atlantic City, on Monday, June 22, under the presidency of Dr. Gerald B. Webb of Colorado Springs. The secretary is Dr. Martin J. Synnott of Montclair, N. J. The program contains a list of fourteen papers on the Abderhalden test, the Wassermann reaction, vaccine therapy, autosero-therapy, and related subjects.

**Medical Society Elections.**—American Society of Tropical Medicine: Annual meeting at the Harvard Medical School, Boston, on May 30. Officers elected: *President*, Dr. Charles F. Craig, U. S. A.; *Vice-Presidents*, Dr. Milton J. Rosenau, Boston, and Dr. Bailey K. Ashford, San Juan, Porto Rico; *Secretary*, Dr. John M. Swan, Rochester, N. Y.; *Assistant Secretary*, Dr. Allen J. Smith, Philadelphia; *Treasurer*, Dr. Joseph D. Weis, New Orleans; *Councillors*, Dr. Samuel T. Darling, Ancon, Canal Zone; Dr. Henry J. Nichols, Washington, and Dr. Victor G. Heiser, Manila.

Northeast Texas Medical Association: Semiannual meeting at Texarkana on June 3. Officers elected: *President*, Dr. R. H. T. Mann, Texarkana; *Vice-President*, Dr. G. A. Mosely, Jefferson; *Secretary*, Dr. E. L. Beck, Texarkana.

Willimantic (Conn.) Medical Society: Annual meeting at Willimantic on June 3. Officers elected: *President*, Dr. Laura S. Hills; *Vice-President*, Dr. W. P. S. Keating; *Secretary-Treasurer*, Dr. Charles A. Jenkins.

East Tennessee Medical Association: Annual meeting at Harriman on May 22 and 23. Officers elected: *President*, Dr. George P. Zirkle, Kingston; *Vice-Presidents*, Dr. W. Dexter Padget, Lenoir City, and Dr. Arthur W. Gross, Dayton; *Secretary-Treasurer*, Dr. Hiller P. Larimore, Chattanooga.

Orleans County (Vt.) Medical Society: Annual meeting at Orleans on May 14. Officers elected: *President*, Dr. Robert M. Wells, Orleans; *Vice-President*, Dr. B. D. Longe, Newport; *Secretary-Treasurer*, Dr. James F. Blanchard, Newport.

Vermont Homeopathic Medical Society: Annual meeting at Montpelier on May 27. Officers elected: *President*, Dr. Robert H. Burke, West Burke; *Vice-President*, Dr. Edwin B. Clift, Fair Haven; *Secretary*, Dr. George I. Forbes, Burlington; *Treasurer*, Dr. Fred E. Steele, Montpelier.

**Obituary Notes.**—Dr. Edward A. Reiley of Atlantic City, N. J., a graduate of the New York University Medical College in 1881, and a member of the American Medical Association, the Medical Society of New Jersey and the Atlantic County Medical Society, died at his home on June 9, aged 59 years.

Dr. Murdoch Alexander Lindsay of Halifax, N. S., a graduate of the University of Edinburgh, Scotland, in 1908, and professor of pathology and bacteriology in the Dalhousie Medical College, Halifax, is reported to have been lost in the wreck of the *Empress of Ireland* in the St. Lawrence on May 29.

Dr. Arthur R. Tiel of Matteawan, N. Y., a graduate of the Eclectic Medical College of the City of New York in 1878, died at his home on June 1, aged 60 years.

Dr. Amos Lawrence Mason of Boston, a graduate of Harvard University, in 1863, and of the Harvard Medical School in 1872, physician to the Carney Hospital from 1878 until his death, consulting physician to the Boston City Hospital, formerly associate professor of clinical medicine at the Harvard Medical School, and a member of the Massachusetts and Suffolk District Medical Societies, and the Association of American Physicians, died suddenly from heart failure, at Albany, N. Y., on June 5, aged 72 years.

Dr. James A. Blake of Brooklyn, N. Y., a graduate of the Albany Medical College in 1868, and of the College of Physicians and Surgeons, New York, in 1869, and a member of the New York State and Kings County Medical Society, and the Physicians' Mutual Aid Association, and formerly on the staffs of the Methodist Episcopal Hospital and the Brooklyn Eye and Ear Hospital, died at his home on June 8, aged 71 years.

Dr. Francis Bishop Harrington of Boston, Mass., a graduate of the Harvard University Medical School in 1881, since 1889 a member of the staff of the Massachusetts General Hospital, and for many years surgical chief of staff, a lecturer at Harvard University, and a member of the American Medical Association, the Massachusetts State and Suffolk District Medical Societies, being a former president of the latter, and the American Surgical Association, died at his home in Brookline, after a long illness, on June 8, aged 60 years.

Dr. George Dallas Nutt of Williamsport, Penn., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1869, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania and the Lycoming County Medical Society, died at his home on May 30, aged 69 years.

Dr. D. Winton Dunn of Duquoin, Ill., a graduate of the American Medical College, St. Louis, in 1890, formerly mayor of Duquoin, and a member of the American Medical Association and the Illinois State and Perry County Medical Societies, died on June 7, in the sixty-second year of his age, as a result of pistol shot wounds inflicted the night before by a man with a fancied grievance against the physician.

Dr. John Andrew Lee of Pine Hill, Ala., a graduate of Vanderbilt University, Medical Department, Nashville, in 1887, and a member of the Medical Association of the State of Alabama, and the Wilcox County Medical Society, died at a hospital in Birmingham, on May 29, aged 51 years.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

GENERAL MEDICAL COUNCIL—PRESIDENT'S ADDRESS—ANOMALIES OF REGISTRATION—FINANCES—PHARMACOPŒIA—COMMITTEES AND OFFICERS APPOINTED—CHARGES OF MISCONDUCT—FALSE CERTIFICATES: OF DEATH, OF ILLNESS, AND INCAPACITY FOR WORK — GRESHAM LECTURES ON NURSING—SMALLPOX PREVENTION—AVICENNA'S TOMB —OBITUARY.

London, June 5, 1914.

The General Medical Council has been holding its summer session. Sir Donald Macalister opened with an inaugural address much after the usual pattern. A reference to his illness during the November meeting, with thanks for the help and cooperation he had then, as always, received; to the retirement of some and the deaths of two others, was followed by remarks on the extension of the Medical Act of the dominions and reciprocity under that act to India, Japan, and other countries.

The bill for amending the provisions for the election of direct representatives was mentioned next, the President having been given to understand that "if the conditions were favorable" it will receive support from both sides of the House —a big "if" which may not count for much. The next topic was the unsatisfactory state of the law in relation to certification of deaths. Complaints from coroners pointing out anomalies in registration have led to extracts from the council's minutes being supplied to the Registrar-General who has replied that fresh instructions were being issued and these will effect improvements long desired by the Council. In particular local registrars were to be instructed that any death for which no certificate from a registered practitioner was produced must be reported to the coroner; further the certificate must be by the practitioner in attendance during the last illness. In addition the president held much more should be done to safeguard both the public and the profession and he contemplated that fresh legislation might be necessary. He had been requested to give evidence in two royal commissions as to the inquiries in the purview of the Council and had supplied reports, tables, and other information in answer to questions. As to India he had asked the chairman, Sir C. Ball, to take his place as witness. The king had appointed Drs. McVail and Norman Walker with the president on a board for improving medical and nursing services in Scotland and they had already found the need of better training for midwives.

The finances of the Council were spoken of as satisfactory—at the end of 1913 the old deficit was paid off and the new year started with a balance to the good of £282.

The new edition of the British Pharmacopœia was practically ready for publication and a revised proof would be laid on the table in the expectation that subject to corrections of the final proof it would appear during the summer. As chairman of the Pharmacopœia Committee the president expressed deep obligations to the editors, Professors Tirard and Greenish, and to several committees of reference. The proofs were laid on the table before the session closed. To

the chairman of the education and examination committees he had suggested another cycle of inspection being undertaken. Since the reports of the last cycle a number of new licensing bodies had been ordered by Parliament and are now fully organized for work and it would seem well that the Council should possess detailed information from actual inspection to supply on demand by government.

The President was thanked for his address, tables showing results of competitions for commissions in the services were referred to committee on examinations and other formal business carried through, including appointments of various committees, assistant examiners, and the reception of the financial report.

During the session a number of cases of unprofessional conduct have been investigated and the Council has convicted some and has further expressed itself distinctly as to some others which have been dealt with more leniently. One of the earliest complaints was so carefully gone into that the trial, so to say, went over to the second day. It was that of a practitioner accepting the post of medical officer to an association, formed after the Insurance Act was in operation, knowing members were sought by canvassing and solicitation of the Miners' Union and assisting in the same way. The Council found that the practitioner had by public speeches in the district and advertising in those speeches his qualifications taken a prominent part. He was ordered to appear at the November session and produce evidence of his conduct in the interval.

Another case was one of giving a false certificate as the cause of death which had been proved in the Westminster police court and a fine inflicted. The practitioner pleaded that the certificate was filled in correctly, excepting the omission of the word miscarriage before the immediate cause —peritonitis—and this was done to save the girl's reputation, not to deceive. He had promised not to divulge the patient's secret.

The Council took the gravest view, but as he had been already convicted and punished would suspend judgment until November when he must appear again and produce evidence from medical men and others that in the interval his conduct had been without reproach.

Another practitioner convicted of giving to an insurance agent certificates of deaths of seven persons, none of whom he knew, was struck off the register.

Besides false certificates of death another group of untrue or misleading certificates were brought before the Council. These related to sickness and in regard to some of them the complaints were made by the Lords Commissioners of the admiralty whose counsel stated that at naval ports men were given short leave and sometimes when the time expired certificates were sent in that the man was unable to follow his occupation. It was ascertained in some cases the doctor had not even seen the man and the admiralty felt it would be most unfortunate if they could not rely on medical certificates and therefore they reported cases to the Council. One doctor admitted he had been guilty in his case but declared he had not thought he was doing wrong at the time. He gave the certificate on the representation of the man's landlady, believing he was suffering from another attack of a malady for which he had previously treated him, and he promised never to do so again. He was ordered to appear at the next session with evidence from his medical colleagues and others of his conduct in the interval, etc.

Other cases were brought forward but these will suffice to show how the Council exercises its disciplinary powers. It has only one penalty it can inflict—exclusion from the Register. To enable it to deal with cases for which this seems rather too severe, for the effect of exclusion is to disqualify the offender from practice, the Register being the only legal authority, the Council has adopted the plan of adjourning their decisions, as seen in the foregoing cases. It seems a clumsy way of measuring penalties but only legislation can revise it.

Dental cases are referred to the dental committee for investigation and on its report the Council passes judgment in the same way, viz., either erases the name of the accused from the Dentists' Register or adjourns the decision to another session. The dental committee and the British Dental Association seem alike determined to put down canvassing, advertising, and all unprofessional practices.

At Gresham College, Professor Sandwith has been lecturing on Modern Nursing which he traces to the inspiration of Pastor Fliedner whose first wife began with him a society to befriend discharged prisoners. Out of this grew eleven institutions. There was some opposition when Fliedner bought a small house and fitted it up as a hospital. Women responded slowly to the demand for nurses but those who came were carefully trained and called deaconesses. The example set by Fliedner, said Professor Sandwith, brought a new atmosphere into hospital management—an atmosphere which can be felt now even in our workhouse infirmaries. It was at Kaiserwerth, where Fliedner began, he added, "that Florence Nightingale resolved wholeheartedly to devote herself to the service of God in the service of man."

The Port Sanitary Committee has reported to the London Corporation that the arrangements for preventing the entry of smallpox into the country are inadequate and suggested that vessels arriving from ports where the disease exists or is suspected to exist should be inspected as is done in the case of yellow fever, cholera, etc. The local government board does not favor this course—at any rate for the present.

The Historical Section of the Royal Society of Medicine has approved of a proposal made by Sir William Osler to join the French Society of the History of Medicine to restore the tomb of Avicenna who was buried at Hamadan about 1030 and sadly needs repairs. The original sarcophagus is there. Whatever the position of Avicenna in medicine, he was undoubtedly the greatest of the Arabian physicians.

The Aberdeen University staff has sustained the loss of a distinguished member by the death of Dr. George Dean, professor of pathology since 1908. Some years before being appointed to this chair, he had charge of the serum department of the Lister Institute. He had also been an examiner in bacteriology and held other appointments.

Dr. Alfred Harvey of St. Leonard's, M.D., Aberdeen, 1860, died on May 28 at the age of 87.

Surgeon-Mayor-General Robert Lewer, A.M.S. (retired), died suddenly on May 29 in his seventy-ninth year.

## OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

MEETING OF THE SIXTH NATIONAL CONFERENCE ON CITY PLANNING IN TORONTO—MEETING OF THE ONTARIO MEDICAL ASSOCIATION IN TORONTO—COMING MEETING OF THE CANADIAN MEDICAL ASSOCIATION—COMING MEETING OF THE CANADIAN ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS — HOSPITALS IN ONTARIO — FOTHERGILL MEDAL FOR DR. ADAMI—ADDITION TO ROYAL VICTORIA HOSPITAL, MONTREAL—RECEPTION HOSPITALS FOR THE INSANE IN ONTARIO—RESIGNATION OF DR. F. J. SHEPHERD, MONTREAL.

TORONTO, June 5, 1914.

THE Sixth National Conference on City Planning was opened in Toronto on May 25 by H. R. H. the Duke of Cannaught. The attendance numbered 275, most of whom came from the large cities of the United States. Representatives were present from England and the cities of Canada were well represented. The Duke of Connaught in his opening speech laid stress on the importance of the subject and the need for giving due consideration to it at this stage of the development of our cities, if they were not to suffer from the evils of slums and congested districts which lack of foresight had led to in the countries of Europe. The whole question was one in which prevention was more effective by far than cure, for once a vicious system was firmly established, with vested interests grown round it, the uprooting of the system was likely to prove a lengthy, controversial, and desperately expensive process. To deal with this potential evil substantive legislation was absolutely necessary. The speaker offered three suggestions; the need for the provision of ample park and playground space, the creation of main arteries of communication in cities and last and most important, the securing of proper and adequate housing conditions for the increasing urban population.

Mr. George McAneny of New York made a reply to the address and in the course of his remarks drew attention to the fact that the men and women present were not faddists, but were interested in the problem of the completion of cities along the correct lines of development. Many cities had grown up wildly, and the measure of the correction of their ills was a formidable one from the monetary standpoint. In discussing the growth of the town planning idea the speaker congratulated the Duke of Cannaught on the part which the British nation had played, the inspiration for the work on this continent having come from England. Hon. Clifford Sifton, chairman of the Commission of Conservation of Canada, said that Canada had paid but little attention to the problem of building for the future, and one of the important matters before the convention was to stimulate public interest and intelligence with a view to preparing legislation for submission to the Canadian Government in order that an adequate and comprehensive Town Planning Act might be placed on the statute books of the Dominion. Unlike the cities of Europe and some American cities, Canadian cities were not yet out of control and the next ten years should see the solution of all the housing difficulties and preparation made for the future.

Mr. G. T. Hewitt spoke of the garden city movement and told of the movement for the establishment of model towns in England and declared that the only solution of the problem of homes for the worker lay in the establishment of garden cities.

The Ontario Medical Association opened its thirty-fourth annual meeting in Toronto on May 26. Nearly 200 delegates were present. As at the previous meeting most of the time was devoted to clinics. The outstanding feature of the meeting was the discussion of the proposed separation of the Ontario Medical Association from the Canadian Medical Association. Dr. Adam Wright of Toronto moved that the connection between the two associations should be severed. After a brief consideration, an amendment to Dr. Wright's motion was moved by Dr. Wallace of Hamilton and seconded by Dr. W. A. Powell of Toronto, or, rather a new motion was adopted which places the whole matter upon the shoulders of a special committee, and shelves it for a year by instructing that committee to report back at the next annual meeting. An event of the opening day was the vigorous attack made upon "quackery" and the forms of so-called healing that call for no particular training or education on the part of the practitioner, made by Dr. C. F. McGillivray, president of the association in his annual address. It was pointed out that while the matriculation entrance requirement to medicine was being made harder every year the university course had been lengthened from four to five years. Yet with the qualified members of the profession compelled to measure up to constantly advancing standards the chiropractor, the osteopath, and the Christian Scientist had the way smoothed for them. There was but one way of dealing with the problem, declared Dr. McGillivray, that was to set a high standard and require all to come up to it. He was certain that the faddists would soon disappear if they were required to spend five years in study and pass examinations of a stringent kind. The Government should cooperate with the medical profession to bring this about. The day's programme was divided into two sections. In the medical section five addresses were given dealing with treatment of tetanus by carbolic acid, on tuberculosis, Vincent's angina, and Banti's disease. The afternoon session was devoted to a discussion on the treatment of syphilis. At the evening session Dr. Finney of Johns Hopkins University, Baltimore, gave an address on the cause of failure in operations for cholelithiasis.

The annual meeting of the Canadian Medical Association will take place at St. John, N. B., on July 7 to 10. The address in medicine will be given by Dr. Thomas McCrae, professor of medicine at Jefferson Medical College, Philadelphia. The address in surgery will be given by Mr. J. Rutherford Morison, F. R. C. S., professor of surgery at the University of Durham. The address in obstetrics will be given by Dr. Henry Jellett, F. R. C. P. I., master of the Rotunda Hospital, Dublin. A public lecture will be given by Dr. C. A. Hodgette of Ottawa, medical adviser to the Canadian Commission of Conservation. There will be held a symposium on intestinal stasis, in which Dr. Max Einhorn of New York, Dr. J. T. Case of Battle Creek, Mich., and Dr. L. G. Cole of New York will take part.

According to a report issued recently by Dr. Bruce Smith of Toronto, there are in Ontario 89 public hospitals, 57 private hospitals, 37 refuges, 8 sanatoria for consumptives, 33 orphanages, 3 homes for incurables, and 31 county houses of refuge. During the year ending Sept. 30, 68,738 patients received hospital treatment and 4,058 deaths and 4,210 births occurred. The amount expended

on hospitals during the year was $3,155,340, of which $232,276 was granted by the provincial government.

The Fothergill gold medal of the Medical Society of London for 1914 has been awarded to Dr. John George Adami, professor of pathology at McGill University for his work on pathology and its application to practical medicine and surgery.

Plans are in course of preparation for adding a wing to the Royal Victoria Hospital, Montreal. It will be called the Ross Memorial Pavilion. A small portion of the cost has been subscribed but the greater part of the expense will be borne by Mr. J. K. L. Ross in memory of his father, the late Mr. James Ross. The new wing will provide accommodation for 150 private patients and will increase the total accommodation to 475 beds.

A bill affecting cities was introduced into the Ontario Legislature by Provincial Secretary Hanna. The bill provides for the establishment of reception hospitals for the insane by cities having a population of 100,000 and over. The plans and cities must be approved by the Government and the institution must be under the control of the Provincial Secretary. The cost of the maintenance in excess of the amount provided by the municipalities from which the patients are admitted is to be paid by the provincial government. Dr. F. J. Shepherd of Montreal has resigned the professorship of surgery at McGill University.

2. The Use of Neosalvarsan from a Clinical and Serological Standpoint. J. H. Blaisdell.
3. Cancer of the Tongue Based Upon the Study of Over One Hundred Cases. J. C. Bloodgood.
4. The Use of Iodoform Oil in Joints. E. G. Brackett.

**1. Cancer of the Uterus.**—F. Cobb presents a complete analysis, from the standpoint of end results, of all the cases of cancer of the uterus at the Massachusetts General Hospital for fourteen years, from 1900 to 1913, inclusive, 367 in number, of which 70 were the author's own personal cases. He emphasizes the importance of early diagnosis of cancer of the cervix, shows the possibilities of cure by the extended abdominal operation, and describes certain original methods of operating which are of importance. The commonest early symptom of uterine cancer is bleeding; pain is a late symptom. In every case where a radical operation is inadvisable one should make determined and repeated efforts toward the prolongation of life and relief of pain and hemorrhage. Curettage without the use of the cautery is unwise and the cautery itself probably has a positive influence in checking cancer growth much deeper than the surface actually cauterized. Between cauterizations much good can be done by local applications of either acetone or formalin. In cases in which radium emanations can be obtained they should be tried, not neglecting general treatment, bromide of arsenic, and tincture of iodine, and the judicious use of opium. In reviewing the hysterectomies certain features are pointed out by the author as worthy of special note. Simple vaginal hysterectomy was the safest in the hands of a large number of operators and gave a larger percentage of cures than simply abdominal hysterectomy by numerous surgeons. The important factors in the radical operation are: The preliminary preparation; the anesthetic with special reference to the prevention of shock; the abdominal incision; the freeing and handling of the uterus; removal of the parametrium and glands; control of hemorrhage; prevention of peritoneal infection and implantation metastasis from the growth itself; and drainage and aftertreatment.

**4. The Use of Iodoform Oil in Joints.**—E. G. Brackett discusses this subject. He notes that there are two general types of cases for which the procedure may be used: (1) Those in which there is no active disease at the time, and in which the object of the injection is largely mechanical, as, for instance, cases of old arthritis with adhesions, in which it is necessary to keep the surfaces apart after freeing the adhesions. (2) Those in which there is present active disease, and in which the object of the injection is largely for the effect of the agent employed on the immediate process, as, for instance, in synovitis, of tuberculous, gonorrheal, or other origin. The injection of olive oil is always made by open incision and not by puncture. Sufficient fluid is always left in the joint to keep the capsule under tension, therefore some form of stitch is necessary by which the tension can be maintained at the time of the withdrawal of the syringe. The adhesions in old cases are broken up before the joint is filled with oil and the capsule closed; other than this no violence is done to the cavity of the joint, and no handling is permitted, particularly of the tuberculous joints. Fixation by plaster or splints is seldom used. Olive oil has been used in all of the cases of the series.

8. Ulceration of the Stomach and Duodenum from the Medical Standpoint. A. F. Chace.
9. Fatal Accidents Following the Injection of Antimeningitis Serum. S. P. Kramer.
10. Predetermination of Sex. I. Bram.

**1. Neurotic, Psychasthenic, and Hysterical Children.**—J. P. C. Griffith finds that symptoms of nervousness may be seen even in infants, for instance, in those who cannot sleep in a room without a light, wake on the slightest noise, vomit if moved or disturbed in any way, although never vomiting during sleep, or vomit a food of a new taste. In many cases vomiting in infants is largely a nervous habit. In many instances the giving of a pacifier immediately after the bottle will set the mind at rest and prevent vomiting. As a rule the employment of any such article is to be discountenanced but there are times in which in this way it does good. The condition of simple nervousness is separated by no very sharply marked boundary line from that of psychasthenia. The difference consists in the predominance of the psychic element to an excessive degree in the symptoms of the latter affection. Certain manifestations of hysteria are undoubtedly seen in infancy, but that this is unusual. In childhood hysteria is not common, and there is no difference in the susceptibility of the sexes until puberty is approached, when the disorder becomes more frequent, and is seen oftener in girls. No very exact definition seems possible. One can only speak of hysteria as a psychic neurosis in which there is great emotional excitability; an exalted egoism, a desire to attract attention, defective will power, and imperative and perverted ideas often produced by suggestion or autosuggestion.

**3. Surgical Treatment of Tuberculous Peritonitis.**—A. Judd emphasizes the use of 50 per cent. peroxide

of hydrogen for the purpose of diagnosis, and through oxidation, or possibly by increasing the congestion, to destroy the tubercles. It has seemed that the primary union which the author has had in every case so far has been due in large measure to the liberal use of the same agent. The results have seemed remarkable to the author, and is certainly better than he has been able to obtain in ordinary laparotomy wounds. Thorough flushing of the abdominal cavity is necessary in order that the peroxide may come in contact with all the affected areas. The necessity of getting these patients out of bed as quickly as possible should be borne in mind. One well knows how badly they do, if housed or kept upon their backs. The necessity for aftertreatment in the form of proper hygiene, nutrition, and appropriate medication is alluded to.

5. **Surgery in War.**—A. K. Yoosuf concludes that both in theory and in practice surgery in war is similar to emergency practice in ordinary life. The surgeon must give the same attention to and take the same precautions against infection in the soldier as in the ordinary man. The fate of the wounded depends more or less on the men applying the first aid. A surgeon must not attempt to disinfect a wound on the battlefield. In emergencies operations must be performed in the field hospitals. No probing for bullets must be made on the battlefield. Tourniquets, for hemorrhage, must be applied for not more than four to six hours, as there is danger of gangrene. The *x*-ray is the most valuable diagnostic agent in war. Gunshot wounds of the extremities demand conservative surgery. Penetrating gunshot wounds of the skull indicate operative interference. Gunshot wounds of the chest demand strict antosepsis. Celiotomy is indicated in penetrating gunshot wounds of the abdomen.

6. **Fracture of the Lower End of the Humerus.**—J. D. Whitall states that occasionally a case cannot be dressed in Jones's position owing to compression of the brachial artery. A useful joint function may be preserved with an anterior angular splint, early passive motion, massage, and use of electricity.

8. **Ulcer of the Stomach and Duodenum.**—A. F. Chace concludes that the suggestive symptoms of ulcer are the existence of characteristic pain, vomiting, localized areas of tenderness in the epigastrium and over the Boas point in the back, and hypersecretion, and that confirmatory signs are found in the presence of blood in the vomitus or in the stools, a break in the peristaltic wave in the *x*-ray pictures, and the presence of food particles in the stomach twelve hours after meals. It should be remembered that many cases of ulcer remain latent throughout their entire course. The conditions from which ulcer has to be differentiated are gastric neuroses, cholelithiasis, the gastric crises of tabes, and cancer. One of the greatest difficulties in diagnosticating the foregoing conditions is the fact that gastric ulcer can exist simultaneously with any of them. Gastric neuroses may be differentiated by the irregularity of symptoms, the absence of blood in the vomitus or stools, and the negative character of the *x*-ray examination. In gallstones the pain bears no definite relation to the meals, and often radiates to the right shoulder. Tenderness over the gallbladder, and to the right of the ninth, tenth, and eleventh vertebrae posteriorly is suggestive of gallstones. In cholelithiasis, moreover, one is apt to have hypersensitiveness over Head's zone, and other signs, such as Moynihan's and Murphy's.

9. **Fatal Accidents Following the Injection of Anti-meningitis Serum.**—S. P. Kramer states that in March, 1913, he reported a number of cases of respiratory paralysis following the injection of anti-meningitis serum. Because of the similarity of these accidents to those following the lumbar subdural injection of cocaine, and as the result of an experimental investigation, he concluded that the accident was due to the phenol contained in the serum as a preservative. There was a sudden paralysis of respiration without dyspnea, coming on in from five to twenty minutes after the lumbar injection of serum containing tricresol, exactly as sometimes happens when cocaine is injected into the subdural space. This the author regards as due to acute intoxication of the respiratory center in the medulla by phenol, a well known nerve poison. The cases reported by French observers following the injection of Dopter's serum (without tricresol), are typical cases of serum disease without respiratory paralysis, and are held to be such by the authors who reported them and by Dopter himself. The author warns the profession against injecting serum containing tricresol into the subarachnoid space.

3. **Prevention of Surgical Shock and Postoperative Pain.**—A. B. Cooke notes that the four cardinal principles of anoci-association are: (1) The preliminary administration of a hypodermic of morphine and scopolamine. (2) The use of nitrous exide and oxygen for general anesthesia. (3) The complete blocking off of the operative area by the infiltration of a solution of novocaine. (4) The infiltration of all tissues traumatized which are supplied with sensory end-organs (except the skin) with a solution of quinine and urea hydrochloride. To these the author adds a fifth, referring especially to the prevention of gas pains following abdominal operations, namely, early opening of the bowels. The preliminary hypodermic of morphine and scopolamine is designed to allay apprehension and tranquillize the patient. Nitrous oxide is preferable to ether for general anesthesia, even in face of the fact that it possesses certain inherent disadvantages. The combination of local with general anesthesia may be termed the crucial feature of anoci-association. The anesthetic effect of quinine and urea hydrochloride is maintained for from forty-eight to seventy-two hours; that of novocaine is quite transient. It has been the author's regular plan to begin the administration of calomel in powder form, usually combined with cerium oxalate, twenty-four to thirty-six hours following operation, giving a half-grain of the former and one grain of the latter at a dose every hour until six doses are taken.

4. **Living Lactic Acid Bacilli in Diphtheria.**—E. V.

Goltz and W. D. Brodie note that the average quarantine period of six cases of diphtheria in which the lactic acid bacillus was used was twenty days. The average quarantine period of the six controlled cases treated locally only with Seiler's solution as a gargle was sixteen days. The average quarantine period of fifty-seven cases admitted to the hospital during January, February, and March, 1914, comprising all cases discharged with the required cultures, was twenty-one days. Lactic acid bacilli in the authors' experience hasten the disappearance of the membrane, but do not hasten the disappearance of the diphtheria bacilli from the throat.

5. **The Use of Hirudin in the Transfusion of the Blood.**—H. S. Satterlee and R. S. Hooker state that in making use of herudin for transfusion they employed their regular pipettes and cannulas, but they dispensed with the paraffin coating of the cylinders. They prepared the pipettes by introducing from 3 to 5 c.c. of a 1:500 solution of hirudin in salt solution, flowing this liquid very thoroughly over the interior of this cylinder and draining away the excess through the tip of the pipette just previous to use. From 1.5 to 2 c.c. of this solution or approximately 3 milligrams of hirudin are retained by adherence to the walls of the pipette and for more than twenty minutes this is sufficient to prevent 220 c.c. of blood, drawn into the pipette, from clotting. With the exceptions already noted, the operation with hirudin is conducted in precisely the same way as with the paraffin-coated apparatus. The preparation of the pipettes is the same, except that the first coating of the cylinders with paraffin is omitted. A partial coating with paraffin, however, is advisable. This coating should be done by aspirating the sterile melted paraffin mixture just within the neck of the cylinder and expelling it again. This use of paraffin from the tip to the neck is primarily to insure an airtight junction of the pipette tip with the metal bushing, and of the latter with the neck of the cylinder, but it also has a demonstrable effect in lessening thromboplastin formation during the aspiration of blood, and permits the employment of a minimal quantity of hirudin. The hirudin method may be employed without any paraffin whatever by using a 1:300 solution of hirudin for coating and with care that the interior of the pipette tip is perfectly smooth and brightly polished and that all connections are tight against airleakage, but these contingencies are so surely and easily provided for by aspirating a little sterile paraffin just above the neck of the pipette, that the latter method is to be preferred.

8. **The Early Diagnosis of Lead-Poisoning.**—H. Linenthal concludes that in the diagnosis of plumbism, the most frequent type of occupational poisoning, there is in many quarters a tendency to give too much emphasis to the presence of the lead-line or basophilic degeneration of the red cells. While the presence of these signs is often of great aid in the diagnosis of obscure cases of non-industrial origin, their absence should not prevent a diagnosis when certain symptoms characteristic of early plumbism manifest themselves, more particularly when a history of exposure to contact with lead can be obtained. The history of exposure is the all-important aid in the diagnosis; careful inquiry should be made by the physician as to the details of the patient's work, and he should not be satisfied with a general designation which may not give any indication of exposure to lead.

12. **The Practical Significance of the Adrenals.**—R. G. Hoskins states that the available evidence indicates that the suprarenals secrete a substance of remarkable potency, which selectively affects the tissues having sympathetic nervous control, thereby influencing many vital functions. Suprarenal discharge occurs when the individual is subject to stress, as strong emotions, pain, or asphyxia. The discharge integrates the body for muscular response: (a) by shifting the blood from the vegetative to the motor, nervous, and respiratory organs; (b) by increasing blood pressure; (c) by causing a discharge of dextrose into the blood for the use of the laboring muscles; (d) by dilating the bronchioles, permitting freer breathing, and (e) by reducing fatigue. It also hastens the coagulation time of the blood. The first three functions are of direct clinical importance. During quiet existence the suprarenal secretion, if occurring at all, is below the threshold necessary to stimulate the sympathetic system. Sympathetic activity *per se* is not impaired by suprarenal extirpation. Suprarenal destruction results in fatal asthenia of the skeletal and cardiac muscles. This is probably due to the loss of the suprarenal cortex, not of the specific secreting tissue. Addison's disease is probably due, therefore, to a functional failure of the suprarenal cortex.

*May* 30, 1914.

1. Intrinsic Cancer of the Larynx. Sir St. Clair Thomson.
2. A Note on a Method by which Remedial Agents May be Mingled with the Cerebral Cerebrospinal Fluid. C. A. Ballance.
3. The Treatment of Parenchymatous Syphilis by Intracranial Medication. H. Campbell.
4. The Intrathecal Injection of Salvarsanized Serum. G. W. Spencer.
5. The Occurrence of Ascites of a Non-Tuberculous Origin in Chronic Recurrent Diarrhea in Childhood. F. J. Poynton.
6. An Operation for Undescended Testicle. R. Thompson.

1. **Intrinsic Cancer of the Larynx.**—Sir St. Clair Thomson concludes that cancer of the vocal cords is in its early stages a very slow, progressive, and strictly limited process. Alteration of voice is the principal and may be the only symptom. Persistent hoarseness in any patient calls for a definite diagnosis. Diagnosis is based chiefly on inspection of the larynx. Only in certain cases where the growth is a superficial and not an infiltrating one can it be confirmed by microscopical examination. The growth, even when it occupies almost the entire length of a vocal cord, can sometimes be completely removed by endolaryngeal operation in early cases. But this completeness can only be ascertained when by laryngofissure the remains of the vocal cord and adjoining soft parts have been removed and submitted to the pathologist. Laryngofissure is, therefore, the operation of choice in all cases of endolaryngeal cancer. The operation offers the very best prospects; first, because the disease remains for some time superficial and limited; and, second, because laryngofissure cannot be considered a dangerous operation. Statistical results show a lasting cure in 80 per cent. of the cases and if all cases presented themselves and were diagnosed early there is no reason why the results should not be even more satisfactory.

2. **Remedial Agents and the Cerebrospinal Fluid.**—C. A. Ballance states that salvarsanized serum or other remedies introduced into the subarachnoid space of the brain will reach the nerve cells. There are certain obvious objections to the injection being made into the substance of the brain, and a considerable operation would be necessary if the serum were to be injected into the basal cisternæ. To inject the serum underneath the arachnoid over the cortex might injure the surface of the brain, and the opening made for the passage of the cannula might allow of its subsequent

escape. These considerations seemed to point to the lateral ventricle as the best site for the injection. The author's technique was as follows: The patient was anesthetized and the head arranged in a position as nearly vertical as possible. A trephine opening was made to the right of the middle line just in front of the bregma. The dura was then opened and the inner surface of the right cerebral hemisphere was gently drawn outwards by means of a retractor bent at a right angle. It had previously been ascertained that the anterior cornu of the lateral ventricle was distant 6½ to 7 cm. from the surface of the scalp at the midline on the vertex. A cannula (having a lumen of 1 mm. and a length of 3 inches) was then passed through the anterior part of the corpus callosum about a quarter of an inch to the righ of the middle line. It was felt to enter the anterior cornu of the lateral ventricle. The cannula was fitted with a stylet whose rounded end projected beyond the end of the cannula. The passage of the stylet and cannula through the corpus callosum could not divide any vessel and might be thought of as pushing aside rather than cutting any of the commissural fibers of the corpus. On the entrance of the cannula into the lateral ventricle the stylet was withdrawn and the cerebrospinal fluid escaped, not continuously, for there was a distinct ebb and flow due to the arterial pulsation or to the respiratory movements. A rubber tube attached to a graduate glass vessel was then fixed to the cannula and the infusion into the ventricle commenced, at first with normal saline solution and then with salvarsanized serum. Of the latter quantities varying from 35 c.c. to 60 c.c. have been used. As the infusion proceeded it was noticed that the brain bulged into the trephine opening but on closer inspection it was clear that the bulge was not a brain hernia and that the cortical subarachnoid space was filling up with fluid. The 90 c.c. of fluid (salt solution and serum) took about twenty minutes to infuse and the pressure varied from 6 to 18 inches. No ill-effects have occurred from the injection of the serum into the ventricle. In the first case as the fluid was flowing very slowly the glass vessel was raised when a little respiratory difficulty occurred which was probably due to pressure in the fourth ventricle, the fluid not escaping quickly enough through the foramen of Majendie.

3. **Intracranial Medication in Parenchymatous Syphilis.**—H. Campbell calls attention to the technique adopted by Ballance who decided that the best way to introduce a large quantity of serum into the cranial subarachnoid space would be via the anterior horn of the lateral ventricle, by means of a cannula passed along the side of the falx cerebri through the corpus callosum, and this operation Ballance performed successfully on a case of general paralysis. The patient made a rapid recovery. The operation was performed on another patient and this time five drops of Fowler's solution were added to the serum. Convalescence on this second occasion was attended by a slight mental disturbance, the result probably of the Fowler's solution. The intraventricular operation was undertaken in the belief that by its means a considerable proportion of the serum introduced is enabled to reach the upper cranial chamber, where it can circulate freely over the cerebral cortex. A word of caution is sounded. The plan of treating syphilitic diseases of the central nervous system by the introduction of remedies into the cerebrospinal fluid opens a new chapter in therapeutics, and has a great future before it, but it is one beset with many dangers, and needs to be carried out with the utmost caution, not only as regards strict asepsis but also as regards the remedies employed, and the strength, number and intervals of the injections.

4. **The Intrathecal Injection of Salvarsanized Serum.**—G. W. Spencer concludes that the intrathecal injection of salvarsanized serum offers a hopeful method of treating and arresting the progress of tabes and other parenchymatous diseases of the spinal cord. Before its introduction these cases resisted all efforts, and finally drifted into the asylums and work houses. A cure of the lightning pains can almost definitely be promised. The injections if carried out with special aseptic care and technique do not endanger the patient's life. There is a great future before this treatment when further work will have been done in perfecting it. Physicians now working on definite scientific lines for the cure of a condition which has previously baffled all efforts mainly because the pathology has not been fully understood.

*May 25, 1914.*

**Present Status of Epilepsy Research.**—Loewi devotes considerable space to alcoholic ascendants of epileptics. In Amann's recently published statistics of the disease in Switzerland it readily appears that 5 per cent. of the population are epileptics. The compilation of these figures leaves nothing to be desired, and they serve to discredit many other statistics in common use. Lundborg's statistics for Sweden show a higher percentage of disease than the Swiss figures and a much higher percentage than those of Norway and Denmark, and this excess is attributed to the excessive alcoholic consumption of Sweden. A. Collins finds an alcoholic heritary component in 34 per cent. of epileptics, but Loewi regards the material as too small for statistics. Papers read at the last meeting of the International League for Combating Epilepsy, by von Bechterew, Anfimow and Tamburini, on alcoholic heredity contain little that is new. In fact nothing really new appears anywhere in Loewi's summary on nature and causation. In the treatment of intestinal autointoxication milk enzymes appear to give better results than a more selected diet. In diagnosis we have possible new resources; in addition to Abderhalden's reaction there is Schultz's blood picture —lymphocytic leucocytosis plus eosinopenia.

**Influence of Nutriment on Growth.**—Aron sums up his article as follows: In addition to the well-known dietetic groups described in all physiologies we are now forced to add certain unknown substances, the absence of which causes specific diseases—scorbutus, beriberi, and perhaps pellagra. In regard to feeding in the period of rapid growth the optimum food is a mixture of casein, starch, bran, and butter, with mineral matter. Butter may act partly as a relish. The normal protein and caloric values should be secured. The above optimum, calculated for rapidly growing animals, must be modified for children, for whom vegetables and fruits are demanded. We have also much to learn of the food value of extractives and lipoids, irrespective of their calories

**Nephroparatyphus.**—Klienberger reviews our knowledge of nephrotyphus and of the entirely new conception of typhoid since the passing of the old exclusive enterogenous and unicistic theories. The term nephroparatyphus dates back to about 1905. Two cases are reported of which the atypical typhoid characteristics are marked. In both cases there had been a chronic inflammation of the urinary apparatus with bacillary excretion. In both the disease began acutely, as if the chronic urogenital disturbance had been lighted up, and for a period the general condition appeared to be one of sepsis. Both patients recovered after prolonged illness. The urinary bacteria seemed to stand close to

the hog-cholera group, and could be isolated only from the urine. One patient was attacked with typhoid-like symptoms, with the addition of severe lumbal pains and oliguria. He had already suffered from cardiac and renal (?) crises (lumbalgia). After thorough examination the case was diagnosticated as parenchymatous hemorrhagic nephritis, with suspicion of typhoid or paratyphoid fever, the suspicion having been based on exclusion rather than on positive clinical finds, although the Widal was positive. The paratyphus B, or one closely resembling it was cultivated from the urine, and showed close analogies to the hog-cholera bacillary group.

**"Streaked" Nephritis Following Graves' Disease.**—Huismann refers to a report by Grauppner in 1910 on nephritis following Graves' disease. When half of the affected thyroid had been removed the nephritis became rapidly worse. As a rule in such cases there was persistence or hyperplastic thymus. In nearly all severe cases of Graves' disease we find the status thymicolymphaticus. The nephritis is thyreogenic and terminal in character, showing diffuse epithelial neurosis. As a rule thyroidectomy exerts a favorable result, especially when followed up by the use of thyroid tablets. A question of importance is "does the nephritis by vicious circle destroy the patient? Or, in other words, is uremia the cause of death? There seems to be no evidence that such is the case. Death occurs amid symptoms in which a thyreogenic element stands in the foreground; but the efficient cause may be summed up as an intoxication resulting from a disturbance of pluriglandular interaction. The author's case in brief is as follows: a woman aged 33 had suffered from enlarged thyroid for 15 years. The enlargement began in the midst of health and caused little trouble for years until a picture of Graves' disease was finally involved. When first seen an operation was at once performed. Most of the left lobe of the thyroid was left behind. The patient died before twenty-four hours had expired. The operation had been a success and death occurred amid restlessness and failure of the circulation. Autopsy showed enlarged but normal thymus, hypostasis pulmonum, typhoid-like spleen, and a peculiar type of nephritis. The capsule peeled off to a considerable extent, but was adherent here and there, especially at the upper pole of the right kidney. In the cortex completely necrotic streaks. Glomeruli intact. At the beginning of Bellinis tubes total fatty degeneration of the parenchyma cells. In regard to the exact cause of death the author reminds us that sudden death is common in Graves' disease, whether or not operation has been performed. There are so many ways in which death might occur in theory that it is difficult to rely upon a simple explanation.

**Recent Remedies for Cancer.**—In this number Rapp, an assistant of Czerny, publishes the latter's results with borate of cholin injected intramuscularly, and Keil of Münich relates his recent experiences with mesothorium. In regard to cholin it is the belief that its action is akin to that of *x*-rays and radium. Given subcutaneously it produces untoward results, and Czerny has recently been testing the intramuscular route. The technique is elaborate, so that considerably over a column of the *Wochenschrift* is required to describe it. At best it is an auxiliary to the *x*-rays, radium, and mesothorium. In all desperate or inoperable cases in which all available resources may be pushed at once, cholin, as an artificial radioactive substance, should have a place. In regard to mesothorium, Keil analyzes forty cases of cancer, ten of which were of cancer of the corpus uteri and one was a chorioepithelioma. The remaining twenty-nine cases were examples of cancer of the cervix. Of this combined material, eleven cases seem to have been arrested if not cured. These include six cases of cervix cancer (three primary and three cicatricial recurrence); and five cases of cancer of the corpus (three primary, two recurrence in scar). In the case of chorioepithelioma with metastases, the results on the latter were striking.

### Deutsche medizinische Wochenschrift.

*May* 21, 1914.

**Pulmonary Embolism.**—Ulrichs sums up as follows: even with the most exact attention and observation the distinction between operable pulmonary embolism and other kinds of sudden death, *e.g.* cardiac failure from myodegeneration, cannot always be established. Other affections are mistaken for embolism, while the latter cannot be recognized as such. In one-fourth of all the author's cases, death occurred instantly, while in the remaining number the interval was from 10 minutes up. In one-third of the author's cases the patients were elderly or much weakened, in whom intervention seemed absolutely excluded. The anatomical finds showed that but five cases could be recognized as technically operable. Of this series three patients died instantly and the other two were extremely weak. The author concluded that opportunities for Trendelenburg's operation are few, indeed, but that sooner or later a case must come along in which this intervention is called for. The actual material analyzed seems to be 16 cases, but figures of other men are quite corroborative.

**Syphilitic Myocarditis.**—Rosenfeld reports a case studied by him in great detail. The patient, a woman of 27, fainted during her morning toilet. She had eaten an after-theater supper, but slept well. Three weeks before she had had a similar attack, milder. The second attack left her weak and nauseated. She was in partial collapse and became rapidly worse, despite analeptics of all kinds, until she died. Various antemortem diagnoses were shown by autopsy to be wide of the mark. Death had occurred from a gumma of the heart. The lesion had softened, but in itself could hardly explain the fatal termination. The patient showed numerous evidences of the status lymphaticus. The date of infection was recent—within a year, and gumma is almost always a late lesion. There was mesaortitis with thickening of the intima. Coronaries normal. The softened gumma was seated between the orifices of the aorta and pulmonalis. Above the left semilunar valve was a central necrosis communicating with the abscess. There was a certain amount of fatty degeneration in the heart muscle. According to Virchow syphilis of the heart occurs in two forms, viz.: myofibrous, undistinguishable from the same lesion with other causation, and myocarditis gummosa. The two forms often coexist. "Gummous alteration" of the heart describes the condition and is a frequent cause of sudden death.

---

**Santonine Poisoning in Infants.**—A. Chassevant points out that santonine is not a safe vermifuge in the infant, at any rate, under two years of age. He reports the case of a child who had received two centigrams of santonine in the evening and the following morning a dose of castor oil. Following this medication the child developed convulsions, fever, and somnolence, which symptoms lasted for several days.—*Journal de Médecine de Paris.*

## Insurance Medicine.

**American Association of Medical Examiners.**—The following papers, in addition to those reported last week, will be read at the meeting of this association at Atlantic City on June 22: "Work of the Life Extension Institute, Viewed Especially from the Standpoint of the Medical Examiner," by Dr. A. T. Gaillard, Medical Referee, Travelers' Insurance Company, Philadelphia, Pa. Discussion opened by Dr. Eugene L. Fisk, Director of Hygiene, the Life Extension Institute, New York. "The Eye in Its Relation to Medical Selection," by Dr. John Ranly, Clinical Instructor in Ophthalmology, College of Medicine, University of Cincinnati, Cincinnati, Ohio. Discussion opened by Dr. G. V. Woollen, Medical Director American Central Life Insurance Company, Indianapolis, Ind. "Applied Physical Chemistry in Heart Disease," by Dr. John Aulde, Philadelphia, Pa. Discussion opened by Dr. James H. Stowell, Medical Director North American Life Insurance Company, Chicago, Ill. "Value of Cystoscopic Examinations," by Dr. E. O. Smith, Professor Genito-Urinary Surgery, College of Medicine, University of Cincinnati, Cincinnati, Ohio. Discussion opened by Dr. J. W. Guest, Medical Inspector Equitable Assurance Society, Louisville, Ky. The president of the association is Dr. Henry Wiseman Cook; the secretary is Dr. G. Strohbach, Cincinnati.

**Medico-Social Problems from the Insurance Point of View.**—Sir Thomas Oliver recently delivered an address with the above title before the Insurance Institute, Newcastle-upon-Tyne. In the course of the address he pointed out that if an insurance manager were asked his opinion as to whether there was any change in mortality rates within recent years and any increase upon the claims of his company by one disease more than another, he would unhesitatingly answer that the claims from cancer had risen. From an insurance, not less than from a medical and a racial point of view the increase of cancer calls for careful inquiry. Dr. E. F. Bashford, of the Imperial Cancer Research Fund, does not believe that there is an increased death rate from cancer. The cancer returns are based, he says, mainly upon the number of lives over 35 years of age. It is maintained, therefore, that the incongruity of the age constitution of the population between 1901 and 1911 has led to an overestimation of the cancer death rate in the later years of the inter-censal period. Against this must be placed the statement of the Registrar-General that the mortality from cancer in 1910 was the highest on record, and that while there was a slight decrease among females, this was more than counterbalanced by the increase among males. In 1860 in England the mortality for females from cancer was 500 per million; in 1910 it was 1,070. A similar increase applies to males. The chances of our escape from the malady are said to be 10 to 1. Although no age, practically speaking, is exempt, the disease falls with increasing frequency after 35 upon each succeeding decade. What is taking place in Great Britain has also been occurring in Germany. From the report of the German Cancer Commission Inquiry, 1900, it is learned that cancer is more frequent in the larger towns than in country districts, more frequent in women than in men, and that it is less frequent in both sexes in industrial towns and mining centers than in Berlin and Hamburg. During the 13 years, 1888-1900, the mortality from cancer in Germany in males rose from 373 to 574 per million living persons. As in England so in Germany the increase of cancer in males is mainly due to disease of the stomach and intestines, a circumstance which suggests that the influence of food cannot be altogether disregarded.

Regarding cancer houses as sources of infection, Oliver, judging from his own investigations and from the investigations of others, is of the opinion that the matter is more than a coincidence. As for the transmission of cancer, the questions are asked: Is there any law of transmission? Does the father hand on to the son and the mother to the daughter, or is it a case of cross transmission? There are no British statistics bearing upon these points, but from the report of the German Cancer Commission it is gathered that in 82.9 per cent. of all cases of cancer hereditary influences can be excluded, that is, that in 17.1 per cent. hereditary influences, direct or indirect, were more or less probable. In 84.1 per cent. of 3,408 male patients there was no hereditary history, in 4.7 per cent. there was a history of the father having had cancer, and in 4.3 per cent. the mother had suffered, that is to say a total of 9 per cent. Of 5,739 female patients heredity could be excluded in 82.2 per cent., in 7.2 per cent. there was a history of the disease in the mother and of 3.1 in the father, giving a total of 10.3 per cent. of hereditary influence in female cancer. Not only, therefore, does the mother's influence weigh more for the transmission of cancer than the father's, but the incidence of the disease in the female is more than twice greater than that of the male, although fathers transmit to their sons slightly more frequently than they do to their daughters. Further, Oliver draws attention to the fact that the data obtained by experimental inquiry go to support his opinion of the disease in man; that, however impossible to explain it, the part played by heredity in the causation of malignant disease cannot altogether be ignored.

With regard to athletics, the author states that in his opinion hard athletic exercise is not always the best training for young men who are going to become clerks or who are likely to lead a sedentary life. One of the consequences of hard rowing, running and football playing is an increase in the size of the heart, especially of the left ventricle. While enlargement of the heart may be good enough for the youth of 22, who takes exercise freely, it is not the best for a sedentary clerk of 30. The man of 30 would find himself with more heart than he required, the circulation would be rather embarrassed than lightened, for it is difficult to tone down the heart to the diminished needs of the economy. Oliver thinks that the tendency of the age is to overestimate athletic exercise. It has yet to be shown that from those schools which pride themselves in games and physical culture rather than in intellectual training, the longevity of their pupils is greater, and that when the work of life is summed up they have taken as good a place as those who were pupils in colleges renowned more for a happy mean in mental training and physical exercise.

Sir Thomas Oliver ends by commending compulsory military training, mainly because it teaches discipline, coördinates training, mental and physical, and instils into the young man a sense of duty and patriotism which will do more for a nation than the steeping of its young manhood in sport.

# Book Reviews.

ARTERIOSCLEROSIS; A Consideration of the Prolongation of Life and Efficiency After Forty. By LOUIS FAUGÈRES BISHOP, A.M., M.D., Clinical Professor of Heart and Circulatory Diseases, Fordham University School of Medicine, New York City; Physician to the Lincoln Hospital; Consulting in Cardiovascular Diseases to Mercy Hospital, Hempstead; late Chairman of the Section of Medicine of the New York Academy of Medicine; Member of the American Medical Association, the New York Pathological Society, Alumni Association St. Luke's Hospital, etc. Price $3.50. London: Henry Frowde and Oxford University Press, Hodder & Stoughton; New York: Oxford University Press, 1914.

DR. BISHOP is of the opinion that owing to our latter-day mode of life, and the continual striving to outdo one's neighbor, arteriosclerosis is much more frequent than formerly. He thinks that reaction through the nervous system upon the chemical organs of the body prepares the way for this disease. Of course, the author considers his subject from the clinical standpoint, and after dealing with the causes of arteriosclerosis, one of the most important of which he deems to be auto-intoxication, he goes on to suggest treatment. Dr. Bishop's theory is that many sufferers from high blood pressure and arteriosclerosis are susceptible to the action of certain, though not all, proteins of animal origin, and the therapeutic problem is to discover which are the offending substances. If these can be found the patient may partake of the others with impunity, but if not, the safest way is to cut out all meat, fish, and eggs and rely upon vegetables and cheese to supply the amount of protein essential to health. He is, therefore, an advocate of a regulated diet, the avoidance to a very large extent of animal foods, in the treatment of the class of patients suffering from general cardiovascular disease of chemical, or at least toxic, origin. The volume is distinctly suggestive and original, is well printed, and judiciously illustrated.

PRACTICAL SANITATION. A Handbook for Health Officers and Practitioners of Medicine. By FLETCHER GARDNER, M. D.; Captain Medical Corps, Indiana National Guard; First Lieutenant Medical Reserve Corps, United States Army; Health Commissioner of Monroe County, Indiana; and JAMES PERSONS SIMONDS, B.A., M.D., Professor of Preventive Medicine and Bacteriology, Medical Department, University of Texas; lately Superintendent, Indiana State Laboratory of Hygiene. Illustrated; price $4.00. St. Louis: C. V. Mosby Company, 1914.

THIS volume of about 400 pages aims simply to provide a safe way for the health officer to meet any emergency which may arise. It is compiled from many sources. The book was designed to fill a vacancy in literature. Up to the present there has never been a serious endeavor to provide within the covers of a single moderate-priced volume a plain, non-technical exposition of the duties of the health officer, written by one experienced in the routine and emergencies of the local sanitary service and familiar with the needs of the local health officer. One particularly interesting chapter is devoted to the rat and a summary of recommendations, aids in limiting the numbers of rats and reducing the losses from their depredations. In the appendix are to be found schemes for sanitary surveys of cities, public buildings and schools. As Dr. J. N. Hurty, Health Commissioner, State of Indiana, states in the introduction: "This book treats of public and personal hygiene, entering into details and discussing their many features. Its teachings are true and to date, and it may be confidently stated that if its directions and lessons are heeded the efficiency, wealth and happiness of the commonwealth will be greatly augmented."

DIE CHRONISCHEN KATARRHALISCH-ENTZÜNDLICHEN ERKRANKUNGEN DES DARMES. By Dr. FRIEDRICH CRÄMER. Munich: J. F. Lehmann, 1914.

THE author thinks that the various catarrhal inflammations of the bowel are still worthy of considerable study. He expresses himself as follows: "What has been proposed for the solution of the bowel problem, *i.e.* for the prevention of chronic affections and premature ageing? First: The formation of lactic acid to prevent putrefaction, through milk preparations, yoghurt, etc. Lately Metchnikoff recommends tablets containing three varieties of bacteria, viz.: the *Streptococcus bulgaricus*, *Bacillus bulgaricus*, and glycobacterium, which latter, discovered by Metchnikoff, has the faculty of thriving in the large bowel and splitting up sugars into lactic acid. This lactic acid is supposed to kill the harmful bacteria, to reduce the intestinal poisons to a minimum, and thus to prevent premature old age. This would constitute a biological freeing of the intestine of its toxins.

"Secondly: Reduction of toxin absorption from the bowel through surgical resection of the colon, artificial opening through the appendix (appendicostomy) for the purpose of irrigating the large bowel, measures stimulating peristalsis, elysmata, intestinal lavage.

"Thirdly: Neutralization of the toxins absorbed by the blood from the bowel by means of organic extract. Another important postulate is the maintenance of motility of the movable parts of the bowel, viz., the small intestine, and increased rapidity of transit through the fixed bowel portions, viz., the large bowel.

"The first and third requirements we have been trying to meet for a long time, but we are aware that our success is limited. The second requirement, surgical intervention, is such an incisive measure that we have all cause to oppose it. The results of such severe surgical intervention, as the elimination of the large intestine, are really not encouraging. Lane has operated upon fifty cases for severe constipation; the end-result is claimed to be splendid, but the mortality is 24 per cent. The radical methods do not prevent the formation of extensive adhesions, which again reproduce the old conditions, to relieve which this heroic therapy was instituted."

Crämer's monograph forms a very useful addition to our knowledge of intestinal diseases.

THE UNCONSCIOUS. The Fundamentals of Human Personality Normal and Abnormal. By MORTON PRINCE, M.D., LL.D., Professor Emeritus of Diseases of the Nervous System, Tufts College Medical School; Consulting Physician to the Boston City Hospital. Price $2.00. New York: The Macmillan Company, 1914.

THE author, as a member of the committee appointed by the American Psychological Association to investigate the relation of psychology to medical education, is in a position to know the preliminary psychology that should be a part of the training of every medical student and also of what a course in more practical psychology, such as should precede the special study of psychiatry and neurology, should consist. It is to fulfil the latter need that the present volume is designed. While it serves as an introduction to abnormal psychology through the problems with which it is concerned, many of these problems belong equally to normal psychology. The author endeavors to avoid controversial questions as far as possible and bases his experimental work on the phenomena of memory, conscious and unconscious. By the inductive method he arrives at the conclusion that "mind" includes more than conscious processes; that it includes a vast store house of acquired "dispositions," deposited by the experiences of life; that these acquired dispositions provide material for conscious and unconscious processes. He finds evidence that a conserved idea may undergo subconscious incubation and elaboration, and that unconscious processes may acquire a marked degree of autonomy, may determine or inhibit conscious processes of thought, solve problems, enter into conflicts, and in various modes produce all sorts of psychological phenomena such as hallucinations, impulsive phenomena, abulia, amnesia, dissociation of personality, etc. To the psychiatrist the book probably presents nothing new, but it is a very lucid presentation of the modern view of subconscious mind.

ÜBER BRÜCHE DES KNÖCHERNEN TROMMELFELRANDES; EIN BEITRAG ZUR UNFALL-LEHRE. Von Prof. Dr. HEINRICH WALB, Geheimer Medezinalrat, Direktor der Universitäts-Poliklinik für Ohren, Hals, und Nasenkranken Bonn. Price 3 marks. Bonn: A. Marcus und E. Webers Verlag, 1914.

PROF. WALB reports twenty-five cases of fractures of the bony edge of the tympanic membrane, which, on injury to the head by fall, blow, or thrust are frequently shown by a considerable bleeding from the ear. These fractures mostly heal by primary intention. Hearing is little disturbed, if at all. The traumatic tympanic membrane cases heal without leaving permanent perforations even if the injury is accompanied by an inflammation of the middle ear. If a large, round perforation is found with continual suppuration, the physician may conclude that the disease existed before the accident occurred.

MODERN MEDICINE—ITS THEORY AND PRACTICE. In Original Contributions by American and Foreign Authors. Edited by Sir WILLIAM OSLER, Bart., M.D., F.R.S., Regius Professor of Medicine in Oxford University, England; Hon. Professor of Medicine in the Johns Hopkins University, Baltimore; formerly Professor of Clinical Medicine in the University of Pennsylvania, Philadelphia, and of the Institute of Medicine in McGill University, Montreal; and THOMAS MCCRAE, M.D., Professor of Medicine in the Jefferson Medical College, Philadelphia; Fellow of the Royal College of Surgeons, England; formerly Associate Professor of Medicine, the Johns Hopkins University. Volume II.—Diseases Caused by Protozoa and Animal Parasites. Diseases Due to Physical, Chemical, and Organic Agents; Diseases of Metabolism and of the Respiratory System. Second Edition, thoroughly revised. Price $6.00. Philadelphia and New York: Lea & Febiger, 1914.

PART I consists of papers dealing with protozoan infections and diseases caused by animal parasites, all of which are written by well-known authorities. Dr. R. P. Strong discusses amebic dysentery. The author states that in his experiments he has found that solutions of ipecac have not shown as great amebicidal action as quinine sulphate against free living amebæ in cultures, but in treatment ipecac and emetine have proved successful. Col. Sir David Bruce contributes a paper on trypanosomiasis, revised by Dr. Low. Referring to the question of the extermination of the sleeping sickness, the author points out that the transference of the population to a district not infected by the tsetse fly, with the view of getting rid of the flies by providing them with no human hosts has not been attended by success. It is believed that big game are carriers of the disease and the only means of extinguishing the malady is by the destruction of the big game in an infected area as to the means of prevention and treatment. The subject of syphilis is ably and exhaustively treated by Sir William Osler and Dr. John W. Churchman. It is pointed out that in order to eradicate syphilis both the medical progession and the public *must be educated*. The authors warn against the indiscriminate use of the arsenic preparations in the treatment of syphilis. Especially is the administration of salvarsan contraindicated in the acute stage of syphilis of the central nervous system. Part II is concerned with the diseases caused by animal parasites, and the entire question is generally and lucidly discussed by Dr. C. Wardell Stiles. Part III is devoted to a consideration of diseases due to chemical and organic agents. Dr. Alexander Lambert in writing of the treatment of alcoholism emphasizes the fact that there is no specific for this condition. With regard to the use of narcotics, he points out that the more highly cultivated and mentally developed a race, the more intolerant of pain are its members. Pellagra is still considered under the head of food poisonings. A very elucidative paper on the autointoxications is given by Dr. Alonzo E. Taylor.

Part IV deals with diseases of metabolism, and metabolism is discussed in a general way by Dr. Philip B. Hawk. Dr. Thomas B. Fletcher writing on diabetes mellitus lays stress on the important rôle played by the internal secretions in carbohydrate metabolism. Dr. James M. Anders discusses obesity. Dr. George F. Still draws attention to the fact that the prevention of rickets depends almost entirely on dietetic measures. The surest safeguard is the continuance of breast feeding alone for nine or ten months after birth and the use of fresh milk as the chief article of diet until the end of the second year.

Part VI is given over to diseases of the respiratory tract. Dr. H. Amory Hare writes on diseases of the lungs, Dr. Frederick T. Lord on diseases of the pleura and pneumothorax, and Dr. Henry A. Christian on diseases of the mediastinum.

The volume is of a high standard and reflects great credit on its editors and contributors. It is well printed and clearly illustrated.

GRUNDSÄTZE FÜR DEN BAU VON KRANKENHÄUSERN. Von Obergeneralarzt Dr. THEL, Inspekteur der 5. Sanitätsinspektion, Berlin. Price 6 marks. Berlin: August Hirschwald, 1914.

IN this second edition of his book on hospital building Dr. Thel remarks that the pavilion system is no longer favored, that there is more demand for the building of small hospitals, and that there is a tendency to refrain from planning large wards, and to increase the number of single rooms. Dr. Thel has added some notes on the cost of ground for hospital parks, on the building of small hospitals, and the protecting the patients from noise by means of cement layers and sand filling between the floors.

DIE FREIE SELBSTBESTIMMUNG BEI DER WAHL DES AUFENTHALTSORTES nach dem Reichsgesetz über den Unterstützungswohnsitz. Von Prof. Dr. phil. et med. H. LIEPMANN, Berlin-Oberarzt a. d. städt Irrenanstalt Dalldorf. Price 1.20 marks. Halle a. S.: Carl Marhold, 1913.

IN this discussion of pages 12 and 24 of the German Reichsgesetz on free self-determination in the choice of the place of residence, Prof. Liepmann agrees that the proof that self-determination was not free is given when the mental functions necessary to so important a decision as that of residence are essentially disturbed, and when the diseased processes in the person's brain are so pronounced that the special processes necessary to the choice of residence must inevitably be influenced. In the case of the mentally defective, Professor Liepmann denies their free volition, and he regrets that the laws do not permit the confinement of drunkards in asylums.

KOPFSCHMERZ UND MIGRÄNE. Von. A. CORNELIUS. Price 1.50 marks. Berlin: August Hirschwald, 1914.

CORNELIUS believes that migraine is a severing of nerveends based on a hereditary predisposition, which, appearing periodically, is shown in nervous symptoms and sensorial disturbances affecting the entire body, and accompanied by a peculiar psychical alteration. These attacks occur at comparatively regular intervals in response to irritations in any part of the body, but they are not to be considered as simply independent, but as the irritation symptoms of already diseased nerve-ends having a paroxysmal and overflowing character.

MANUEL PRATIQUE DE LA MÉDICATION HYPODERMIQUE. Par MM. les Docteurs G. BOSC, Ancien Interne des Hôpitaux de Paris; FERNET, Ancien Interne des Hôpitaux de Paris, Assistant a l'Hôpital St. Louis; H. GILLET, Ancien Interne des Hôpitaux de Paris; MAUTÉ, Ancien Interne des Hôpitaux de Paris; Saïssi, Ancien Interne des Hôpitaux de Paris; TOURNADE; GALLOT, Dentiste; et par L. LECOQ, Pharmacien de 1re Classe, Ancien Interne Médaille d'or des Hôpitaux de Paris. 2e Edition. Price 2 francs. Paris: Laboratoire D'Hypodermie, 1914.

THE subject of hypodermic medication is fully covered in this volume. The first part takes up the technique of the different methods of injection of sterilized solutions. The second section discusses the application of the hypodermic method in general therapeutics. Local anesthesia is discussed in the next section. The hypodermic method in the treatment of syphillis is taken up in the next section. There are separate sections on serum therapy, vaccine therapy, toxin therapy; on the applications of the hypodermic method in the specific treatment of tuberculosis; on the injections of quinine in the treatment of malaria; on local anesthesia in dentistry; and on the applications of the hypodermic method in diagnosis. The volume contains a large number of formulæ.

DIAGNOSEN AV BARNETUBERKULOSENS KLINISKE INITIALFORMER. By HERMAN G. GADE, Tillægshefte til *Norsk Magazin for Lægevidenskaben*, Januar 1914. Kristiania: Steen'ske Bogtrykkeri, 1914.

THE diagnosis of incipient tuberculosis in children is the theme of this volume. The first part discusses the syndrome associated with tuberculosis of the bronchial lymph nodes. The anatomical basis for the clinical picture of this condition is set forth with the aid of lucid diagrams. The pathological anatomy and pathogenesis is then taken up. It is pointed out that Rilliet and Barthez found tuberculosis of the bronchial lymph nodes in 86 per cent. of autopsies, Fröbelius in 99.2 per cent., Steiner and Neureuther in 94 per cent., and Neumann in 78 per cent. The second section of this work deals with the symptomatology, diagnosis, general symptoms, and local symptoms of early tuberculosis in children; the objective diagnosis by means of percussion and auscultation; and the *x*-ray methods of diagnosis, including a discussion of the normal thoracic picture. There are appended a large number of admirable *x*-ray pictures of the thorax, showing the initial forms of tuberculosis of the lungs and of the bronchial lymph nodes. This volume covers a useful field and should prove of distinct service not only to the pediatrist, but also to the *x*-ray specialist and phthisiologist.

## AMERICAN SURGICAL ASSOCIATION.

*Annual Meeting, Held in New York City, April 9, 10, and 11, 1914.*

THE PRESIDENT, DR. WILLIAM J. MAYO, IN THE CHAIR.

**The Prophylaxis of Cancer.**—DR. WILLIAM J. MAYO of Rochester, Minn., said that all vertebrate animals suffer from cancer in situations affected by their habits or conditions of life, leading to local lesions in the protective mechanism. We should look upon local lesions as an invitation to cancer without regard to just what the actual cause of cancer may be. The term precancerous should be limited to those conditions which clinically and microscopically cannot be said to be surely benign or surely malignant. The character of the cells was changed; they lacked differentiation, but as yet there was no infiltration of the surrounding tissue. This cellular change was found in the periphery of malignant growths and in conditions which afterward developed malignancy. The local lesion was the invitation and the precancerous condition the probable acceptance. Sites of local irritation were divided into three groups: (1) Congenital, or acquired neoplasms, such as moles, warts, and benign tumors which might undergo malignancy; (2) trauma, which strongly influenced the development not only of sarcoma, but of carcinoma; (3) chronic irritation, which was the most important of all the precancerous conditions, whether the result of mechanical, chemical, or infectious agencies. It was important to apply the evidences of local chronic irritation in the production of cancer to the solution of problems as regarded the development of cancers on the internal mucous surfaces of the body. For example, cancer of the gall-bladder from gallstone irritations and cancer of the stomach following gastric ulcer. Fifty per cent. of cancers of the pelvis of the kidney were demonstrably superimposed on extensive renal calculi formation. Carcinoma of the appendix usually occurred in association with chronic obliterative processes. In the sigmoid and rectum, the irritation in diverticula may have given rise to malignant disease. Cancer of the stomach occurred in 30 per cent. of all cancers in civilized man, but was not common in primitive races or in lower animals. When cancer of a certain organ was found in only one class of individuals or one species, it meant a single cause, as in the case of betel-nut cancer and Kangri cancer. Cancer of the stomach must be due to one cause; if many, the lower animals and primitive races would be more often affected. Something in the habits and customs of civilized man in connection with the cooking and preparation of food must be responsible for this large percentage of cancer of the stomach. A comparative investigation would be of value.

**Some Problems in the Early Diagnosis and Treatment of Sarcoma of the Long Bones.**—DR. WILLIAM B. COLEY of New York City said the results were submitted of 121 cases coming under personal observation. Of the cases in which the mixed toxin treatment was used either before amputation in the hope of saving the limb, or immediately thereafter in the hope of preventing recurrence, 19 had remained well for from three to fifteen years. In the cases in which the toxins were not used four had remained well for over three years. Attention was called to the extreme malignancy of sarcoma of the long bones, especially of periosteal sarcoma. Of the older statistics quoted by Butlin nearly a generation ago, in 143 cases of periosteal sarcoma of the long bones only one remained well after three years from the date of operation. Of 106 cases observed in the last decade at St. Thomas' Hospital in London 53 were suffering from periosteal sarcoma, and only one of these remained well three years after operation. Of the total number of cases, including the central or myeloid type, only ten were alive and well three years after operation. A very important point was that the preliminary use of the mixed toxins had resulted in the saving of the limb in nine cases in the speaker's own experience. Combining this with the experience of other men, the toxins had proved successful in about 20 cases. The results of this series of cases established beyond reasonable doubt the advantages of the preliminary use of the toxins before sacrificing the limb; and, after operation, as a prophylactic against recurrence. Early diagnosis required accurate clinical knowledge of all the conditions most likely to stimulate sarcoma; and also a great amount of actual examination and careful clinical study of a large number of cases of sarcoma of the long bones. The tactile sense was of inestimable diagnostic value. While the *x*-ray might often be misleading in the early stages of sarcoma of the long bones, it might also be of valuable help in making early diagnosis, and large experience in interpreting the *x*-ray was required. The advantages and disadvantages of exploratory operation and microscopical examination of the specimen removed were discussed at length. With the history and clinical signs strongly positive the speaker would not subject the patient to the risk of an exploratory operation, but would immediately perform the operation indicated. The chief requirements for the early diagnosis of sarcoma of the long bones might be summarized as follows: (1) A more careful study of all known clinical data. (2) A large clinical experience in the diagnosis of sarcoma of the long bones. (3) Early *x*-ray examinations in all suspected swellings of the long bones, especially those following trauma. (4) Exploratory operation and microscopical examination of the tissue removed in selected cases, but *not* as a routine measure. (5) The importance of not placing implicit reliance upon the negative report of the pathologist, especially when in conflict with clinical and *x*-ray evidence that is strongly positive.

DR. C. A. PORTER of Boston reported a case of sarcoma of the upper lumbar vertebra in a boy of 19 in which large doses of the Coley toxins were given and the boy was now perfectly well one year and a half since operation.

DR. JOHN H. GIBBON of Philadelphia had one case of periosteal spindle-cell sarcoma in a girl of 17; prompt recurrence after incomplete operation, refusal of shoulder joint amputation. She was then given the toxins and *x*-rays; it was now five years with absolutely no evidence of recurrence. In another case Dr. Allen operated for a recurrent spindle-cell sarcoma of the forearm. Prompt recurrence taking place, the patient was put on the toxins and *x*-ray treatment. The growth melted under it, and at present, eight or nine months since the treatment was started, there was no evidence of recurrence.

DR. THOMAS W. HUNTINGTON of San Francisco reported two satisfactory cases treated with the Coley toxins.

DR. ARCHIBALD MACLAREN of St. Paul, Minn., said Dr. T. deWitt drew his own toxins from a case of erysipelas and, using them, obtained a real result. In one case of partial removal of the spindle-cell sarcoma of the parotid treated by the toxins there was recurrence inside of a year. Under the toxins the growth entirely disappeared. There was again a return which disappeared after an ordinary attack of typhoid fever. In five years the woman died with general sarcomatosis, so that the original condition must have been sarcoma. There was no question that the growth disappeared after typhoid fever, nor was there any question of its complete disappearance under the administration of the toxins. Now, what was it?

DR. HOWARD LILIENTHAL believed in the postoperative use of Coley toxins in every case of sarcoma and also in cases of carcinoma of the breast. He had used the toxins regularly and consistently, and had had few recurrences.

DR. WILLIAM L. RODMAN of Philadelphia had had no case of recovery after the use of the toxins for lesions in the long bones; yet had had cases in which the condition was improved after the use of the toxins when the lesions were in the throat and in one case in the parotid gland.

DR. N. B. CARSON of St. Louis reported the case of a patient seen many years ago, with a tumor under the clavicle with a diagnosis of sarcoma. The Coley toxins were used and the tumor gradually disappeared. In another case in the practice of a colleague the whole lower abdomen was filled with what was taken to be a sarcoma. Under the use of Coley toxins the tumor gradually disappeared and the patient was well three years after treatment. He had sometimes used the toxins in sarcoma without success, and frequently in carcinoma with no success whatever.

DR. WILLY MEYER of New York City said the point mentioned by many speakers of the Coley toxins having no effect in carcinoma is substantiated in his observation; neither had it any effect in endothelioma. In a case of sarcoma of the chest there were all the typical symptoms of tumor in the anterior mediastinum—compression of veins, etc. The patient, a doctor, insisted upon thoracotomy, but was asked to first see Dr. Coley. After discouragement because of fever and

chills, he again asked for operation, and was again dissuaded. Dr. Coley not long ago told the speaker that this patient had written him that he was so much better that he wanted to continue the treatment at his own home. There was no doubt that sarcoma, and inoperable sarcoma particularly, needed the Coley toxins besides the *x*-ray treatment.

Dr. Stanley Stillman of San Francisco reported a case of sarcoma of the chest wall attributed to the irritation produced by leaning over a boat in fishing, the tumor entirely disappeared upon the Coley toxins. The man, however, had mediastinal metastasis, and died just as he was thought to be getting well; the parent growth entirely disappeared.

Dr. Charles H. Peck of New York reported one case of incompletely removed sarcoma of the submaxillary region operated upon five years ago, which was treated afterward with the Coley toxins, and was followed by a complete cure. He had used the toxins in a number of cases, but this is the only one with beneficial results.

Dr. John B. Murphy of Chicago said we were indebted to Dr. Coley for keeping alive an element of hope in showing that there was something that we did not understand, and that did occasionally produce an alteration in the clinical course and brought a good result.

Dr. Arthur Dean Bevan of Chicago was prepared to accept the fact that in the course of thousands of cases a limited small number, which if all of the cases were taken into consideration amounted to a considerable number, but a small percentage had been influenced by the use of toxins. In 75 or 100 cases he had never seen a cure from the use of the toxins in either carcinoma or sarcoma, though he had seen marked effects and continued to use the toxins in inoperable cases. In his experience the *x*-ray had been of very much more benefit in both inoperable carcinoma and sarcoma than the toxins.

Dr. Coley, in closing, said he had little idea that the paper would provoke such a discussion and so favorable a one. Despite the serious discouragements, no one could see the benefit in the cases that were hopelsssly inoperable without believing there was something valuable in the toxins, and with that belief he had been obliged to continue the work. Dr. Lilienthal had reported the only case of melanotic sarcoma cured by the toxins, although there was one case in Leeds, England, now well three years. Of 80 successful cases out of 715 which he had personally treated, 52 patients were well from 3 to 20 years after the treatment. He believed the greatest value of the toxins was as a prophylactic after amputation. Cure of even a small percentage of inoperable sarcoma proved it to be of great value.

**The Two-Stage Operation, Especially in Its Relation to Treatment of Cancer.**—Dr. George W. Crile of Cleveland, O., said the newer developments in surgical technique, by which most of the danger and most of the suffering and discomfort even of surgical operations had been eliminated, had enabled the surgeon to utilize fully the advantages of two-stage operations for cases heavily handicapped by lowered vitality, while in cancer cases the danger of immediate reimplantation was minimized. Critical cases of acute infections of the pelvis, of the appendix, or of the gall-bladder might be more safely treated by a preliminary drainage, the operation being completed after the margin of safety had widened. If we adjusted the operation to the patient, rather than the patient to the operation, the mortality rate which now accompanies the surgical treatment for cancer of the stomach, intestine, larynx, and tongue would be greatly reduced.

Dr. Fred B. Lund of Boston said he had employed the two-stage operation in ulcer and cancer of the stomach only in cases in which the patient was very weak. In cases in which there was doubt of the diagnosis of cancer he would be more inclined to use the two-stage method than in those in which he was sure of cancer, because not only might cancer progress during the waiting stage, but it might be more extensive than anticipated and the adhesions from the previous gastroenterostomy might hamper a thorough operation at the second stage.

Dr. James E. Moore of Minneapolis had for a long time been a firm advocate of the two-stage operation in selected cases. He knew of no more satisfactory procedure than, with enlarged prostate and infected bladder where ether anesthesia would be fatal, to make a small incision suprapubically, under a local anesthetic, and drain the bladder. He was also in accord with Dr. Crile in reference to appendectomies. There was a strong tendency to undertake too much and to interfere with some of the undertakings of the Almighty. Many times he had opened a large abscess and not being able to find the appendix without ripping things up had left it, and after recovery from the operation did a second operation, followed again by recovery.

Dr. Howard Lilienthal of New York said it was now five years since he emphasized in a paper published in the *Annals of Surgery* what he thought was the importance of the two-stage operation in resection of the pylorus. Since then he had concluded that the method was even more valuable than he at first thought. In ulcer cases particularly it was of importance.

Dr. Arpad G. Gerster of New York said there was no doubt that the two-stage operation, where indicated by special conditions, was a very useful expedient, but the argument advanced by Dr. Moore that in appendicitis we were doing too much and thus interfering with the designs of the Lord might be applied to all surgery, which was all an interference with the designs of the Lord. There was a great difference between doing a two-stage operation where necessary, and doing it under all circumstances. He believed the broad application of this principle as a routine was entirely unnecessary. If he ever had to be operated on he would be willing to run a little additional risk in order to get through at one clip.

Dr. Frederic Kammerer of New York said his experience in carcinoma differed from that of Dr. Lilienthal, for after a gastroenterostomy at the first stage he had found the removal of the tumor at the second stage much complicated. It was his belief that it was better and easier to do a resection and gastroenterostomy at one time.

Dr. Alexander Primrose of Toronto agreed with Dr. Gerster that the two-stage operation should not be the routine method of procedure. For example, Dr. Crile spoke of the value of drainage of loops of gangrenous bowel; here the speaker would take issue with him under certain conditions, and in illustration would refer to volvulus high up in the small bowel where the gangrenous area existed within some twelve inches of the duodenojejunal juncture; there the excision of the bowel was made, or, rather, drainage with partial excision because no further operation could be done, and we had here the further difficulty of nutrition to contend with. We were compelled to do a second operation in twelve days, and the condition of adhesions was such that the operation was exceedingly difficult and the patient succumbed. We could have possibly saved this life if we could have performed immediate operation in the first stage. In acute appendicitis also, he thought the gangrenous and septic appendix was a source of great danger and should be removed if at all possible. His experience was that there was trouble locally with danger of spreading infection along the lymphatics and resulting subphrenic abscess when the appendix was left in and the abscess drained.

Dr. Crile said that, of course, he did not propose the two-stage operation for everything, but naturally for the healthy risks which he had stated at the beginning of his paper. The only way to determine whether it was best to break down the walls of adhesions in a circumscribed abscess in acute appendicitis was to make a long series of observations. He could show over 200 cases of all sorts of acute appendices, not those in which the resections were easy, but all kinds of cases, without a fatality.

**Systemic Blastomycosis.**—Dr. Charles A. Powers of Denver reported two cases both of which were fatal. The first had been studied bacteriologically for nearly two years, the cultures of the microorganism being carried successively from one animal to another. Blastomycosis generally resulted in death when it became systemic. Prolonged and increasing doses of potassium iodide and of cupric sulphate might possibly be of value. The condition generally began with cutaneous or subcutaneous lesions and generalization might be prevented by very early and very wide excision of the affected tissues. Early diagnosis of the cutaneous and subcutaneous condition was of prime importance.

Dr. McNeil said examination of the slides showed this material to be not the ordinary type of blastomycosis, but distinguished by the fact that the parasite reproduce not by budding, but by endogenous spore formation. The character of the microorganism differed from the ordinary blastomyces and should be separated from the general group of parasites causing

blastomycosis. A definite specific name should be given it, such as toxoides granuloma. About twenty-four cases had so far been recorded, with only two recoveries. In one instance the limb was amputated while the disease was localized in the thigh. The other was a case reported by Wolbach in which thorough surgical treatment obliterated the disease.

Dr. Arthur Dean Bevan of Chicago said that, shortly after Gilchrist announced his first case of this disease the speaker saw a case, which was reported in the literature as the Hcktoen-Hyde-Bevan case. He tried a series of experiments in this particular case with bichloride of mercury internally, with no effect; potassium iodide with marked effect—an extensive lesion clearing up almost entirely as a gumma was found disappearing under the iodide. In a considerable series of cases, however, this was not always true, but the drug had a marked effect on the organism. Later he used copper with some effect.

Dr. N. B. Carson of St. Louis: Some time ago we seemed to have an epidemic of blastomycosis and two or three of the cases were of the systemic type, all of which died. They seemed to tolerate drugs very badly. We tried varying forms of treatment and in the local cases with very good results.

Dr. Emmet Rixford of San Francisco said there was some confusion on this subject. The term blastomycosis was given to the disease which Dr. Powers and Dr. McNeil had reported. The organism was very different from the blastomyces, that is, the fungus which multiplies by budding. The cases mentioned by Dr. Bevan were cases of true blastomycosis. The disease reported by Dr. Powers was entirely limited to California and to a single valley, San Joachim valley. The first case was found by the speaker in 1894. Dr. Stiles of Washington to whom the material was submitted gave the name coccidiodes. Shortly thereafter he found a second case in which the organism was distinctly different as were also the clinical manifestations. The organism in this second case was much larger. There were high fever and great depression, and death occurred within six weeks of the first manifestation of the lesion. In the first case which lasted two years nothing did any good except vigorous local surgical procedures. Before the man died his face, eyes, and mouth, were destroyed. There were lesions in his bones and at autopsy his lungs were found to be completely consolidated with innumerable white tubercles about the size of oldish miliary tubercles. The adrenals were as large as duck eggs and consolidated with caseous material.

Dr. Powers said his pathological friends gave him these various names, but as he was hardly able to handle the pronunciation of them, he decided to stick to the original term, blastomycosis. The point which he would like to drive home is that, as in both of his fatal cases, the condition began as a small skin nodule or a small abscess beneath the skin. The best hope of preventing dissemination and, therefore, of preventing the mortality which attended the systemic form, lay in the early and wide excision of these nodules.

**The Value of Gluzinski's Test in the Diagnosis of Gastric Ulcer.**—Dr. John Nicolaysen of Christiania, Norway, said Kocher in 1912 recommended Gluzinski's test as a means of making the differential diagnosis between ulcer and cancer of the stomach. Ulcer was as a rule accompanied by hyperacidity while cancer was attended by an atrophic catarrh which caused the disappearance of the free hydrochloric acid. When cancer developed upon the basis of an ulcer there might be demonstrated at an early stage of the disease an insufficiency of hydrochloric acid production. This was made by giving two test meals, one following immediately upon the other. While the amount of free HCl would increase from the first light meal to the second heavier (beef) one in cases of ulcer, it would decrease in cases of cancer of the stomach. The author and his assistant, Dr. Grondahl, had examined 86 cases of ulcer of the stomach and duodenum, cancer of the stomach, gastroenteroptosis, appendicular dyspepsia, and gallstones. Of the cases of cancer, only two had free HCl in the gastric contents. These gave Gluzinski's reaction, to wit: the amount of free HCl decreased in the second meal. But the same insufficiency of function was also found in cases of gastroenteroptosis. In all cases of ulcer but one, there was found a pronounced increase in the amount of free HCl in the second meal. Gluzinski's reaction was reliable, nevertheless, its result was to be considered only as a symptom which must be judged in conjunction with the other symptoms and the history of the case.

**Résumé of the Röntgenological Diagnosis of Surgical Lesions of the Stomach and Duodenum.**—Drs. George Emerson Brewer and Lewis Gregory Cole of New York City said the most satisfactory diagnostic method up to the present time had been serial röntgenology, *i.e.* the study of 50 or 60 röntgenograms of the patient in various postures, taken in several series at intervals of two hours until the stomach is empty. They had perfected a true röntgenocinematographic machine, capable of making 50 röntgenograms of a single cycle, or 200 röntgenograms of an individual peristaltic contraction from the fundus to the pylorus. The information gained by such an examination included size, position, and shape or type of the stomach; activity of peristalsis and width of peristaltic contractions; character of the systole and diastole; depth of the rugæ and the direction in which they ran; degree of dilatation and the motor phenomena of the descending and horizontal duodenum; character of the pyloric sphincter and of the cap (pilleus ventriculi). The interpretation of findings had been worked out by a study of about 20,000 röntgenograms of 680 cases. A report on 27 consecutive cases examined röntgenographically by Dr. Cole and operated upon by Dr. Brewer showed the accuracy of the method.

**Pylorectomy or Excision of the Ulcer-Bearing Area.**—Dr. William L. Rodman of Philadelphia said that if ulcers were situated at or near the pylorus, as they were in about 80 per cent. of all cases, and the pyloric end of the stomach and proximal portion of the duodenum could be easily mobilized, pylorectomy, which got rid of the present ulcers and prevented future ones to a large extent, removing as it did, four-fifths of the ulcer-bearing area, was certainly the operation of choice. If, however, the converse obtained, the stomach and duodenum being bound down by adhesions to adjacent viscera, simple gastroenterostomy, the anastomosis being made about the middle of the stomach, or preferably to its left, should be practised. If the symptoms were not relieved within a reasonable time, then pylorectomy might be performed.

**A Method of Subtotal Gastrectomy.**—Dr. Francis T. Stewart said the method of subtotal gastrectomy consisted in removing the diseased segment of stomach from left to right, after performing end-to-side anastomosis between the lower portion of the incision which amputated the stomach and the upper part of the jejunum, the operation being so conducted that the suturing necessary to unite the stomach to the intestine was completed before either viscus was opened.

**Jonnesco's Membrane.**—Dr. John E. Summers of Omaha read this paper. The Jonnesco-Jackson-Reid membranes, he said, should be considered as congenital; they could always be demonstrated in every individual should the incision admit. They were purposive and intended by Nature as ligamentary supports preventive of intestinal stasis rather than causative; and if this was so, they should be divided only after they had become restrictive of intestinal function from loss of nervous and muscular tone resulting from chronic intestinal toxemia. The so-called "white line" was the line of fusion of the duodenal and colonic peritoneum with the parietal peritoneum after rotation had been completed, and could be made manifest by rotating the attached hollow viscus in a direction continuous with the course of the blood-vessels and fibers of the membrane, a direction opposite to the fetal rotation. These membranes, although present in children, seldom produced symptoms in them because intestinal peristalsis was sufficiently powerful to overcome minor difficulties. Most of the sufferers were from thirty to sixty years of age.

Dr. Jabez N. Jackson of Kansas City, Mo., said that, when he first presented this subject in 1908 most of the Fellows said there was no such thing; now it was said to be a congenital condition in everybody. Although he had seen a considerable number, he was still in doubt as to its etiology. He wished to say that under no circumstances would he consider anything to be Jackson's membrane, unless it could be positively demonstrated to be producing mechanical interference with the gut, and had become the subject of surgical discussion, just as a tendon became surgical when producing a contracture. Regarding treatment of this pericolic membrane, there were two distinct factors that could be absolutely demonstrated—the presence of constriction and, following this, the presence of obstruction. Removal of the obstruction was not suffi-

cient, and he had combined the idea of the Germans of plicating the cecum and removing the membrane without removal of the gut.

**Ligation of the Innominate Artery for Subclavian Aneurysm.**—Dr. C. A. HAMANN of Cleveland reported the case of a woman aged 68 years, who was operated upon in February, 1913. Partial resection of the clavicle was done in order to facilitate access to the vessel; the innominate was tied with a double-braided silk ligature and the right common carotid with chromicized catgut. Prompt healing of the wound occurred, and the aneurysm was completely cured. Fourteen months after the operation the patient was found to be in good condition and there was no trace of the aneurysmal sac to be felt. There had been 53 cases of ligation of the innominate artery up to the present time; of these 14 recovered, the most frequent cause of death was secondary hemorrhage.

**Technique of Intrathoracic Operations.**—Dr. ALEXIS CARREL of New York said the report of intrathoracic operations by American and European surgeons showed that pleurisy was still a frequent complication. In the experimental operations performed lately by the writer, this complication was completely avoided by a few technical details which prevented the irritation and infection of the pleura. Through a small opening a silk membrane was introduced into the pleural cavity. Afterwards two large compresses made of a sheet of absorbent cotton and two sheets of black Japanese silk were introduced into the pleural cavity and used for walling off the operating field. The pleura was never seen by the operator or touched by his fingers. This would protect against the germs of the air, and the blood from the operating field was absorbed by the cotton inside the compresses.

**Auricular Fibrillation from Traumatism Occurring in a Heart Previously Normal.**—Dr. GEORGE E. ARMSTRONG of Montreal reported the case of a man 46 years of age, who had been shot in the chest. The bullet entered the fourth intercostal space a little to the left of the left border of the sternum. Fluoroscopically the bullet could be distinctly seen in the pericardium. It was quite free and readily changed its position when the man was rolled from side to side. Tracings showed complete auricular fibrillation. The pulse was irregular and of poor volume. Twelve hours after the bullet had been removed the pulse, which had previously been 130 to 140, slowed down to 90 and became quite regular. The tracing taken then showed normal auricular and ventricular contraction.

**The Interpleural Exposure of the Heart by Means of Longitudinal Section of the Sternum.**—Professor REHN of Frankfort, Germany, recommended this operation in which the pleura was not opened. The incision was made from the left second chondrosternal articulation to the middle of the xiphoid process, then it followed the left costal arch; the latter incision was deepened, rectus and transversalis abdominis were cut, and the incision continued along the under surface of the costal arch and the sternum above. The finger easily separated the delicate fibers of the diaphragm and entered the mediastinum. The xiphoid process was now either pushed aside or removed. A well-rounded sponge was passed up into the mediastinum and pushed the pleura out of the way on both sides. The sternum was split up to the third or even second chondrosternal articulation, and was then forcibly held back by hooks and the pleura protected by gauze. The anterior surface of the pericardium was now freely exposed and could be opened as far as desired. The heart was just as easily accessible and the incision offered an especially good opportunity to compress the venæ cavæ.

**Surgical Intervention in Cases of Pulmonary Infections.**—Professor ANTOINE DEPAGE of Brussels said the results of Forlanini's method for lung tuberculosis were most favorable in cases in which one lung only was affected and in which there were no pleural adhesions. Forlanini's treatment by artificial pneumothorax was rather medical than surgical, though based on a surgical principle.

**Pulmonary Abscess and Bronchiectasis.**—Dr. HOWARD LILIENTHAL of New York reported fourteen operations in 11 cases of non-tuberculous intrapulmonary infection. There were five cases of brochiectasis with one death in the hospital and one death a year later of hemorrhage; 3 cases of acute abscess with two recoveries; 1 chronic apical abscess recovered: 1 extensive gangrene died; 1 fetid bronchitis, with minute abscesses mistaken for brochiectasis, died. The various operations were: For direct drainage; free opening of the pleura; multiple rib resections; Tuffier's extra pleural tamponade; in one convalescent case not yet discharged the entire right lower lobe was removed for bronchiectasis.

**Surgical Treatment of Tuberculosis of the Lungs and Bronchiectasis.**—Professor C. HENSCHIEN of Zurich said that severe and moderate cases of unilateral tuberculosis of the lungs, cavernous as well as infiltrated, could be cured by lung collapse and compression. The treatment should begin with an attempt at artificial pneumothorax; if the latter was impracticable on account of adhesions, then extrapleural thoracoplasty was indicated, with which in the clinic in Zurich out of 122 cases 20 per cent. were clinically cured, 34.6 per cent. considerably improved, and 26 per cent. improved. In certain selected cases extrapleural pneumolysis and plugging also gave favorable results.

**The Surgical Aspects of Bronchiectasis.**—Drs. JAMES G. MUMFORD and SAMUEL ROBINSON of Clifton Springs, N. Y., read this paper. They said that granted bronchiectasis was commonly the result of bronchial obstruction by foreign body, tumor, or disease, the first indication should be the removal if possible of this obstruction. Bronchoscopy for the removal of a foreign body had not infrequently arrested bronchiectasis. In the earlier stages of the disease, nitrogen gas injection producing artificial pneumothorax was indicated, and should always be tried. Pleuropneumolysis, or extensive rib resection, was a dangerous procedure, with additional dangers in bronchiectasis. In late cases of bronchiectasis, where the disease was obviously confined to one lobe, lung resection was the sole source of relief.

**Bronchiectasis.**—Dr. WILLY MEYER of New York said his paper was written to give a picture of the present status of this disease and because, so far, there was no treatise on this subject in the English language. It might be said that bronchiectasis was to-day a surgical disease, since other forms of treatment merely alleviated. It must be borne in mind that bronchiectasis was an affection of the bronchial tree, not of the pulmonary parenchyma. Hence, methods of benefit in tuberculosis could here have the same effect. A definite diagnosis was not easy. Stereoscopic radiography was here of great assistance. Since it had been shown that injection of a number of cubic centimeters of fluid into the bronchi was well borne, he expected to try insufflation of argyrol, with the idea of enabling the radiographist to show more distinctly the contour of the walls of the distended bronchial cavities. The larger cavities of the lung were best treated by pneumotomy and in localized and early cases this had given a number of cures. Loosening of the lung in conjunction with the costal pleura from the endothoracic fascia (pneumolysis) and the filling of this cavity with a transplant of fat tissue or omentum kept in cold storage (Tuffier) had given some good results. A paraffin filling of the cavity might be of use, as also thoracoplasty with resection of a number of ribs. The loosening of the lung from its adhesions with the pleura and fastening its base further up on the diaphragm, giving the complementary space a chance to close by granulation was of benefit in one case of Garre's Sauerbruch's and Brun's method of ligating branches of the pulmonary artery, which the speaker had done three times, produced marked connective-tissue formation in the affected lobe and firm adhesions between pulmonary and costal pleura, thus allowing the lobe to be compressed by thoracoplasty and phrenicotomy to be performed later. In not a single case had a real cure been obtained. Only the removal of the diseased lobe or lobes of the lung—pneumectomy—could effect real cure in these patients. The efforts of the surgeon must be continued in the direction of overcoming the obstacles to this radical interference. There were on record eight pneumectomies for bronchiectasis with a mortality of 50 per cent.

Dr. GERARDO M. BALBONI of Boston said his experience with artificial pneumothorax comprised 61 cases treated during the last three years; 57 were cases of pulmonary tuberculosis; 4 were non-tuberculous; there were 2 lung abscesses and 2 cases of brochiectasis. The experience with these four non-tuberculous cases was pertinent to this discussion. One lung case and one abscess case might be regarded as cured; the other two as improved. The puncture method was used in all these cases. The chief dangers associated with this method of treatment are pleural shock, gas embolism, spontaneous pneumothorax from rupture of the lung, and rupture of the mediastinum. It was best to pro-

duce the pneumothorax gradually by frequent injections of nitrogen, bringing it to the desired volume and pressure. It should be maintained uninterruptedly for the entire period of treatment to bring about anatomical healing.

**Pleural and Pulmonary Complications in Tropical Abscess of the Liver.**—Dr. JAMES E. THOMPSON of Galveston said that infection of the lung and pleura occurred by direct extension and metastasis. The former was by far the more common. When the abscess penetrated the lung and opens into a bronchus, the patient would spit up chocolate-colored pus. Spontaneous cures had been reported where the abscess was completely evacuated by this route. Usually the liver abscess emptied itself partially and continued to drain intermittently through the lungs. Amebic infection spread to the lungs and produced cavitation. The prognosis was very unfavorable. Many authors placed it as high as 84.8 per cent. The author's mortality was 45.4 per cent.

**Double and Anomalous Forms of Empyema.**—Dr. KENNETH A. J. MACKENZIE of Portland, Ore., reported in detail four of his own cases of double empyema occurring during an epidemic of influenza in the Northwest in the year 1899. In all cases either bilateral simultaneous thoracotomy or bilateral thoracotomy with a few days' interval between operations was done. A preliminary report of a substitute for acute operative pneumothorax is submitted. The plan was to replace the serous or purulent fluid of pleurisy or empyema by a non-toxic and non-absorable fluid, such as petrolatum or liquid paraffin. The method offered the advantage of relieving empyema without the shock of a traumatic pneumothorax. The hydrocarbon would act as an inhibitor of bacterial growth. By holding the surfaces apart until inflammation was allayed, dense adhesions were prevented. The non-absorbable and non-toxic fluids might prevent progression to the purulent stage. This procedure might be substituted for compression of the lung by nitrogen gas in the care of tuberculosis.

**Visceral Pleurectomy for Chronic Empyema.**—Drs. CHARLES H. MAYO and E. H. BECKMAN of Rochester, Minn., said that in a considerable percentage of cases of chronic empyema the lung would expand to a greater or lesser extent if visceral pleurectomy, combined with gridironing of Ransohoff, was performed. In the experience of the authors, the operation was not as severe or as dangerous as the Schede operation. Patients should be carefully prepared for operation by securing drainage at the most dependent part of the cavity, by reducing the infection to a minimum, and the resistance of the patient to the maximum by vaccines.

**Arthroplasty for Intraarticular Bony and Fibrous Ankylosis of Temporomandibular Articulation.**—Dr. JOHN B. MURPHY of Chicago reported nine cases of this operation. It consisted in the division of the mandible at its condyles, the removal of a third of an inch of the entire diameter, the interposition of the temporal fascia and fat flap, and closure of the wound; then the separation of the teeth on the operated side by a block for two weeks and the institution of passive motion after the third week. The pedicled flap, consisting of the mucous membrane of the soft and hard palates, had rendered excellent service in the interalveolar cicatricial type of contractions. Of the nine cases he had been able to trace eight. In seven the result had been ideal. In the eighth, in which the coronoid process and the zygoma were involved, restriction of motion resulted.

**Cancer of the Tongue.**—Dr. JOSEPH C. BLOODGOOD of Baltimore said it had been demonstrated in this study of over 100 cases that the failure to cure when cancer of the tongue was fully developed was due chiefly to the neglect to remove the muscles of the floor of the mouth below the cancer. The high mortality after operations for cancer of the tongue was chiefly due to the removal of the floor of the mouth without removing at the same time a section of the lower jaw. The investigation had also shown that if a lesion of the tongue is subjected to immediate operation within a few weeks after the onset of the lesion the chances of a permanent cure were best. In this stage it would usually be sufficient to remove the local lesion with a good margin of healthy tissue, and this removal should be accomplished with the electric cautery. The center of the lesion should be preserved for microscopic study. While the chances were that the lesion would be found to be benign, should it prove to be cancer, the possibilities of cure were almost 100 per cent. The majority of cases of cancer of the tongue sought surgical aid at an unnecessarily late period. In every case the patient was warned—there was always something to be seen and felt in the tongue or floor of the mouth. If such a lesion was investigated at once, a local operation with the electric cautery should be sufficient; in a later stage removal of the glands and repeated cauterizations of the mouth lesions; in still later stages, resection of the jaw must be done. In the 14 cases personally operated upon by these newer methods in the past five years, there had been no postoperative mortality, and so far but one patient was dead from recurrent carcinoma, and there was evidence of recurrence in only one case.

Dr. MORESTIN of Paris said the prognosis of cancer depended chiefly on the time of treatment and upon the methods employed. The complete extirpation of the menaced or invaded lymphatic vessels and glands was absolutely necessary—as essential as the removal of the cancer, which should be done by cutting wide of the tumor mass. For instance, in the case of carcinoma of one side of the tongue, which was very common and quite typical, the part of the organ corresponding to the diseased section should be extirpated, as well as the floor of the mouth and all the subclavicular, carotid, and submaxillary glands and those glands lying below the hyoid bone. The carotid region should be carefully closed by sutures uniting its muscles—the external wound should be completely closed, the bucco submaxillary wound packed and food given only through the stomach tube until cicatrization of these wounds was completed. The patient should be allowed to get up on the day of the operation or on the following day.

**The Function of the Gastroenterostomy Opening in Cases of Permeable Pylorus.**—Professor HENRI HARTMANN, Paris, France, read this paper. He said it was generally accepted that in presence of a permeable pylorus, the gastrojejunal opening tended to close in consequence of its physiological uselessness, the chyme following the pylorus. This was an error. The gastrojejunal stoma well lined by mucous membrane, without ulceration whatever, without any scar tissue, remained permeable forever. He has collected 44 cases of obliteration of the gastrojejunal anastomosis; 37 cases of pyloric or subpyloric stenosis, 4 indisputable cases of peptic ulcer, 3 cases of free pylorus. The radiological examinations, made on patients with a permeable pylorus, who underwent gastroenterostomy, confirmed the results of experiments on dogs. Briefly then, there was no more fear of an anatomical obliteration of the gastrojejunal opening in the cases of a permeable pylorus than in any other case. This anastomosis was physiologically useful when it was established in the pyloric antrum in the neighborhood of the greater curvature.

**Extirpation of the Spleen for Diseases of the Blood.**—Dr. RANZI of Vienna reported 20 extirpations of the spleen for diseases of the blood, performed at the Surgical Clinic of Prof. v. Eiselsberg, Vienna. The indications for these operations made by Professor Eppinger were: hemolytic icterus (3 cases), pernicious anemia (5 cases), Banti's disease and hypertrophic cirrhosis of liver (9 cases), thrombophlebitic forms (3 cases). Four patients died after the operation. The results in the other 16 cases were very satisfactory. The patients, formerly very weak and obliged to keep their beds, had regained their strength and weight and were again able to work, especially the cases of pernicious anemia. In pernicious anemia the extirpation was very easy; in other cases sometimes very difficult on account of the excessive adhesions and enlarged blood vessels. The operations were performed under local anesthesia.

**Results of Treatment of Cystic Disease of the Breast.**—Drs. ROBERT B. GREENOUGH and CHANNING C. SIMMONS of Boston read this paper, of which the following were the conclusions: (1) Of 83 cases of partial operation for cystic disease of the breast, 17 or 20 per cent., were successful. (2) In 4 cases carcinoma occurred in the breast tissue left by the partial operation, 4.8 per cent. (3) In 5 cases the disease recurred only in the other breast, 5.9 per cent. (4) In 8 cases the disease returned in the breast tissue left by the first partial operation, 9.6 per cent. (5) The occurrence of carcinoma in cases of cystic disease, estimated at about 10 per cent. of cases, demanded radical treatment in all but the mildest cases. (6) The operation of choice should remove all of the gland tissue of the

affected side, and when the disease was bilateral, of both sides. (7) This could best be accomplished by subcutaneous amputation, leaving the nipple and areola, or by elliptical amputation. (8) Where grave doubt as to diagnosis was present, elliptical amputation was to be preferred. (9) Local excision of nodules in the breast, suspected of being malignant, should never be performed. (10) The operation of local excision or partial plastic resection should be restricted to the earliest and mildest types of cystic disease. In such cases plastic resection was to be preferred.

**Blepharoplasty by a Pregrafted Flap.**—Dr. C. L. GIBSON of New York said the older operations for plastic repair of the eye-lid were, for the most part, defective from exaggerated shrinkage and the raw surface was made to lie in contact with the eyeball. The author's method consisted in preparing a flap which was lined with a skin graft entirely healed and provided against eventual shrinkage of the flap. The grafted skin which came in contact with the eyeball, assumes the character of mucous membrane and furnished a free edge and movable eyelid. The operation was done in two stages. The best flap was a modification of that devised by Fricke, the flap being taken from the skin above and external to the external canthus. At the first stage a horizontal incision, starting at the external canthus, was made corresponding to the length of the proposed flap. This incision was underminded so that a pouch was made into which the skin graft was tucked, raw edges in contact. This was allowed to heal in place, and in about ten days the second stage was completed by cutting away the diseased area of the eyelid and transplanting the pregrafted flap into the defect and suturing it accurately into place. The results of this operation physiologically and cosmetically had been most satisfactory. The operation was destined to compete favorably in the treatment of malignant growths of the eyelid with the newer remedies, such as radium and *x*-ray which, however, lacked a guarantee of permanent cure as attained by such radical operations.

**Uncomplicated Tuberculous Foci in Bones and Their Treatment.**—Dr. THOMAS W. HUNTINGTON of San Francisco dealt with cases in which the focus existed (*a*) as an incipient lesion, but sufficiently advanced to cause symptoms; (*b*) as a lesion that had recurred after a period of quiescence. In neither case had it become the seat of mixed infection or invaded the adjacent joint. Exception was taken to the conservatism of the orthopedist where the focus was accessible through an extracapsular route. Attention was called to the too frequent and humiliating failures at the hands of men of great skill and experience, and to the general surgeon was suggested the propriety of assuming jurisdiction in early cases. The term "latency" in this connection was regarded as a misnomer.

**Fracture of the Patella.**—Dr. W. BEECKMAN DELATOUR of Brooklyn reported a total of 101 fractures in 87 patients. Three were simultaneous of both patella and in one there was also a fracture of the cervical vertebra. Upon these cases there were 96 operations with no operative mortality, and in all useful joints resulted; in four motion was somewhat limited. The operation consisted in a curved transverse incision across the knee above the patella, suture of the tears in the lateral capsule and across the front of the patella with chromic catgut. These were reinforced by a suture passed through the patellar tendon above and then below in mattress fashion, and tied. The object of the suture was to relieve the transverse sutures of strain when there was contraction of the quadriceps muscle. Early passive motion was important. A posterior splint should be worn for at least 12 weeks. Operation was as a rule, done at the end of 48 hours. Results where the bone was broken in several fragments were as good as in the simple transverse cases.

**Frontal Sinus Suppuration.**—Dr. HOWARD A. LOTHROP of Boston said Intranasal treatment for frontal sinus suppuration should always be given a thorough trial before instituting more extensive operations. The results of external operation in obstinate cases were manifested by many successes obtained by all methods and also by many failures. The problem presented was the healing of suppuration in a natural bone cavity surrounded entirely by rigid walls. No method known took full advantage of the anatomical possibilities. The following technique was suggested: A small opening was made in the frontal bone just above the upper extremity of the nasal process of the superior maxilla. The sinus was explored. The probe was passed through the ostium into the nose and left in this position while the anterior ethmoid cells were broken through with a small curette. Then, working from above, but chiefly from below, all the dense bone situated at the base of the nose was removed. This included the interfrontal septum, the nasal spine, the nasal crest, the upper, thick ends of the nasal bones and nasal processes. Thereby both sinuses were made into one, a thin shell of bone remained in front of the level of the ostium; and as the adjacent portion of the septum of the nose was likewise removed, an instrument could be passed through either nostril into either sinus and could be swept across from one side to the other. In certain cases it was desirable to epidermize the frontal sinus and this was accomplished by turning a flap from the upper eyelid.

## PRACTITIONERS' SOCIETY OF NEW YORK.

*Two Hundred and Sixty-first Regular Meeting, Held March 6, 1913.*

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

**Some Recent Therapeutic Procedures in Acute Infections.**—Dr. MEARA presented this case—a girl of ten with a history of severe digestive disturbances during the first year of life and comparatively good health thereafter until 9 years, when appendix was removed. In the spring of 1912 a persistent dry cough, slight temperature, and loss of flesh suggested tuberculosis. All laboratory tests and *x*-ray plates were negative. In March she had her first attack of asthma; was then more or less ill until July when she developed bronchopneumonia. She was given autogenous vaccine made from pneumococcus isolated from sputum, also complete outdoor life and a generous diet. She improved greatly and had quite recovered when in October she developed a colitis followed by asthma. She was now placed in St. Luke's Hospital and at this time many rheumatic nodules were found and a blowing systolic murmur at apex. On careful questioning there was a history of "growing pains," sort throat, stiff neck, and painful joints. These manifestations yielded to salicylates, but shortly after there developed innumerable attacks of asthma which persisted all winter interspersed with a variety of other infections. Blood cultures were negative. In January, 1913, her chest was clear, but she developed an otitis media followed by a mastoiditis. On February 1 she had a pneumonic consolidation of left upper and lower lobes. On February 8 she got stupor, stiff neck, and headache which led to a lumbar puncture with negative findings. These symptoms were removed by exploring the mastoid wound and evacuating pus from the sphenoid sinus. Asthma recurred, continuing with varying severity through March. On April 9 she developed diphtheria; she received 5,000 units antitoxin intravenously at 11 P. M. and 5,000 units intravenously at 10 A. M. next day, and 5,000 units intramuscularly at 6:30 P. M.; next day 3,000 units intramuscularly. Cultures were negative after the nineteenth. Urine showed albumin, granular casts, and many leucocytes; all this time the asthma persisted. Complement fixation tests against organisms isolated from tonsils and sputum were positive for a hemolyzing streptococcus and a green producing capsulated streptococcus (probably pneumococcus). The patient was taken to the country about June 1. At first she improved markedly, but about July 10 rheumatism recurred severely as a polyarthritis, erythema nodosum, and carditis with fever. She emaciated rapidly and developed a hematuria, bleeding from the rectum and multiple petechiæ. Urine was markedly diminished and contained blood, much albumin and many casts. The child was stuporous and the whole appearance suggested a malignant infection. A strongly positive complement-fixation test against *Streptococcus viridans* was obtained. Using the father as a donor, patient was transfused first on July 18, receiving 280 c.c. She improved slowly, but remained very ill, and on August 1 was again transfused, 300 c.c. of blood being given. She continued to improve and on August 8 260 c.c. was transfused; on August 15 220 c.c.; on August 22 260 c.c.; on August 29 280 c.c. were transfused. After the last transfusion she developed a general urticaria. Improvement had been steady; diarrhea had ceased and one week later she was out in an automobile, and has since continued in good health. All attempts to connect the asthma with a definite exciting cause had failed. Sputum cultures

showed various kinds of streptococci and pneumococci. Anaphylactic tests of many substances were all negative. Vaccination was encouraging, but by no means convincing. The organisms isolated were all members of the group whose transmutations have been studied by Rosenow.

Dr. Wm. H. Park said the development of the case was full of interest for him in view of work they had been doing recently upon some of the diseases which this child happened to have. It might be of interest to bring up the fact that normal people sometimes had and sometimes had no protective substances in the blood. Schick's intracutaneous toxin test for the presence of diphtheria antitoxin proved antitoxin to be present in 70 per cent. of healthy persons. Schick pointed out that about 80 per cent. of children got antitoxin from their mothers, as infants, which lasted for perhaps one year; a percentage developed it, so that at the end of two years there were less than 60 per cent. with antitoxin. Later in life the percentage again rose. Such persons did not require immunization because they were already immune. Many normal persons were found to have more antitoxin than the average of those who recovered. Some children who had never had diphtheria had as much as 12-15 units of antitoxin. It was a difficult matter to measure antibodies, but undoubtedly normal adult persons carried protective substances. With the usual amount of pneumococci and streptococci in the air passages people carried antibodies antagonistic to them. In the case of the child quoted who had had two injections of 5,000 units intravenously and then one intramuscularly, the results of experiment and observation clearly proved that a single injection of 10,000 units was more effective than those of 5,000. The antitoxin remained in the blood four or five days. When you gave a child 5,000 units that child would have about four units per c.c. during the first 24 hours, enough to neutralize 1,000 times as much toxin as could possibly be present. It was like applying oil and lime water to a burn and expecting the burn to recover without waiting for the necessary time. The diseased tissues took time to recover. At the present time very few children in the Willard Parker Hospital got more than one dose. Dr. Rosenow had done much work upon causing variations in organisms, but other workers found it difficult to believe that one could change one definite organism into another of a definite type. You could rob an organism of its characteristics. You could take a hemolyzing streptococcus and grow it under circumstances which made it less and less hemolyzing, but put it back into animals and it would get back its properties; but it was doubtful if you could change it into a pneumococcus. At to the question of getting vaccine from non-toxic substances, there had been many attempts by Vaughan to split the organism and to use the non-toxic part. In certain diseases the toxic part was the only important one. In others the non-toxic parts might give rise to antibodies which would be bactericidal against the organism, but the results so far were disappointing.

Dr. Meara said that a medical friend had had a severe experience with horse asthma. On the occasion of a tracheotomy for laryngeal diphtheria, the patient coughed and sprayed the doctor who decided to take antitoxin. He had 1,000 units or 3 or 4 c.c. and had an immediate anaphylactic shock as soon as the needle was withdrawn. His asthma became very intense. He was given adrenalin and atropine, but his asthma increased and he became black in the face with intense dyspnea and inability to expire. His lungs were expanded to the utmost extent. They had recourse to the rather severe treatment of squeezing air out of him by brute force. He then had a profuse urticaria. The next day the fascial planes of the neck were markedly emphysematous. He was rendered immune for a time.

Dr. Park said that he knew of two physicians in the past two months who had been subject to horse asthma. They had received antitoxin in small divided doses of 25 c.c. with no bad effects. He added that enough should be given in the first dose, such as 10,000 units to severe cases in children, and in adults 20,000. With these large doses, no toxin remained in the body after a few hours, but the blood contained an enormous surplus of antitoxin.

Dr. Thacher asked if that applied to tetanus antitoxin.

Dr. Park said that it did. Thus in a severe case that finally recovered Dr. Nichols gave a second dose, but bled the child first to find whether it was necessary. The child's blood was found to contain five units in each cubic centimeter. The need of the large dose was not to match the amount of toxin but rather to rapidly gain access to all parts of the body.

Dr. Brannan asked Dr. Park if Dr. McCullum of the Boston City Hospital still gave repeated large doses and what was his maximum total dose.

Dr. Park replied in the affirmative, that Dr. McCullum gave repeated doses of 10,000 units each up to the maximum of 250,000 units.

Dr. Robert A. Cooke said that the case Dr. Meara had presented showed one of the evidences of a reaction that it was customary to regard as an evidence of sensitization of the human to foreign protein, namely, asthma. In this case there had been attempted the determination of a specific factor for the asthma, by means of the cutaneous reaction, later to be described; and Dr. Meara thought it would be of interest to discuss briefly in this connection the studies that had been made in cases of asthma and hay fever during the past three years. He said that his interest in this work had been stimulated by a personal experience with the reaction—its immediate dangers and discomforts as well as the later advantages—and it had occurred to him that the principle of this reaction could be applied as a rational therapeutic measure. Two facts were now generally accepted with regard to the anaphylactic or sensitization state. First, that it was the first step in the process of immunity, and, secondly, that in the human, the clinical type of the reaction depended on the cells that were sensitized. Of the pathogenesis of human sensitizations but little was known. Heredity was, however, an important predisposing factor in the majority of cases. For example, one patient had hay fever of the fall type in association with asthma; her mother had the early type of hay fever and sensitization to fish, and the grandparent, on the same side, was sensitive to horse. Again, a boy of six years had spring hay fever and sensitization to egg; his father had sensitization to egg. In other words, certain individuals inherited a capacity for abnormal bioplastic activities, which might or might not take the same form as those of their affected forebears. But direct inheritance by passive sensitization might also take place. Etiologically considered, asthmatic paroxysms might be specific or non-specific. (a) Specific: due to absorption of native protein from (1) upper respiratory tract, "inhalation asthma"; (2) intestinal tract, "food asthma"; (3) chronic infectious foci, "bacterial asthma." (b) Nonspecific: a heterogeneous group of causes, such as climatic changes, dust, irritating vapors. A careful study of true asthma showed that these factors were not operative in the early stages, but after an individual had developed the asthmatic habit, so to speak, there seemed to be opened up reflex paths along which stimuli from various organs as brain, stomach, intestine might reach the bronchi. Inhalation asthma was the commonest form and was usually associated with coryza, and due to animal or vegetable protein. These latter constituted the well-known cases of hay fever, a few with but usually without asthma. The usual specific factors in the early cases of seasonal coryza and asthma were grasses: timothy, June, red top, rye, wheat; flowers: daisy, dandelion, rose, honeysuckle; trees locust, chestnut. In late cases the inciting agents were ragweed, goldenrod, salt-marsh grass, clematis, aster, and others. The diagnosis was made in general on the history with the final determination of the particular pollens, by means of a cutaneous reaction. A solution of the pollen injected intradermally would, in individuals sensitive to that form of protein, give a reaction beginning in five to twenty minutes, and consisting of an urticarial wheal, surrounded by a zone of hyperemia and usually associated with considerable itching. In non-sensitive cases there was no reaction. These solutions were prepared as follows: The dried and pulverized pollen-iferous portion of the flower was extracted in a weakly alkali-saline solution, precipitated by two volumes of acetone, and the precipitation redissolved in saline. They were standardized by their nitrogen content and doses expressed in fractions of a milligram of nitrogen. One 1/1000 milligram intradermally gave a good positive reaction in sensitized individuals. Having determined the specific factor in any case, he had gone a step further and attempted an active immunization. Some ten years ago Dunbar showed that it was possible, by injections of pollen extract in the horse, to produce a serum which had some therapeutic effect in hay fever. He tried the active immunization in the human, but desisted on account of violent reactions

following injections. Dr. Cooke had to establish his dosage empirically, and, as a result of experience with over one hundred cases, it might be said that an initial dose of 0.01 milligram nitrogen subcutaneously, did not give rise to constitutional symptoms. The best results were obtained in the seasonal cases, by giving four or five injections at week intervals before the attack, and continuing injections every week or ten days until within two weeks of the end of the season. In this way it necessitated about ten injections. Of twenty-five early cases treated the previous year, all were progressing satisfactorily up to July, when about half developed symptoms which were found to be due to pollens of new varieties just coming into bloom. Of eighty late cases, 50 per cent. gave satisfactory results; about 20 per cent. were improved and 30 per cent. no result. In no sense was this immunity permanent and treatment was required each year. There was a group of sensitization cases that he did not believe suitable for immunization, purely on account of the short duration of immunity. This included the cases sensitive to animal emanations and the food proteins. They should avoid the sources of trouble. This applied equally to the cases sensitive to certain perfumes and sachets, as orris. There was still a good deal of work to be done, but the results thus far obtained showed that the procedure was rational and the hyptothesis justified.

Dr. J. A. Miller asked whether in hay fever cases, sensitization to food proteins was a factor. Did the ingestion of certain forms of proteins cause persistance of the asthmatic attacks.

Dr. Cooke said that there was a sensitization to proteins by ingestion in which case that particular protein when ingested would always induce an attack. During an attack of asthma from some other cause, there might be an exacerbation of the trouble from ingested foods, but it was not likely that this was the protein of the food but rather a reflex affair and therefore not specific.

Dr. Miller asked if the diet had to be regulated in these cases.

Dr. Cooke said yes, in those in which diet played a part, whether acting specifically or as non-specific reflex.

Dr. Edward Lindemann said that Dr. Meara had so fully covered the case of the ten-year-old girl, that he could add only a word as to his impressions of the child as he first saw her. He had had considerable experience with many children, as resident at Bellevue, and at a children's hospital in Boston. The child looked to him moribund. Dr. Meara had not expected that anything could be done that would be of service. Blood transfusion was justifiable as a last resort. He was no less surprised at the result than Dr. Meara. From observations on the case in which the prominent conditions were of chronic sepsis, severe anemia and finally multiple petechial hemorrhages secondary to sepsis, and of observations upon five other cases, he was convinced that the transfused blood contained bactericidal elements. An important distinction was to be made between blood and blood serum. In transfusion the passive immunity was greatest, immediately following the introduction of the blood. A modification of the patient's blood took place with the introduction of fresh blood, which seemed to possess the power of inhibiting bacterial action. Later the blood introduced lost its activity and the bacterial activity became renewed; at this point the condition of the patient was unrelieved. With small doses the disease subsided for a time only and then recurred, so that unless blood were introduced repeatedly the bacterial activity was only checked but not removed. The parallelism of anemia to actual resistance was well known. Anemia produced sepsis and sepsis produced anemia in a vicious cycle. In the terms of the red blood cells, the hemoglobin produced an active immunity. Transfusion developed an immunity by destroying the organism causing the disease. In support of this theory he would present a few facts which were well known in work on immunization. The reactions were of different characters and might be briefly summarized: toxins and antitoxins, bacteriolysins, agglutinins, precipitins, cytolysins. The antitoxin immunity was not a bactericidal one. Diphtheria antitoxin, for instance, had no effect on the diphtheria bacillus. Opsonins and phagocytosis were other forms of immunity. Streptococcus and staphylococcus immunity could not be grouped among the toxin and antitoxin group or the cytolysin group, but were to be counted among the phagocytosis group. Rats' blood seemed to be highly immune to anthrax. The immunity did not seem to be embodied entirely in serum; there were other elements which were important factors. Workers in phagocytosis found that when resistance was low the phagocytic power was very low and that when resistance was high the phagocytosis was high. In chronic infections adaptation was another striking feature; for instance, he found that an organism would live with a host for a long time; there was constituted a sort of harmony and this might persist for a long time without injury to the host. Ultimately the host killed the organism or the organism killed the host. The phenomena had caused Welch to raise the hypothesis that just as the individual could form antibodies or protective substances, so could parasites form protective substances against the host. All of these facts went to show that the problems of immunity did not lie entirely with serum but were bound up in other elements of the blood. What has taken place in this case had not only been with blood serum but also a change in the condition of the white cells of the blood and possibly with complement. For instance, if one considered bacteria in certain forms of this immunity, substances known as bacteriolysins were formed. One assumed that bacteria must fix bacteriolysins. This meant diminution of bacteriolysins in the blood and in such cases one expected to find the immunity power of the blood decreased. In fatal infections this was borne out. In the staphylococcus and streptococcus infections the immunity had the nature of opsonic and phagocytic action. There was a change in the complement. Complement played a part in infections. Possibly there was an activity of the actual leucocytes introduced into the whole blood where the patient's own leucocytes were unable to cope with the disease. In streptococcus infections there seemed to be a definite erythrocytolysis or hemolysis of the red cells. In long standing streptococcus and staphylococcus infections extreme anemia was produced by the hemolyzing toxins, elaborated by these organisms. In the whole blood valuable substances were introduced which cured the anemia. Dr. Lindemann reported one case of infection of the uterus going on for several weeks, resulting in hemorrhage and severe anemia and sepsis. After the transfusion the temperature remained practically normal. He showed charts of other cases in which, after the transfusion, the temperature gradually came to normal. In no case of chronic infection that had been transfused did the patient fail to recover. In one case of acute infection in a child of six years there had been a fatal ending, but in acute cases there was a totally different condition to deal with.

Dr. Thacher asked in how many cases of sepsis transfusion failed and in how many was it successful.

Dr. Lindemann said transfusion was successful in all but one of seven cases of sepsis in which he had tried it.

---

**Patent Ductus Arteriosus.**—W. Essex Wynter reports the case of a female patient, aged 35, who was admitted on December 19, 1913, for hysterectomy on account of uterine fibroids. The patient had been admitted twice during the past two years, once at St. Mary's Hospital, and once at St. Bartholomew's Hospital; at the former, operation was thought inadmissible on account of the heart condition. The same doubt arose at the Middlesex Hospital, but the view that the murmur was due to a patent ductus having been arrived at, no objection remained either to the operation or to the anesthetic. Total hysterectomy was performed on December 20 by Sir John Bland-Sutton. No trouble was experienced with the anesthetic, the patient bearing the operation well and making a very rapid recovery. The patient had scarlet fever at the age of seven. "Cardiac weakness" had been diagnosed for five years since the third and youngest child was born. With the dysmenorrhea which occurred during that time, there were often associated pseudoanginal attacks. A loud systolic murmur was heard in the third left intercostal space, accompanied by a thrill. There were no appreciable cardiac changes or enlargement. The temperature was normal and there was no dyspnea, even on exertion. The patient played hockey and cricket in girlhood, and activity had not been restricted by the heart condition. No secondary changes, such as enlarged liver or edema, had occurred. By the *x*-ray screen the heart appeared normal in size and position, but there was bulging of the pulmonary artery above the heart shadow (second and third ribs).—*Proceedings of the Royal Society of Medicine.*

## Books Received.

*The* Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Traitement Efficace et Pratique de la Tuberculose Pulmonaire. Par le Dr. J. F. Larrieu. Paper; 62 pages; price 2 francs. Librairie Vigot Frères, Paris.

Diseases of the Heart. By John Cowan, D.Sc., M.D., F.R.F.P.S. Cloth; illustrated; 438 pages. Lea & Febiger, Philadelphia and New York.

Twelfth Annual Report of the Bureau of Science to the Honorable the Secretary of the Interior. By Alvin J. Cox. For the year ending June 30, 1913. Paper; illustrated; 131 pages. Bureau of Printing, Manila.

Recent Studies of Tuberculosis. Medical Symposium Series, No. 3. A reprint of articles published in the *Interstate Medical Journal*. Paper; illustrated; 299 pages; price $1.50. Interstate Medical Journal Company, St. Louis, Mo.

Blood-Pressure in Medicine and Surgery. By Edward H. Goodman, M.D. Illustrated; cloth; 226 pages. Lea & Febiger, Philadelphia and New York.

Radium and Radiotherapy. By William S. Newcomet, M.D. Illustrated; cloth; 315 pages. Lea & Febiger, Philadelphia and New York.

Luxor as a Health Resort. By W. E. Nickolls Dunn, M.B., M.R.C.S., L.R.C.P., and Geo. Vigers Worthington, M.B., B.C., M.R.C.S., L.R.C.P. Cloth; illustrated; 36 pages; price 1/6 net. H. K. Lewis, London.

Serology of Nervous and Mental Diseases. By D. M. Kaplan, M.D. Illustrated; cloth; 346 pages; price $3.50 net. W. B. Saunders Company, Philadelphia and London.

Practical Therapeutics. By Daniel M. Hoyt, M.D. Second Edition, Revised and Rewritten. Cloth; 426 pages; price $5.00 net. C. V. Mosby Company, St. Louis.

Hygienisches Praktikum. By Dr. Med. Paul Uhlenhuth and Dr. Med. Hermann Dold. Cloth; illustrated; 272 pages; price $1.25. Urban & Schwarzenberg, Berlin.

Taschenbuch der Augenheilkunde. By Dr. Curt Adam. Cloth; illustrated; 395 pages; price $2.00. Urban & Schwarzenberg, Berlin.

Collected Studies from the Bureau of Laboratories, Department of Health, City of New York. Dr. William H. Park, Director. Volume VII, 1912-1913. Paper; illustrated; 463 pages.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., assisted by Leighton F. Appleman, M.D. June 1, 1914. Volume XVI, No. 2. Paper; illustrated; 460 pages; price $6.00 per annum. Lea & Febiger, Philadelphia and New York.

Die Prognosenstellung bei der Lungentuberkulose. By Dr. D. O. Kuthby and Dr. A. Wolff-Eisner. Illustrated; paper; 572 pages; price $4.50. Urban & Schwarzenberg, Berlin and Wein.

Bacteriology for Nurses. By Isabel McIsaac, R.N. Second Edition. Cloth; 179 pages; price $1.25. The Macmillan Company, New York.

Manual Pratique de Diagnostique Bacteriologique et de Technique Appliqué. By R. Le Blaye and H. Gugenheim. Cloth; 441 pages; price 8 francs. Vigot Frères, Paris.

Spiritual Healing. Report of a Clerical and Medical Committee of Inquiry into Spiritual Faith and Mental Healing. Cloth; 56 pages; price 30 cents. The Macmillan Company, Ltd., London.

Materia Medica for Nurses. By A. S. Blumgarten, M.D. Cloth; 644 pages; price $2.50 net. The Macmillan Company, New York.

Black's Medical Dictionary. By John D. Comrie, M.A. Cloth; illustrated; 858 pages; price $2.50 net. The Macmillan Company, London.

The Simpler Natural Bases. By George Barger, M.A., D.Sc. Price, $1.80 net; cloth; 215 pages. Longmans, Green & Company, London, New York, Bombay, and Calcutta.

## Therapeutic Hints.

**The Medicinal Treatment of Acute Bright's Disease.**—Norbert Ortner states that tannin has long been a favorite drug in the reduction of albuminuria. It is strongly recommended by Pribram of Prague in the following prescription:

℞ Sodium tannate, 0.10 to 0.20 gram.

This dose should be given in cachet form. Three to five cachets should be given daily. Not more than 1 gram a day should be administered. Ortner has repeatedly tried this prescription but without marked success. In his experience with subacute nephritis after scarlet fever, he has often used quinine tannate as follows:

℞ Quinine tannate 0.10 to 0.20 gram.

This drug should also be given in cachet form, two to four times a day. Ortner has more recently used tannalbin, 2 to 3 grams a day, but without affecting in the least the progress of the disease as such:

℞ Tannalbin, 1 gram.

This may be given in a cachet two or three times a day. But Ortner now prefers the alkalies to tannin, particularly bicarbonate of sodium, 6 to 8 grams a day, or lithium benzoate or carbonate, 1 to 2 grams. Their administration has repeatedly been followed by a rapid increase in the amount of urine and decrease in its blood content. The alkalies also reduce the congestion. Almost all other drugs recommended have even less in their favor than tannin and tannalbin. Provisionally, methyl violet or methylene blue, 0.10 gram in wafers, or sodium benzoate may be employed for their bactericidal effect. Methyl violet possibly also reduces the albuminuria. Sodium benzoate may be prescribed as follows:

℞ Sodium benzoate, 3 to 4 grams.
Distilled water, 170 grams.
Syrup of orange, 20 grams.

Of this solution one tablespoonful should be given every two hours. The salts of strontium have been strongly recommended by French authors and have been tried in Vienna on Drasche's recommendation. Strontium bromide, strontium nitrate, and strontium lactate are used, the last most frequently. It is prescribed as follows:

℞ Strontium lactate, 6 to 8 grams.
Distilled water, 170 grams.
Syrup of orange, 20 grams.

Of this solution one tablespoonful should be given every two hours. Ortner considers that a venesection, taking 300 c.c. of blood from the vena pediea according to Baccelli's procedure is more effective than is the use of any styptic. In a short time, sometimes in 24 hours, it will reduce the blood content of long standing to a mere microscopic trace or may even cause it to disappear entirely from the urine.

**A New Solution of Iodine.**—Giovanni Zanetti has found that benzol is an excellent solvent for iodine, and furnishes a preparation that is quite efficacious for surgical antisepsis. A 10 per cent. solution of iodine in benzol is called by the author "iodo-benzol." This solution penetrates the skin with greater ease than does tincture of iodine. The advantages of the benzol solution are, in addition, the facts that it contains a high percentage of iodine, that it has a marked stability, and that it is much cheaper than the alcoholic solution of iodine, that is commonly used for surgical purposes.—*Il Policlinico.*

### THE SERVICE OF MEDICINE TO CIVILIZATION.*

BY VICTOR C. VAUGHAN, M.D.,

ANN ARBOR, MICH.

PRESIDENT OF THE AMERICAN MEDICAL ASSOCIATION.

FELLOW members of the American Medical Association: I wish to express my appreciation of the honor conferred on me in being called to officiate as your President at this time. I had been content to serve in the ranks, and I have regarded this position as too honorable to be sought, or to be lightly regarded when spontaneously bestowed. During my term of office I will give you my most devoted service.

In ancient times, civilization was born, grew for a few generations and fell into decay. In all instances it was local and covered only small areas. Its habitations were oases in the world-wide desert of ignorance and superstition, and after an ephemeral existence all were buried in the sand. Relatively small bodies of men occupying salubrious regions developed the elements of science and for a few centuries flourished. Their superior knowledge gave them dominion over their less fortunate neighbors, who were converted into slaves. Conquest brought disease and the local civilizations were obliterated by contagion. History is replete with instances in which triumphant heroes have brought to their rejoicing countries with their prisoners of war invisible and intangible agents of death, which have ultimately vanquished the victors.

The Egyptians of the Pharoahs drained the land, built aqueducts, disposed of their dead hygienically, reared temples and cities, maintained law and order, developed the elements of literature and science and devised and employed simple machinery. In speaking of the ancient Egyptians, Diodorus says: "The whole manner of life was so evenly ordered that it would appear as though it had been arranged by a learned physician, rather than by a lawgiver." Herodotus declared ancient Egypt the healthiest of countries, but filled with physicians of whom "one treats only the diseases of the eye, another those of the head, the teeth, the abdomen, or the internal organs." Writing of a later time, Gibbon said: "Ethiopia and Egypt have been stigmatized in all ages as the original sources and seminary of the plague." It is evident that in the time of its great civilization Egypt was salubrious; coincident with the decline in the learning and wisdom of its people it was visited and desolated by pestilence. That Egypt had lost its salubrity as early as the period of the exodus of the Israelites is shown by many passages in the Bible in which the chosen people are threatened with the diseases of Egypt if they neglect or violate the laws. Moses, "learned in all the wisdom of the Egyptians," codified his sanitary rules and regulations in the form of religious rites and ceremonies and thus secured their observance among the faithful even down to the present time.*

The Greek developed the most glorious civilization of antiquity because he was the most ardent student of science, but he was unable to cope with malaria and bubonic plague, and his descendants have been in bondage to malaria for nearly twenty-four centuries. The medicine of Hippocrates, the wisdom of Socrates, the philosophy of Plato, the plays of Aristophanes, the laws of Pericles, and the science of Aristotle could not save the Greek from the degrading effects of disease, and under its withering influence the civilization of this great people slowly but surely decayed. Its matchless marbles were thrown into the waste, its magnificent temples were allowed to crumble, its altars were deserted, its literature became insipid, its philosophy lost its virility, its science was forgotten, and the children of this blighted civilization were sold in the slave markets of Rome and in later generations paid tribute to the Slav and the Turk. There certainly were eminent Greek scientists and physicians for centuries after Hippocrates, but they were not products of Greek soil. They developed in Asia Minor, Egypt, Italy, and elsewhere. It is of interest to note in this connection that malaria, according to Jones, was introduced into Greece in the fifth century, B. C., and the fourth century showed the decline of Hippocratic medicine. Neuburger says: "The sons and grandsons of Hippocrates, as well as his immediate disciples, Apollonios and Dexippos, were at the head of that series of physicians who laid emphasis upon theoretical conjecture and gave to medicine in the fourth century B. C. its speculative coloring." Taken with the fact that other departments of learning showed similar retrogression at the same time, this sequence between the introduction of malaria and the trend of medicine toward speculation is worthy of record. That pestilence aided the barbarians in the final desolation of Greece is indicated by the following quotation from Thumb:

* President's address before the American Medical Association, at the Sixty-fifth Annual Session, Atlantic City, June, 1914. From advance proof through the courtesy of the editor of the *Journal of the American Medical Association.*

*Neither the papyrus of Ebers nor that of Brugsch throws any light on the problems discussed in this article. Indeed the value of both these papyri was at first overestimated. They are now regarded as compilations and consist largely of lists of remedies and furnish no information concerning epidemics or their effects upon the people, except to indicate that hookworm or bilharzia infection, one or both, at that time (about 1500 B. C.) afflicted the Egyptians. These parasites may have contributed to the deterioration of the people: this is a suggestive possibility.

At a time when the German tribes began moving, that is to say, at the end of the third century A.D., a gradual immigration of Slavonic tribes into the Balkans began; their invasions became more and more frequent, since the Goths chose Western Europe as the goal of their conquering expeditions and left to the Slavs an open passage into the Balkan countries. But a real Slavonization of some Greek territories took place only in the eighth century, and attained its highest point when a horrible plague in 746 depopulated the Greek territories.

I am aware of the fact that some have objected to considering the present inhabitants of Greece as descendants of ancient Greeks. The former have been designated as "so-called Greeks," "a bastard people," "a mosaic of Vlacks, Arnauts, and Slavs." Some years ago Fallmerayer made the very positive statement that "no drop of ancient Greek blood flows in the veins of the modern Greek." Thumb has shown the absurdity of these statements and declares that cranial measurements, local names, customs, and religion show that while some admixture with the Slav has taken place, the modern Greek is a lineal, and on the whole a fairly pure descendant of those who established the greatest civilization of antiquity. Modern Greek Christianity is only a modification of ancient Greek paganism, in which gods have been supplanted by saints. "Charon the old ferry-man in the underworld is to-day the god of death; he conducts the souls in a dreary procession to his realm. As in antiquity, a copper coin is put into the mouth of a dead person as a fee for the ferry into the other world. The ancient Moirai or fates (to-day, Mires) still determine the fate of the new-born child, spin and cut the thread of life. The bride is conducted into her new home, the dead are buried with ceremonies which the Greeks used already two thousand years ago. A sick person seeks recovery by lying down to sleep in the church of a saint, like those persons who once made a pilgrimage to the temple of Asklepios in Epidaurus. The Greeks of to-day are descendants of the ancient Hellenes, not in the sense in which every modern Greek could trace his origin back to an ancient Athenian or Spartan, but in the sense that in the modern people ancient blood flows largely and in some districts almost purely, and still more in the higher sense that the modern race shows a development of the Greek population of the ancient world."

The broken remnants of older civilizations found refuge and asylum in the salubrious climate of the Italian peninsula and soon its hillsides were covered with vines and olives while its plains and valleys bore abundant harvests. Rome was built and her empire promised to extend to the remotest parts of the world, but the ancient Roman contributed but little to science, and we are told by the historian that "a pestilence raged for fifteen years (251-265) and carried off one-half of the inhabitants of the Empire." The seat of civilization was moved to the shore of the Bosphorus, but the lamp of science was well-nigh extinguished and the clouds of the middle ages enveloped the world and shrouded its inhabitants for more than a thousand years. "A fabulous and formless darkness overcame the fairest things of earth."

If one reads the history of the decline of the Roman Empire, he can hardly fail to see that disease was an important factor in that retrograde movement, which involved the greater part of the then known world. Jones and Ross find the earliest reference to malaria among the Romans in the comedian Plautus, who died 184 B. C., and they quote Terence, who died 159 B. C., and whose language is explicit in showing not only the prevalence of malaria, but also the recognition of the different forms. From that time on, reference to the wide prevalence of malarial diseases, not only in the open country, but also in the city, is frequent and definite. Jones says:

There is then, every reason for supposing that malaria was unknown in Italy in early times, was well known at the beginning of the second century B. C., and that it gradually became more common during the next two hundred years. If this be so, it is at least a plausible conjecture that it was introduced by Hannibal's Carthaginian mercenaries. Africa seems to have been the original home of the disease, and it is probable that some of his troops were infected. The constantly repeated devastation of Italy in the second Punic war would be sure to turn a large part of it into marshy land, thus affording a convenient breeding-place to the mosquitos which were infected by the malarial patients among the Carthaginians. The similar conditions of Attica during the closing years of the fifth century B. C. offers a striking parallel. This opinion does not rest on mere conjecture. We are told by Livy that in the year 208 B. C. a severe epidemic attacked Italy. It did not cause many deaths, but resulted in much lingering disease, that is, most probably, chronic malaria.

Malaria, however, was not the only disease which contributed to the degeneration of the Roman people. I have already referred to the pestilence of the third century, which is said to have destroyed half the inhabitants of the vast empire within fifteen years. This certainly was not malaria. Moreover, this was not the first great pestilence which afflicted the Roman Empire. Neuburger says:

The "plague," so called by Galen or Antonine, was first introduced from Syria by the Roman army. . . . The extraordinary contagiousness of the epidemic is emphasized in all contemporary reports. There appear to have been a variety of simultaneous manifestations, the descriptions indicating afflictions chiefly resembling smallpox, or dysentery, but adequate criteria on which to express an opinion are wanting. The "plague" commenced 165 A. D., claimed innumerable victims and lasted at least fifteen years.

Jerome writes: With peace, order and good government, a curious lethargy fell on the warrior state deepening into a coma in which it died so quietly that neither the contemporaries nor we moderns can fix the date of the decease. The fact, however, finally became apparent when the phenomena of decay were indubitable and the world, deprived of the master, fell back helplessly into a condition hardly more advanced than in the ages before its subjection, save that it had the imperishable memory of Rome to give it hope, direction and courage.

In the fourth century the seat of government was removed to Byzantium. It is probable that this change was, in part at least, determined by the insalubrity of Italy. Early in the fifth century Rome was pillaged, but the real conquerors of Rome were not the Goths and Vandals, but malaria and the plague. Disease continued to devastate Italy. Creighton says:

About the year 668 the English archbishop-elect, Vighard, having come to Rome to get his election confirmed by the pope, Vitalanius, was soon after his arrival cut off by the pestilence with almost all who had gone with him. Twelve years after, in 680, there was another severe pestilence in the months of July, August, and September, causing a great mortality at Rome and such a panic at Pavia that the inhabitants fled to the mountains. In 746 a pestilence is said to have advanced from Sicily and Calabria and to have made such devastation in Rome that there were houses without a single inhabitant left.

From that time on the plague periodically spread over Italy until the seventeenth century, while malaria has been in continuous possession down to our own time. We are told that the epidemic of 1348 reduced the inhabitants of the Eternal City to 20,000.

We are familiar with the graphic description of the plague in Florence by Bocaccio, who wrote:

Such was the cruelty of Heaven, and perhaps of men, that between March and July following, it is supposed, and made pretty certain, that upwards of a hundred thousand souls perished in the city only, whereas, before that calamity, it was not supposed to have contained so many inhabitants. What magnificent dwellings, what noble palaces were then depopulated to the last person, what families extinct, what riches and vast possessions left, and no known heir to inherit, what numbers of both sexes in the prime and vigor of youth —whom in the morning neither Galen, Hippocrates, nor Esculapius himself, but would have declared in perfect health—after dining heartily with their friends here, have supped with their departed friends in the other world.

There are but few passages in literature so tragic as the short record of the plague of the fourteenth century begun by the friar of Kilkenny, but soon interrupted by his death:

I friar, John Clyn, of the order of Friars Minor and of the convent of Kilkenny, wrote in this book those notable things which happened in my times, which I saw with my eyes, or which I learned from persons worthy of credit. And lest these things worthy of remembrance should perish with time and fall away from the memory of those who are to come after us, I, seeing these many evils, and the whole world lying, as it were in the wicked one, *among the dead, awaiting death*—as I have truly heard and examined, so have I reduced these things to writing; and lest the writing should perish with the writer, and the work fail altogether with the workman, I leave parchment for continuing the work, if haply, any man survive, and any of the race of Adam escape this pestilence and continue the work I have commenced.

That the period of the Byzantine Empire (395-1453) was one of general degeneracy is shown on every page of the historian. It produced no literature of merit, and "the study of nature was regarded as the surest symptoms of an unbelieving mind." Neuburger says:

The Byzantines merely followed the downward path. Surfeited with tradition, which made modes of thought appear inevitable, because customary, filled as a nation with overweening self-conceit, fed by the glories of the Graeco-Roman past, they neither could nor would destroy the historic bridge nor replace the crumbling ruin with a new edifice. It lay outside the sphere of their interests to enter into that conscious emulation of antiquity which, emphasizing the growing contrast between past and present, and eliminating the obsolete and the inert, is the essence of mental cultivation. Forgetting that it was the free development of the national spirit which constituted the greatness of the past, they went so far as to smother its liveliest expression by denying, in their rigid adherence to Attic speech, all part in literature to the language of the people. The more incapable did the Byzantines become of grasping the spirit, the more tenaciously did they cling to the letter—a reflection of the mania for titles and ceremonies in political life—and thus they dragged the inanimate mechanism, the dry bones of antiquity through a thousand years, instead of erecting a new edifice on the foundations of antiquity.

The physician and historian, Procopius, in his account of the great pestilence in the reign of Justinian "emulated the skill and diligence of Thucydides in the description of the plague at Athens." Of this epidemic Gibbon says:

In time its first malignancy was abated and dispersed; the disease alternately languished and revived; but it was not till the end of a calamitous period of fifty-two years, that mankind recovered their health, and the air resumed its pure and salubrious quality. No facts have been preserved to sustain an account, or even a conjecture, of the numbers that perished in this extraordinary mortality. I only find that during three months, four and at length ten thousand persons died each day at Constantinople, that many cities of the east were left vacant, and that in several districts of Italy, the harvest and the vintage withered on the ground. The triple scourge of war, pestilence and famine afflicted the subjects of Justinian, and his reign is disgraced by a visible decrease of the human species, which has never been replaced in some of the fairest countries of the globe.

This epidemic spread over the whole of Europe and it took more than a century to reach England, where "it fabled long after in prose and verse as the great plague of Cadwalladers time." Then for quite a thousand years it reaped its periodic harvests as often as immunity was lost in new generations.

The historian, as a rule, confines his descriptions to martial and political events and consequently gives a wholly erroneous idea of true conditions. Gibbon says: "If a man were called upon to fix the period in the history of the world, during which the condition of the human race was most happy and prosperous, he would without hesitation, name that which elapsed from the death of Domitian to the accession of Commodus" (from 96 to 180 A. D.). Noah Webster, in his work on epidemics and pestilence, quotes the preceding with the following just comment:

It is certain that, at this time, the Roman Empire was in its glory, and governed by a series of able and virtuous princes, who made the happiness of their subjects their principal object. But the coloring given to the happiness of this period is far too brilliant. The success of armies and the extent of empire do not constitute exclusively the happiness of nations; and no historian has a title to the character of fidelity, who does not comprehend, in his general description of the state of mankind, moral, and physical, as well as political evils.

Let us make brief inquiry into the diseases of this "most happy and prosperous" period. It was preceded by, it begun in, continued in, and closed in pestilence. That the plague was endemic in Italy at that time and that it developed in epidemic form with each increase in susceptible material there can be no doubt. Of the epidemic of 68 A. D. Tacitus says:

Houses were filled with dead bodies and the streets with funerals; neither age nor sex was exempt; slaves and plebeians were suddenly taken off, amidst the lamentations of their wives and children, who, while they assisted the sick, or mourned the dead, were seized with the disease, and perishing, were burned on the same funeral pyre. To the knights and senators the disease was less mortal, though these also suffered in the common calamity.

About this time the plague appears to have spread over the whole of Asia, northern Africa and Europe. According to Short, the deaths from this disease in Scotland between 88 and 92 A. D. amounted to not less than 150,000. This was probably not less than one-fourth, possibly one-half, the population of Scotland at that time.

In the year 80 A. D. the deaths from the plague in Rome at the height of the epidemic numbered 10,000 a day. It is estimated that the population of Rome at that time was somewhat more than one million. Exacerbations of the disease in Rome are recorded for the years 102, 107, and 117 A. D. According to Short, 45,000 died of the plague in Wales in 114. The year 167 A. D. is noted for an unusually severe outbreak of the plague at Rome, where it continued for many years. In the year 173 A. D., the Roman army was threatened with extinction by disease, and special epidemics, or rather exacerbations of the epidemic, prevailed in Rome in 175 and 178 A. D. That the "happy and prosperous" period was followed by a continuation of

the plague is shown by the following quotation from Herodian:

A great pestilence raged throughout Italy at that time (about 187 A. D.), but with most violence in the city, by reason of the great concourse of people assembled from all parts of the earth. The mortality among men and cattle was great. The Emperor, by advice of physicians, retired to Laurentium, on account of the coolness of the place, which was shaded with laurels. It was supposed that the fragrance of the laurels acted as an antidote against the contagion. The people in the city also, by the advice of physicians, filled their noses and ears with sweet ointments and used perfumes, etc.

Under the spell of the historian we have been inclined to regard the period when the greater philosopher, Marcus Aurelius Antoninus, sat on the throne of the world, as the golden age. Let us therefore listen to a few words from his personal attendant, courtier and historian, who writes:

Unless he, M. Antoninus, had been born at this juncture, the affairs of the empire would have fallen into speedy ruin; for there was no respite from military operations. War raged in the east, in Illyricum, in Italy, and in Gaul. Earthquakes with the destruction of cities, inundations of rivers, frequent plagues, a species of locusts ravaging the fields; in short every calamity that can be conceived to afflict and torment man scourged the human race during his administration.

It is estimated that during the dark ages the average of human life was less than twenty years. A high birth-rate was necessary to keep the race alive, but notwithstanding this, Europe was sparsely inhabited. At the time of the Norman Conquest the inhabitants of England numbered between two and two and one-half million, probably nearer the former, for they had not reached the greater number a hundred years later. Creighton says: "It would be within the mark to say that less than one-tenth of the population was urban in any distinctive sense of the term. After London, Norwich, York and Lincoln, there were probably no towns with five thousand inhabitants." Indeed, urban life, as we now know it, was quite impossible in this age of pestilence and would soon become so again were the functions of preventive medicine related.

Most of the great epidemics of the middle ages were designated as *pestilentia* or *magna mortalitas*. In the most deadly visitations the bubonic plague is so accurately described that there can be no doubt about its identity, but it must not be supposed that the people enjoyed any high degree of health even in those periods when this contagion languished on account of exhaustion of susceptible victims. Ergotism, under the name of Saint Anthony's fire, was endemic in France and adjacent territories; Normandy was filled with lepers, but Christ's poor were not confined to that country. England was regarded as the special home of hunger, but abundance was a stranger to the masses in every land. The mysterious sweating sickness, apparently brought to England with Henry Tudor in 1485, developed in five distinct epidemics which were characterized by the fact that the mortality was greater among the rich than the poor. Typhus, known as *morbus pauperum*, prevailed largely in the jails, on ships, and among the squalid inhabitants of the cities. Even the discovery of America carried to Europe the scourage of syphilis, which was spread over Italy by the soldiers of Charles VIII, and within a few years reached the most distant parts of Europe. Smallpox appeared in England in the sixteenth century, having journeyed, according to the most reliable authority, all the way from the Orient. That tuberculosis, diphtheria, dysentery, and other diseases, still with us, prevailed during the middle ages is shown by the records, but they were overshadowed by the higher mortality of those mentioned above. Improved agriculture has extinguished the fire of St. Anthony, except in the most benighted provinces of Russia. The great fire in London in 1666 destroyed the infected rats and relieved England of the bubonic plague, which had been endemic in that country since 1349. Something more than one hundred years later the discovery of Jenner robbed smallpox of its horrors, wherever vaccination is properly enforced. The investigations of Howard improved the sanitation of jails and workhouses, and did much to eradicate typhus.

The claim has been advanced that the infectious diseases have benefited the race by the destruction of the unfit. This idea I have combated most vigorously since our study of typhoid fever in the Army in 1898. My colleagues and I found that out of 9,481 soldiers who had previously been on the sick report and could not be regarded as possessing standard health 648, or 6.8 per cent., contracted typhoid fever; whereas, out of 46,384 men who had no preceding illness, 7,197, or 15.3 per cent., developed typhoid fever. More than 90 per cent. of the men who developed typhoid had no preceding intestinal disorder. Under ordinary conditions the strong, busy man, especially the one whose activities demand wide excursions from his home, is more likely to become infected than the one whose sphere of action is more limited on account of infirmity. The reason for this is too obvious to need statement, and it follows that more men than women and more adults than children have typhoid fever. Moreover, the case mortality is greater among the strong, because death in the infectious diseases is often due to the rapidity with which the invading organism is broken up by the secretions of the body cells and the protein poison made effective. From this I have concluded that contagion, like war, destroys the very flower of the race. This view is sustained by the historians of the pestilences of former times.

Thucydides in his description of the plague at Athens says: "Moreover, no constitution, whether in respect of strength or weakness, was found able to cope with it; nay, it swept away all alike, even those attended to with the most careful management."

Procopius in his account of the Justinian epidemic states that youth was the most perilous season, and females less susceptible than males.

Cogan, in describing the outbreak of typhus at Oxford in 1577, writes: "The same kind of ague raged in a manner over all England, and took away very many of the strongest sort, and in their lustiest age, and for the most part, men and not women and children, culling them out here and there, even as you would choose the best sheep out of a flock."

In his account of the plague of 1665 in London, Boghurst makes the following statement: "Of all the common hackney prostitutes of Luteners-lane, dog-yard, cross-lane, Baldwins-gardens, Hatton-gardens and other places, the common criers of oranges, oysters, fruits, etc., all the impudent drunken, drubbing bayles and fellows and many others of the *rouge route*, there is but few missing—verifying the testimony of Diemerbroech that the plague left the rotten bodies and took the sound." Like testimony comes from an account of the plague at Moscow: "Drunkards and persons of

feeble temperament were less subject to attack."

Davidson observed that typhus fever was more frequent among the robust than the weak. He states that out of 429 cases the spare and unhealthy taken together made only about 17 per cent. He adds that the death-rate among the poor was one in twenty-three, while among the well-to-do it was one in four. The greater mortality of typhus among the higher classes has been noted by Barber and Cheyne and by Braken.

Hurty, nearly a century ago, wrote: "A fever which consigns thousands to the grave, consigns tens of thousands to a worse fate—to hopeless poverty, for fever spares the children and cuts off the parents, leaving the wretched offspring to fill the future ranks of prostitution, mendicancy and crime."

Creighton says:

The best illustrations of the greater severity and fatality of typhus among the well-to-do come from Ireland in times of famine, and will be found in another chapter. But it may be said here, so that this point in the natural history of typhus may not be suspected of exaggeration, that the enormously greater fatality of typhus (of course, in a smaller number of cases) among the richer classes of the Irish families, who had exposed themselves in the work of administration, of justice, or of charity, rests on the unimpeachable authority of such men as Graves, and on the concurrent evidence of many.

A surgeon in the British navy at the time of William III and Anne tells how he was led to practise bleeding in fever as follows:

I had observed on a ship of war, whose complement was near 500, in a Mediterranean voyage in the year 1694, when we lost about 90 or 100 men, mostly by fever, that those who died were commonly the young, but almost always the strongest, lustiest, handsomest persons, and that two or three escaped by such natural hemorrhages, which were five or six pounds of blood.

The middle ages were indeed dark physically, intellectually, and morally. Here and there, now and then, some man of genius towered above the general low level of his contemporaries and not infrequently he paid dearly for his audacity. For some centuries the Arab, especially in Spain, stood out alone as the torch-bearer of science, and he, when driven back into the insalubrity of Northern Africa, lapsed into barbarism. Neuburger writes:

Fortunately the fate of medieval medicine was not dependent on Byzantium alone. An admirable illustration of the doctrine of conservation of energy is afforded by the fact that, with the decline of intellectual energy at home, a contemporaneous development of Greek medicine took place abroad, which, if at times misguided, was yet full of vitality, whilst the medical art of the newly arisen world of Islam reached a height unsurpassed during the middle ages.

In the greater part of Europe, ignorance and disease held full sway. In the midst of great calamities "the will-o-the-wisp of superstition is an irresistible attraction and offers the only ray of hope." Strong men, neglectful of their earthly duties, betook themselves to secluded places and lost themselves in dreams of a heavenly paradise. Mysticism, fanaticism, and superstition dominated all conditions of men. Rulers, illiterate, immoral, and even incestuous, occupied palaces while the masses died of starvation. The history of the time is a record of diseased, degenerated, demented man. There can be no doubt that disease has overthrown civilizations in the past, and there is no surety that it may not do so again. The recent outbreak of the plague in Manchuria and its more recent appearance in Cuba are not without their warnings. It remains to be seen if those who control our government have the intelligence necessary to protect our country against the invasion of pestilence. The failure to provide for camp sanitation in 1898, the behavior of California officials on the finding of plague in San Francisco, and the general indifference of national and state authorities toward the eradication of disease discouraged the hope that intelligent patriotism is widely distributed among us. As a contemporary of Mr. Dowie and Mrs. Eddy and as a citizen of a country in which the osteopath and chiropractic flourish, I feel some embarrassment in speaking of the fanaticism and ignorance of the dark ages.

The history of medicine is that of mankind. Born in naked ignorance, bound in the swaddling clothes of credulity and nursed on superstition, medicine has had its savants and its fakers, its triumphs and its failures, its honors and its disgraces. It has attracted and still attracts to its ranks men of the purest motives and those who are impelled by the basest desires. It can be said without fear of contradiction that medicine has done more for the growth of science than any other profession, and its best representatives in all ages have been among the leaders in the advancement of knowledge, but the average medical man conforms in intellect and character to the community in which he lives. The food of the faker is ignorance and he thrives where this commodity is most abundant. The uncontrolled fool moves to his own destruction. This is the only way in which Nature can eliminate him. A wise government protects its incompetents from medical and other fakers, but such government can exist only where wisdom predominates.

A study of epidemics shows that in the presence of widespread contagion mankind in the mass tends to revert to the barbaric state. This is the unvarying testimony of all authorities, medical and lay, secular and religious, who have made the records. The historian Nibuhr, in discussing the report on the plague in Athens by Thucydides says: "Almost all great epochs of moral degradation are connected with great epidemics." F. A. Gasquet, abbot president of the English Benedictines, in his history of the black death, writes: "The immediate effect on the people was a religious paralysis. Instead of turning men to God, the scourge turned them to despair, and this not only in England, but in all parts of Europe. Writers of every nation describe the same dissoluteness of manners consequent upon the epidemic." A Venetian historian notes the general dissoluteness which followed the disease and its effects in lowering the standard of probity and morals. Covino of Montepellier bears testimony of the baneful effects of the scourge on the morals of those who escaped, and concludes that such visitations exercise the most harmful influence on the general virtue of the world. William of Nangis, in his history of the plague in France in 1348, concludes with the following:

But alas! the world by this renovation is not changed for the better. For people were afterwards more avaricious and grasping, even when they possessed more of this world's goods than before. They were more covetous, vexing themselves by contradictions, quarrels, strifes, and lawsuits.

Many similar references could be given, but these suffice to show that disease breeds ignorance, immorality, and strife. Our inquiries into the influence of disease on civilization, however, have brought out the fact that people living in compara-

tive health have within a few generations made beginnings, at least, some, highly creditable, in government, literature, and science. The Hellenic tribes of Greece built up their wondrous civilization within a few centuries. It is true that Rome was not built in a day, but the seven hills were covered with houses and temples, the great aqueducts brought abundant supplies of pure water from the mountains and the wonderful sewers remain as evidence of sanitary skill, and all this was accomplished in a relatively short period measured in the history of the race. The world moved forward at a rapid pace with the dawn of science in the last century. It is not extravagant to prophesy that with ten centuries of freedom from disease, both inherited and acquired, the world would be regenerated and the superman be born.

It is not necessary to turn to history for examples of the degrading effects of disease on man. We see it to-day in the physical inferiority, intellectual weakness, and moral irresponsibility of those peoples who are still under the domination of malaria and kindred diseases. My illustrious predecessor in this office, Dr. Gorgas, has demonstrated what scientific medicine may accomplish in these pestilential regions, and it is within reason to look forward to the time when the tropics may supply choice locations for civilized man. In like manner the valleys of the Tigris and Euphrates are being reclaimed and Babylon and Nineveh may again become seats of learning and culture. The modern sanitarian is quite competent to rebuild the home in which the cradle of civilization was rocked.

After the last epidemic of the plague in London in 1665 the death rate, so far as it can be ascertained, fell to between 70 and 80 per 1,000. During the next century it fell as low as 50, but fluctuated with recurring epidemics of typhus and smallpox. In the nineteenth, it gradually and quite constantly decreased and is now about 14. In 1879-80, the first year in which the mortality statistics of the United States possess sufficient accuracy to be of any value, the death rate in the registered area was 19.8; in 1912 it was 13.9—a decrease of 30 per cent. During the same time the mortality from typhoid fever has decreased 50 per cent.; that from scarlet fever 89 per cent.; that from diphtheria 84 per cent.; that from tuberculosis 54 per cent. Hoffman states that had the death rate for tuberculosis in 1901 continued there would have been 200,000 more deaths from this cause from that date to 1911 than actually did occur, or the actual saving of lives from death by tuberculosis accomplished in that decennium averaged 20,000 per year. A battle in which 20,000 are slain stirs the world at the time and fills pages of history later. Preventive medicine measures its successes by the number of lives saved, and 20,000 a year preserved from death from one disease is no small triumph. In the last century the average of human life has been increased fifteen years and this increase could be duplicated in the next twenty years if the facts we now possess were effectively employed.

Hoffman further states that the addition to the material wealth of this country secured by the reduction of deaths from tuberculosis within ten years amounts approximately to 6,200,000 years of human life, covering its most productive period. Medicine discovered the facts which have made this great work possible and has directed their application. With evidence of this kind before them, will our lawmakers listen to those who demand recognition as practitioners of medicine without proper qualification?

The further developments of medicine, both curative and preventive, depend on scientific investigations. The public is the beneficiary and should in every way encourage medical research. By the application of discoveries already made, the burden of disease has been lightened, sickness has become less frequent and less prolonged, a greater degree of health has been secured, the efficiency of the individual and of the nation has been increased, and life has been prolonged and made more enjoyable. The federal government and the states should sustain and promote scientific research. That government is the best which secures for its citizens the greatest freedom from disease, the highest degree of health, and the longest life, and that people which most fully secures the enjoyment of these blessings will dominate the world.

Medicine consists of the application of scientific discovery to the prevention and cure of disease. All else which may go under the name of medicine is sham and fraud. Without advancement in the physical, chemical, and biological sciences there can be no progressive movement in medicine. Scientific knowledge is gained only by observation and experiment. Before the time of Jenner, we are told by the historian, it was unusual to meet in London one whose face was not marked by smallpox. There was a popular belief that one who had cowpox was immune to smallpox. Jenner put this belief to a scientific test and the result was the discovery of vaccination, and this secured the abolition of this disfigurement and a marked reduction in mortality.

In 1849, a village doctor, with a crude microscope, studied the blood of animals sick with anthrax and compared it with that of healthy ones. He discovered the anthrax bacillus. This work was extended by Daviane, Pasteur, Koch, and others, and from this the science of bacteriology has been developed. The particulate causes of many infectious diseases have been recognized, isolated, and their effects on animals demonstrated. Many of the mysteries of contagion have been revealed and the conditions of the transmission of disease made known. The fundamental principles of preventive medicine have been developed into a science which is to-day the most potent factor in the progress of civilization.

Finlay suspected a certain mosquito to be the carrier of the virus of yellow fever. Reed and his coworkers demonstrated the truth of this theory, and the work of Gorgas has freed Havana from the pestilence, and the construction of the Panama Canal is an accomplished fact.

We are sorry for the Greek, whose bodily health, mental strength, and moral sense were depressed by the invisible and insidious organisms of malaria, and truly his memory deserves our sympathy. He had no microscope, and how could he detect or even suspect that the mosquitos which had annoyed his ancestors for generations had armed their lancets with deadly poison brought from Africa? The Greek had never heard of quinine and the other cinchona alkaloids. He did not know the land whose forests were even then elaborating those products, which, centuries later, were of greater value than gold to man, and proved to be an essential help in the uplift of mankind. Laveran discovered the *Plasmodium malariæ*. Ross studied its life history and the fetters of this disease, which has so long retarded the progress of man, have been broken.

Mitchell and Reichart investigated the poisonous properties of snake venon. Sewall immunized animals with it. Ehrlich studied the similar bodies, abrin, ricin, and diphtheria toxin, and von Behring and Roux gave the world antitoxin, the magical curative value of which has greatly reduced the mortality from this disease. The experiments of Villemin demonstrated the contagious nature of tuberculosis, long suspected and frequently denied. The diligent research of Koch resulted in the recognition and isolation of the causative agent, and since this discovery the mortality of the Great White Plague in Europe and the United States has been diminished more than half, and it is within the range of sanity to look forward to the time when the former "Captain of the hosts of death" will be known only by the fearful records he once made in the history of man's struggle to be relieved from the heavy tribute paid to infection.

We boast of a great civilization, but this is justified only within limits. Science more nearly dominates the world than at any time in the past. Learning permeates the masses more deeply, but credulity and ignorance are widely prevalent. In this country of nearly one hundred millions, there are thousands whose greed impedes the progress of the whole, tens of thousands whose ignorance retards their own growth, and other thousands who live by crime and procreate their kind to feed on generations to come. We have our schools, colleges, and universities, while our almshouses, insane asylums, and penal institutions are full. In our cities we see the palatial homes of the ultra rich, the splendid temples of trade and commerce, the slums of want and poverty, and the homes, both rich and squalid, of vice and crime. No nation in this condition can be given a clean bill of health. Our hill tops are illuminated by the light of knowledge, but our valleys are covered by the clouds of ignorance. We have not emerged from the shadows of the dark ages. The historian of the future will have no difficulty in convincing his readers that those who lived at the beginning of the twentieth century were but slightly removed from barbarism, as he will tell that the school, saloon, and house of prostitution flourished in close proximity; that the capitalist worked his employees under conditions which precluded soundness of body; that the labor union man dynamited buildings; that whilst we sent missionaries to convert the Moslem and the Buddhist ten thousand murders were committed annually in our midst, and that a large percentage of our mortality was due to preventable disease.

Evidently there is much to be done before we pass out from the shadows of ignorance into the full light of knowledge. In this great work for the betterment of the race the medical profession has important duties to perform. I do not mean to imply that the uplift of mankind devolves wholly on the medical man. The burdens are too many and too diversified, the ascent too steep and the pathways too rough for one profession to hope to reach unaided the high plateau we seek. Moreover, other callings have no right, and should have no desire, to shirk the moral responsibilities, which rest alike on all. But in past ages, medical men have been the chief torch-bearers of science, the only light in which man can safely walk, and we must keep and transmit to our successors this trust and honor. I know of no scientific discovery, from the ignition of wood by friction to the demonstration of the causes of infection and the restriction of disease, which has not sooner or later assisted in the betterment of the race. It may be added that nothing else has so aided man in his slow and halting progress from the pestilential marshes of ignorance to the open uplands of intelligence.

In so great a work as the eradication of preventable disease, all intelligent people must cooperate. The law must support it by proper enactments, and these must be enforced with justice and intelligence; it must recognize that the right to enjoy health is quite as sacred as that to possess property; that to poison men in factories and mines, to pollute drinking water supplies, to adulterate foods, and to drug with nostrums is manslaughter. Religion must teach the sanctity of the body as well as that of the soul, that ignorance is sin and knowledge virtue, that parenthood is the holiest function performed by man, and that to transmit disease is an unpardonable sin. The teacher must know hygiene as well as mathematics. The capitalist must recognize that improvement in health and growth in intelligence increase the efficiency of labor. There never has been a time when scientific medicine has had so many and such efficient and appreciative helpers as it has to-day. Our sanitary laws are for the most part good, but their administration is weak, on account of ignorance. The pulpits of the land are open, for the most part, to the sanitarian. The respectable newspapers are most effective in the crusade against quackery and disease. The philanthropist has learned that the advancement of science confers the greatest and most lasting benefits on man.

There is a moral obligation to be intelligent. Ignorance is a vice and when it results in injury to any one it becomes a crime, a moral, if not a statutory one. To infect another with disease, either directly or indirectly, as a result of ignorance, is an immoral act. The purpose of government is to protect its citizens, and a government which fails to shelter its citizens against infection is neither intelligent nor moral. To transmit disease of body or mind to offspring is an unpardonable sin. In a reasonable sense it is worse than murder, because it projects suffering into the future indefinitely.

That medicine has become a fundamental social service must be evident. To return one incapacitated by illness or injury to the condition of self-support benefits not only the individual, but the community, in as much as it increases its productive capacity. Infirmity is a direct burden on the individual and scarcely less direct on the community. Weakness in any part diminishes the strength of the whole. It is a fully established principle in social economy that widespread intelligence and growth in knowledge are beneficial to the state.

It was in full recognition of this that the framers of the Ordinance of 1787 wrote into that immortal document. "Religion, morality, and knowledge being necessary to good government and the happiness of mankind, schools and the means of education shall forever be encouraged." The Territory of the Northwest, the government of which was provided in this ordinance, was at that time a vast waste of forest and prairie, furnishing a scant and precarious subsistence for savage tribes and attracting to its borders a few of the most hardy sons of civilization. The knowledge for whose growth and diffusion the wise provision was

made, has drained the malarial marshes, converted wild prairie and tangled wood into fruitful orchards and fertile fields, dotted the whole area with neat villages, reared great cities, linked all parts with steam and electric roads, and provided comfortable homes and abundant food for millions. The men who wrote the Ordinance of 1787 left a great inheritance which is temporarily in our possession. Let us write into this great document: "Every ill which can be relieved shall be removed, and every preventable disease shall be prevented." The wisdom of our fathers has secured for us a greater measure of health and a longer term of life; let us do as well for those who are to possess this fair land in the next generation. Let us live not only for ourselves and the present, but for the greater and more intelligent life of the future.

Not myself, but the truth that in life I have spoken,
Not myself, but the seed that in life I have sown
Shall pass into ages—all about me forgotten,
Save the truth I have spoken, the things I have done.

All things are relative and health is no exception. With a greater degree of health among all, religion will become more effective for good, morality will have a deeper significance and a wider application, and knowledge will multiply and distribute its blessings more widely.

In the further improvement of the physical, mental, and moral conditions of the race, medicine should continue to be a leader. There is no other calling so essential to this movement, and in order to more thoroughly fit itself for this important task the profession should first of all look to its own betterment. The medical man should possess intelligence of high order, manifest industry without stint, and show the highest integrity in all he does. That it is the aim of this Association to attract to its colors men possessing these qualifications and to deny admission to others is shown by the advance in the standard of medical education, the enforcement of medical registration laws and the denunciation of every form of medical charlatanism. In all these directions the profession has the support of the more intelligent men in other callings. The improvement in medical training secured within recent years in this country is without a parallel in the history of education. The requirements for admission to the medical schools have been rapidly advanced and standardized; the number of medical schools has been reduced from 166 to 104 by obliteration and combination, much to the improvement of all, and a far better class of matriculates has been secured. The courses of instruction have been lengthened and made more scientific. Each good medical school is doing more or less of research which is not confined to laboratory investigators, but is fast finding its way into hospitals. Indeed, some of our clinical men are now making most valuable contributions. Every medical man should have much of the spirit of research. It is the pabulum on which medicine feeds and without it the profession atrophies and starves. It is the glory and strength of the profession that it is not bound by dogma and pays no heed to *ipse dixits*. I have no sympathy with the idea that medical research should be largely relegated to special non-teaching institutions. These have their function and we rejoice in their foundation and support and hope that they may multiply, but the man who is devoid of the spirit of scientific investigation has no place in medicine as student, practitioner, or teacher, and the most elaborate medical training without opportunity for scientific observation is barren. Besides, opportunities for medical discovery should be widely distributed. Science makes no provision for an aristocracy. There can be no papal bulls issued in the domain of medicine. The workers must be many, all must be free to pursue knowledge in their own way, and all must be compelled to prove their claims, for "life is short, art is long, opportunity is fleeting, experiment fallacious, and judgment difficult."

In this work of self-improvement the profession has had the aid of the more intelligent law makers and administrators. In carrying out these progressive changes there has been much sacrifice of money and personal pride by many members of the profession. Large schools have willingly submitted to marked reduction in the numbers of their students and consequently in financial support. A medical education costs more in time and money than that demanded by any other profession, and the emoluments of the average practitioner have decreased as preventive medicine has become more effective. No other profession pays so heavily the great cost of eradicating the infectious diseases, but this is the function of medicine and no sacrifice should be regarded as too great. While intelligent medical men have been leading the crusade against greed, ignorance, and disease, our legislative halls have been crowded with the representatives of sects, cults, and charlatans demanding legal recognition. If I mistake not, herculean efforts will be made in the near future to lower the standards demanded of the medical practitioner. These endeavors have been promised aid from those who have heavy financial backing, but if we are worthy of the trust which we bear, we will not yield. We must appeal to the good sense of the people for whose welfare we labor. We must show what scientific medicine has done for the public good and point out the greater things it may do with increased opportunity. It must be admitted that in the crusade for the restriction of tuberculosis many physicians have manifested but little interest. This is shown by their slowness to employ methods of early diagnosis and consequently by their failure to recognize the disease in its curable stage, also by their unwillingness to comply with the laws of notification. It is an undeniable fact that there are many medical men who know less about hygienic measures than the more intelligent of the laity. With advancing knowledge among the masses these professional fossils will be correctly labeled and properly shelved in the local museums of antiquities.

I believe that medicine is now attracting excellent young men. It should appeal to this class. It does not point the way to great financial reward, but it offers a service unsurpassed by any other calling. The historian tells us: "For the Roman patriot the only worthy stage was the forum or the battlefield; every other pursuit was left in the hands of slaves and could not free itself from the taint of servitude." Modern medicine offers a field in which the advancement of knowledge, the improvement of health conditions, and the saving of lives are the measures of success.

Preventive medicine, still in its youth, has accomplished great things. As I have stated, within the past thirty years in this country the mortality from tuberculosis has been reduced more than half and with scarlet fever and diphtheria the results have been more striking. Within the past ten

years the average life has been increased four years. Great epidemics which once devastated continents are no longer known in the more intelligent parts of the world. In fact, it may be said that the death rate is now an excellent measure of intelligence. In 1911 the death rate in London was 15 per one thousand, while that of Moscow was 27.3. Preventive medicine is the keystone of the triumphal arch of modern civilization, and its displacement would precipitate mankind into relative barbarism. Should the health administrators of any great commercial center fail, for even a few months, to exercise the function of restricting disease, the history of the epidemics of the middle ages might be repeated. Great things have been done, but greater tasks lie before us, and their accomplishment depends on the scientific wisdom of our profession and the intelligence of the people. Without the harmonious adjustment of these forces the greatest efficiency cannot be secured. While the mortality from tuberculosis has been reduced half in the past thirty years, we must not assume that the total eradication of this disease will be accomplished in the same number of years. Only the more progressive members of the profession have taken the initiative, and only the more intelligent members of the community have responded. Intelligence and the sense of moral responsibility must grow as the work proceeds. It remains for all who have the welfare of the race at heart to plan wisely and carry forward courageously the campaign against greed, ignorance, and disease.

The sanitarians of this country seem to be in harmony in regard to the general procedures to be followed. These are embodied in bills recently introduced in the legislative assemblies of a number of States. In New York an excellent bill was passed and its operation is now being inaugurated under the directorship of Dr. Biggs, whose long and effective service in the city of New York demonstrates the wisdom of his selection. I regard it as highly fortunate that the operation of this new and important law is to be directed by one so well qualified.

My own ideas are embodied in the "Amberson bill" of the Michigan legislature of 1913. Among the provisions of this bill the following may be mentioned: The State is to be divided into health districts. In each such district a health commissioner is to be appointed for a term of four years. The fitness of the commissioner is to be determined by the State Board of Health after examination. The salary of the commissioner varies with the population of the district, but in most instances would run from three to six thousand dollars. There is to be an additional appropriation for laboratory expenses and for carrying out the purposes of the act.

It shall be the duty of the health commissioners to be vigilant in the work of disease prevention and the conservation of the public health, and to enforce all health laws of the state and health ordinances of their respective localities, together with all rules and orders of the state board of health; to collect and report to the state board of health morbidity statistics and to make a monthly report of the work done by them in narrative form to the state board of health and in such tabular form as may be prescribed by the state board of health. Copies of such reports shall be retained by each commissioner in permanent record books. They shall make such sanitary inspections and surveys of the district as may be required from time to time by the state board of health or by the city for which appointed, or by resolution of the board of supervisors of each county. They are hereby authorized and invested with the power to enter on and inspect private property at proper times in regard to the possible presence, sources or cause of disease, to establish quarantine and in connection therewith to order whatever is reasonable and necessary for the prevention and suppression of diseases; to close schools, churches, theaters, or any place of public assemblage, to forbid public gatherings in order to prevent or stay epidemics; to collect statistics concerning insanity, feeble-mindedness, tuberculosis, and other infectious diseases, to inspect slaughter-houses, and markets of all kinds where food is sold. They shall inspect at least once each six months and make a sanitary survey of the publicly owned buildings and institutions within their respective jurisdiction and shall keep a report thereon as part of the records of their office. They may inspect any school buildings or grounds within their jurisdiction as to sanitary conditions and shall have power to close any school when the sanitary conditions are such as to endanger or imperil the health or life of the pupils attending the same. They shall include all such sanitary inspections in their monthly reports to the state board of health. They shall at all times be subject to the orders of the state board of health in the execution of the health laws of this state and may perform any duty where required by the state board of health, or any member of said board acting for the entire board, which might be performed by said board of health or an officer thereof.

Further duties of the health commissioners are defined in the bill, and I have given only enough to show the purpose and scope of its provisions.

The successful operation of such a law would require the highest class of sanitarians. They must possess intelligence, industry, and integrity. They must be devoted to their work, remembering that the Father of Medicine said: "Where love of mankind is, there also is love of art." With these qualifications I believe that such a law might be operated with great benefit to the people. Is the medical profession of this country prepared to do this work? I believe that many of the recent graduates of our best schools are fitted for this highly important function. They may need special training in the courses in public health now being inaugurated. If I mistake not, our profession will soon have wide opportunity to demonstrate its usefulness in this direction. If the public makes this demand, preventive medicine will have the opportunity to do a patriotic service which has never come to any profession at any time. With proper facilities and helpers, such commissioners might within a few years become acquainted with the conditions surrounding every permanent resident within his jurisdiction, and with properly qualified administrators of the law much might be done to abate disease, improve health, increase efficiency, eradicate the venereal diseases, stamp out vagrancy, pauperism, prostitution, alcoholism, and crime. Crime is a disease due to heredity or environment, one or both. We now permit it to breed and multiply in our midst. Its causes must be determined and eliminated and its habitations must be discovered, disinfected, or destroyed. We have heard too much about the rights of the individual; let us know more about his duties. Too much stress has been laid on the sacredness of private property and too little on the duty of all to contribute to the welfare of the whole. Preventive medicine has demonstrated in a practical way the force of the biblical statements that no man liveth to himself alone, and that every man is his brother's keeper. Preventive medicine is the most potent factor in the socialistic movement of the day with which every good man feels himself more or less in sympathy; besides it is at the same time the most powerful weapon against the anarchy with which some would threaten us.

If preventive medicine is to bestow on man its

richest service, the time must come when every citizen will submit himself to a thorough medical examination once a year or oftener. The benefits which would result from such a service are so evident to medical men that detail is not desirable. When recognized in their early stages most of the diseases which now prevail are amenable to treatment. The early recognition of tuberculosis, cancer, diabetes, nephritis, heart disease, etc., with the elimination of the more acute infectious diseases would add something like fifteen years to the average life, besides saving much in invalidism and suffering. The ultimate goal of science is the domination of the forces of nature and their utilization in promoting the welfare of mankind. Science must discover the facts and medicine must make the application for either cure or prevention.

The local health authorities for which the bills referred to make provision must be supervised by State Boards of Health or State Commissioners. Many of our State Boards of Health are already doing much, but this is little compared with what they might do. They should be absolutely free from party dictation, should be made up of men both qualified and interested, and their executive officers should be distinguished for their knowledge of sanitation. Their appropriations should be greatly increased, for health is a purchasable commodity. Pure water, pure food and even pure air cost money, but they lead to health, which is worth more than gold to both the individual and the State.

Our present national health service is doing most excellent work. It demonstrated its strength in eradicating the plague in California and the suppression of yellow fever in New Orleans. It has charge of the administration of the laws affecting the admission of immigrants, so far as their health is concerned, and it performs this service well. The Public Health Service is now investigating the pollution of certain rivers, studying trachoma in the mountains of Kentucky, pellagra in South Carolina, and the spread of typhoid fever in certain districts. The Hygienic Laboratory at Washington has made valuable researches in addition to the routine work of the examinations of vaccines and serums. This bureau should be developed into a department with a member in the cabinet. The study of contagion in our midst is quite as important as anything within the range of the activities of the Departments of the Interior, Agriculture, and Commerce and Labor. Our health relations with other nations concern us quite as much as our trade relations. The one thing above all others against which our doors should be shut is disease, whether it be of plant, animal, or man, whether it be of body, mind, or morals. The highest function of the State is not to make millionaires out of a few importers or to find profitable investments for its surplus wealth in foreign lands, but to advance to the highest degree the health, intelligence, and morality of its citizens.

In each State there should be a hygienic laboratory equipped with able men supplied with facilities for the study of sanitary conditions and for the prosecution of scientific research. The Hygienic Laboratory at Washington should be developed into a great institution for research which would improve the conditions of life. The greatest asset of any nation is the health of its citizens and the people who secure this in the highest degree will dominate the earth for the dominion of the superman, when he comes, will extend from pole to pole, not by force of arms, but by example and education.

Younger members of the profession: One who is soon to be mustered out of service, on account of disability and old age, salutes you. An old soldier who has served in the ranks nearly forty years, steps from his decimated regiment, lifts his cap and cheers you, as you pass by in your new dress and armed with weapons of greater efficiency than was known when he enlisted. The cause is the liberation of the race from the bonds of superstition and ignorance and it is a glorious one. The contest began before the genus *homo sapiens* came into existence. Countless generations have served their time, some well, some ill, and have passed into oblivion, but their partial victories have made you stronger and placed on you a greater responsibility. Your intelligence is greater, your judgment is sounder, and your effectiveness has been increased. Where the past has failed or only partially succeeded, your success will be greater. But the battlements of ignorance still bristle with heavy-fire guns. Only a few of the outposts of the enemy have been captured. It is for you to do and then like all your predecessors to die. You stand to-day within the firing line. Go on courageously and when eons of the future have become the past, the superman, born out of the struggles of his predecessors, will demolish the last citadel of ignorance and vice, and firmly plant on the highest peak of the mountain of knowledge the flag of human progress, and when the silken banner shall unfold there shall appear on it this legend:

*Pra gloria omnium nationum et hominum honore.*

Department of Medicine, University of Michigan.

## SPLENECTOMY FOR PERNICIOUS ANEMIA: REPORT OF A CASE.*

By WARREN COLEMAN, M.D.,
AND
J. A. HARTWELL, M.D.,
NEW YORK.
(From the Cornell Division of Bellevue Hospital.)

In March, 1913, Eppinger and Decastello reported three cases of pernicious anemia upon which they had performed the operation of splenectomy. Other cases have since been published in Germany[1] and one case in this country by Harpole and Fox.[2]

We report the following case in order that it may assist in determining ultimately the value of the procedure.

Andrew K., 27 years old, a plumber by occupation, was first admitted to Bellevue Hospital, September 10, 1911, suffering from a high grade anemia for which no cause could be found but which appeared to belong in the group of simple anemias. After treatment with syrup of the iodide of iron, Blaud pill, and sodium cacodylate, the patient improved to such an extent that he was discharged November 1.

On June 23, 1913, the patient again entered the hospital. He had been employed as a street car conductor but became so weak that he was compelled to stop work. He denies syphilis.

The most essential features of the physical examination were: the characteristic lemon-yellow color of the skin and scleræ; extensive pigmentation of the lower half of the abdomen with many

*Presented in abstract at the meeting of the Association of American Physicians, held in Atlantic City, May 12, 1914.

areas of leucoderma; a number of teeth had been lost, the remaining teeth were in bad condition, and, in addition, the patient suffered from a severe type of pyorrhea alveolaris; the spleen extended three fingers' breadth below the free border of the ribs and presented a hard, sharp edge.

The blood picture on June 24 was as follows: red cells, 1,600,000; Hb, 50 per cent.; color index, 1.6; marked aniso- and poikilocytosis, slight polychromatophillia; 1 normoblast to 200 white cells; leucocytes, 6,000; polymorphonuclears, 59.5 per cent.; transitionals, 3.5 per cent; lymphocytes, 32 per cent.; large mononuclears, 3.5 per cent.; eosinophiles, 0.5 per cent.; mast cells, 1 per cent. The Wassermann reaction was negative on June 24, 1913. The stools contained neither parasites, ova, nor blood. (Later examinations were likewise negative.)

During the ensuing four months various typical symptoms of pernicious anemia were observed, such as low, continued fever, with occasional exacerbations, attacks of diarrhea, progressive weakness, increasing intensity in the coloration of the skin and sclerae, and high pulse-rate.

Also, during this time, all of the better known methods of treatment were employed; iron alone or combined with Fowler's solution, Fowler's solution or sodium cacodylate alone. Examination of the gastric contents showed a low total acidity and an absence of free hydrochloric acid, and the patient was given large amounts of this acid. The pyorrhea alveolaris was brought under control with trichloracetic acid or with iodine. In addition, the patient was transfused four times by Dr. Edward Lindeman by the syringe-cannula method. The last transfusion was interrupted after 100 cc. of the donor's blood had been injected because hæmolysis was occurring. Two hours later the patient had a severe chill, the temperature rising to 103.8° F.; four hours later he passed two ounces of blood-stained urine, and, at the expiration of five hours, he was sweating profusely and suffering from dyspnea.

Except for short periods when the patient was better subjectively, his condition became progressively worse. At various times the blood gave evidence of transient attempts at regeneration, as indicated especially by an increase in the number of normoblasts, but the general tendency was toward further deterioration.

July 8, examination of the blood gave the following result: red cells, 824,000; Hb, 23 per cent. (Dare); color index, 1.4; marked aniso- and poikilocytosis; slight polychromatophilia; 26 normoblasts to 100 white cells; no megaloblasts; leucocytes, 2,000; polymorphonuclears, 64 per cent.; transitionals, 2 per cent.; lymphocytes, 30 per cent.; large mononuclears, 3 per cent.; eosinophiles, 1 per cent.

On September 26 the blood showed: red cells, 1,448,000; Hb, 38 per cent. (Dare); color index, 1.3; moderate aniso- and poikilocytosis; no normo- or megaloblasts or polychromatophilia; leucocytes, 5,000; polymorphonuclears, 47 per cent.; transitionals, 2.3 per cent.; lymphocytes, 45.3 per cent.; large mononuclears, 1.3 per cent.; eosinophiles, 2.6 per cent.; mast cells, 0.6 per cent.

About this time our attention was attracted to the cases reported by Eppinger and by Decastello in which benefit appeared to have followed splenectomy, and the advisability of performing the operation upon our patient was taken under consideration. In view of the emphasis which Eppinger laid upon the urobilin content of the feces as a measure of the hemolytic activity of the spleen, Dr. John H. Richards attempted to determine this for us, but was unable to find a method which was free from objection.

Since all other methods of treatment had failed to benefit the patien and the outlook appeared hopeless without operation, this was advised.

On Oct. 27 the blood presented the following picture: red cells, 1,744,000; Hb, 29 per cent. (Dare); color index, 0.8; marked aniso- and poikilocytosis; slight polychromatophilia; no normoblasts or megaloblasts; leucocytes, 2,600; polymorphonuclears, 60.5 per cent.; transitionals, 1.5 per cent.; lymphocytes, 29.5 per cent.; large mononuclears, 5.5 per cent.; eosinophiles, 3 per cent.

The operation was performed October 29, under ether, in the following manner: A straight incision was made through the left rectus from the last rib to below the umbilicus, and was carried through the peritoneum. The spleen was non-adherent and easily delivered without putting traction on the pedicle. Double rubber-protected clamps were placed on the pedicle and the spleen cut away. The pedicle was ligated with two double No. 3 plain catgut sutures. The abdominal wall was sutured in layers, plain catgut for the peritoneum, chromicised gut for the fascia, and silk-worm gut for the skin. There were no difficulties encountered in the operation and owing to the lack of adhesions the procedure was accomplished without loss of blood.

During the postoperative course the patient suffered from the fifth to the fourteenth day from very severe pains in the upper left quadrant of the abdomen. This has been noted in two other cases where an enlarged spleen had been removed. The cause is not explained.

Dr. Richard Weil was kind enough to study the spleen for the presence of hemolysins and has furnished the following report:

"The spleen was delivered to me immediately after operation. Two portions of the organ were at once removed and prepared for hemolytic tests in the following manner: One portion was weighed and then thoroughly crushed in a mortar. To it were then added nine times its own weight of physiological salt solution. The suspension was shaken for two hours in a mechanical shaker, and was then centrifuged. The supernatant fluid was used in the tests to be later described. A second portion was added to 95 per cent. alcohol in the same proportions as above described. This portion was then centrifuged, and the supernatant fluid used in the hemolytic tests. A histologically normal spleen, obtained at autopsy from a cardiac case, was prepared as a control in the same fashion. The red cells were obtained from four human beings, comprising two normal individuals and two cases of pernicious anemia, one of which was the individual who supplied the spleen. These cells were washed in three changes of normal salt solution, and were then made up to a 5 per cent suspension.

"In making the tests, one cubic centimeter of each of the suspensions of red blood cells was treated with one cubic centimeter of the splenic extracts. The extracts were diluted in graded proportions for a quantitative estimation of their hemolytic activity. The results need not be given in detail; suffice it to say, that no differences of moment could be detected between the action of the normal spleen and that of the case of pernicious anemia upon the red blood cells."

We are indebted to Dr. E. E. Butterfield of Dr. Norris' laboratory for the pathological report: "Spleen measures 14 x 10 x 4.5 cm. Weight approximately 300 g. Organ is firm; capsule is uniformly opaque. In the middle of the anterior border there is a small cyst filled with clear fluid measuring 5 mm. in diameter. Section is dark red in color. Splenic follicles are very numerous and enlarged, the largest, 1½ to 2 mm. Otherwise the section is uniform and presents no other noteworthy gross lesions."

"Histological Examination.—The most striking characteristic of the microscopic section is the extreme vascularity of the organ.

"The lymph follicles are well preserved and rather large; they consist almost exclusively of small lymphocytes; there are no germ centers. On the margin of the follicles occasional eosinophiles and large, non-granular cells are found. Central arterioles are normal in appearance.

"The sinuses are wide and filled chiefly with red blood corpuscles. Numerous polymorphonuclear eosinophiles, polymorphonuclear neutrophiles, and occasional nucleated red cells are also found in the sinuses. There are numerous cellular strands running irregularly through the pulp. The strands are composed of neutrophile and eosinophile myelocytes, groups of cells of the plasma cell type, and occasionally nucleated reds, some of which show nuclear figures. Clusters of three or more neutrophile myelocytes with nuclear figures are also encountered in the splenic veins. Capsule and trabeculæ normal. No hemosiderosis.

"Conclusion.—The cytological details of the splenic picture are essentially those of erythrogenesis and myelogenesis. The lymphatic elements are normal or slightly hyperplastic. There is little or no regressive change and no definite evidence of blood destruction. The red blood cells are intact and the phagocytosis of red cells encountered frequently in the spleen in other conditions is absent."

The patient's recovery from the operation was rapid. By November 3 the lemon-yellow color of the skin and scleræ had disappeared and he presented the appearance of a patient with severe secondary anemia.

November 11 the blood examination was: red cells, 1,605,000; Hb, 31 per cent. (Sahli); color index, 1.0; marked aniso- and poikilocytosis; slight polychromatophilia; 12 normoblasts to 200 while cells; leucocytes, 4,500; polymorphonuclears, 71.6 per cent.; transitional, 2.6 per cent.; lymphocytes, 18 per cent.; large mononuclears, 7.6 per cent.

On November 17 the leucocytes had risen to 12,000; they reached 16,000 on December 6 and 22,400 on January 6. Similar increases in the number of leucocytes have been reported in other cases, and Musser and Krumbhaar[3] found that it occurs after experimental splenectomy in animals.

The only other essential change in the blood picture was observed on December 29, when, with 1,280,000 red cells and 27 per cent. Hb, 51 normoblasts and 11 megaloblasts were noted in counting 200 leucocytes.

The patient improved both subjectively and objectively for a time after the operation; he grew stronger and was up in a chair for a part of each day. Later he lapsed into his former condition and, following the suggestion of Bramwell,[4] was given neosalvarsan in doses of 0.2 gm., January 13, 1914, intramuscularly, and January 20 and 29 intravenously. As the patient continued to grow weaker the last two doses of the series were not administered.

On January 13, before the administration of the neosalvarsan, the blood examination was as follows: red cells, 1,760,000; Hb, 25 per cent. (Dare); color index, 1.4; marked aniso- and poikilocytosis; slight polychromatophilia; 18 normoblasts and 8 megaloblasts to 200 leucocytes; leucocytes, 14,200; polymorphonuclears, 49 per cent.; transitionals, 7 per cent.; lymphocytes, 36 per cent.; large mononuclears, 7 per cent., and eosinophiles, 1 per cent.

February 25, examination of the blood gave the following result: red cells, 1,264,000; Hb, 18 per cent.; (Dare) color index, 0.7; aniso-, poikilocytosis, and polychromatophilia marked; 111 normoblasts and 16 megaloblasts in 200 white cells; leucocytes, 17,450; polymorphonuclears, 46 per cent.; lymphocytes, 44 per cent.; large mononuclears, 8 per cent.; eosinophiles, 1 per cent.; mast cells, 1 per cent.

The use of the neosalvarsan makes it impossible, of course, to draw any conclusion as to the effects of the splenectomy except in the interval before its administration. In this interval there was no evidence of more than temporary improvement, as has previously been stated.

At the present time, April 24, six months after the operation, the patient, while looking better and feeling better, is just beginning to sit up. The blood examination is as follows: red cells, 1,060,000; Hb, 22 per cent. (Dare); color index, 1+; marked aniso- and poikilocytosis; slight polychromatophilia; 52 normoblasts and 3 megaloblasts to 200 white cells; leucocytes, 18,400; polymorphonuclears, 45.5 per cent.; transitionals, 3 per cent.; lymphocytes, 32 per cent.; large mononuclears, 10 per cent.; eosinophiles, 9.5 per cent.

# PRIMARY LUPUS OF THE LARYNX.*

By EMIL MAYER, M.D.,

NEW YORK.

THREE cases of lupus of the larynx, two of them primary, have been under my care during the past year, recalling the study made of this affection by the writer and presented to the American Laryngological Association at its Nineteenth Annual Congress in 1897.[1] Their histories are subjoined together with a brief résumé of the few similar cases that have been recorded in the past seventeen years, thus permitting a comparison with the viewpoint then existing, as also of noting the progress made, especially in the diagnosis and treatment of this affection.

CASE I.—L. K., male, aged 44 years, Roumanian by birth, came to my service in the dispensary of Mount Sinai Hospital on April 20, 1913. He gave a history of cough without pain or hoarseness. He claimed to have been well until recently, when he had been told that he had tuberculosis. His physician noted a white spot on

*Read before the American Laryngological Association at its thirty-sixth annual congress at Atlantic City, N. J., May 25, 1914.

his tonsil and sent him to me for examination. The white spot proved to be a concretion in the tonsil. The laryngoscope showed a surprising condition of affairs accompanying such a meager history. His epiglottis was one large infiltrated mass with irregular nodules, having lost all its original appearance; both arytenoids were infiltrated; there was an infiltrate at the right false cord, and breaking down in various parts. The lungs were examined by Dr. Taschman, who found widespread tuberculosis of the lung, a small cavity at the left apex. His entire absence of distress with the far-advanced destruction made the diagnosis of lupus of the larynx in its final stages as the only tenable one. At no time during the after treatment was there appreciable dysphagia or dyspnea, and he died ten months later of his tuberculosis.

Case II.—D. W., male, aged 36 years, was admitted to Mount Sinai Hospital, service of Dr. Howard Lilienthal, December 31, 1913. He gave a history of having had a cough four years ago, was treated for four weeks when he recovered. His present illness began seven weeks ago, when he began to have some difficulty in swallowing and hoarseness; his breathing was difficult. He had been referred to the hospital for treatment. Examination showed marked stridor with respirations; no pulmonary disease found.

January 2.—Examined by Dr. Mayer: "The entire epiglottis is involved in an enormous mass which extends into and covers almost completely the lumen of the larynx. The arytenoids are so swollen and indurated that no view of the interior of the larynx is obtainable. Owing to the extensive obstruction in the larynx, a preliminary tracheotomy is advisable before removal of a portion of the growth for examination." January 2.—Wassermann test made by Dr. Kaliski: Negative.

January 3.—Tracheotomy performed under local anesthesia by Dr. Lilienthal.

After recovery, on January 19, under cocaine anesthesia, two pieces of tissue were punched out from the epiglottis, by the writer, and sent to the pathologist, Dr. Mandlebaum, who reported tuberculosis (lupus).

January 27.—The entire protuberating mass of the epiglottis I now removed with punch forceps, under cocaine with little or no discomfort to the patient; his breathing at once improved and his dysphagia ceased.

On January 30 his tracheotomy tube was removed and on February 3 he was discharged from the hospital.

He attended my service in the dispensary for local treatment thereafter.

Pulmonary examination showed no sign of tuberculosis. This, together with the presence of the enormous mass of slow formation and without symptoms until his respirations became impeded made the diagnosis of primary lupus of the larynx at an advanced stage of the affection indubitable.

Case III.—I. H., male, aged 50 years, was seen by myself April 20, 1914, and is of interest here only as a case of secondary lupus, for it is associated with a similar affection in the right upper jaw on the cheek, in the antrum of Highmore on the right, and in the nose on the same side. The same absence of distressing symptoms, with no pulmonary involvement, in spite of far-advanced tumefaction and destruction of the larynx, characterizes this as a case of lupus, and the lesion of the mucous membrane of the jaw bears this out, though we have no means of ascertaining positively whether the larynx was the original site or not.

G. Brat[2] mentions five cases of primary lupus of the larynx which he examined in the clinic of Burger. "The disease begins almost always in the aditus of the larynx, the epiglottis is nearly always affected; the aryepiglottis folds in 45 per cent., the interarytenoid region in 42 per cent., while it very rarely affects the subglottic region. Subjective and functional disturbances are often entirely missing and the disease is discovered quite accidentally. Pain, cough, and expectoration are very rare." He says further: "In comparison to other tubercular diseases of the larynx, lupus is entitled to stand alone. Lupus of the larynx compares with lupus vulgaris of the skin; ulcerative tuberculosis of the larynx with similar conditions of the skin; and tubercular laryngeal tumor with scrofuloderma."

F. Massei,[3] in recording a typical case of lupus of the larynx in a girl aged 10, eventuating in tuberculosis, thinks the distinction between lupus of the larynx and tuberculosis should not be made.

J. Durazzo[4] reports a case in a female aged 22.

Oppenheim[5] reports a case in a male aged 28.

Talbot R. Chambers[6] presented a case in a female, aged 21, where he successfully excised the epiglottis.

Thomas J. Harris[7] reports a case in a woman aged 73. This patient had been seen by Jonathan Wright three to four years before Harris saw her, at which time two-thirds of the epiglottis was present, and the diagnosis lay between epithelioma and lupus. Later the epiglottis became totally destroyed.

H. E. Smyth[8] presented a case of this affection in a male, aged 47 years, at the New York Academy of Medicine. This case was examined and discussed by Gleitsmann, Douglas, and Mayer.

St. Clair Thomson[9] reports a case in a woman aged 22.

In the discussion of an article on lupus of the mucous membrane of the upper air passage by M. Senator,[10] Edmund Meyer (Berlin) stated that he had observed a case of primary lupus of the larynx in a patient whose age and sex is not given.

Dundas Grant[11] mentions a case in a boy aged 10.

Rosenberg[12] reports two cases: One, a female aged 36, a very mild case in which the epiglottis, aryepiglottic fold and false cords were involved, but not the true cords. Spontaneous recovery ensued. In the other case, a female, aged 15, a diaphragm was formed in the region of the vocal cords producing hoarseness and great dyspnea. The conjunctival reaction was negative in both cases.

L. Neufeld[13] found twenty-four cases of primary lupus of the larynx recorded in the literature up to the time of his publication (1908).

He records a case of this affection in a female. There was recent hoarseness. On the laryngeal surface of the epiglottis there were six brownish-red nodules, whitish at their apices; the false cords were indurated and had the same prominence as the epiglottis. For the existing dyspnea the right false cord was removed, subsequently the left false cord was also removed, and its base treated with lactic acid, with good results eventually.

G. F. Guild[14] mentions a case of this affection in a female aged 43. Tracheotomy followed by thyrotomy and removal of diseased tissue with no recurrence in eight years.

Bornasch[15] (St. Petersburg) reports a case of primary lupus of the larynx, age and sex of patient not given.

E. Baumgarten[16] reports a case of this affection in a female aged 18, in which there were white linear scars on the free border of the epiglottis, nodules on its laryngeal surface as also on the false cords. No tuberculosis was present. Tuberculin caused severe reaction in the larynx. He considers the affection to be a tuberculosis of the mucosa.

Donelan[17] presented to the Laryngological Section of the Royal Society of Medicine a case of laryngeal tuberculosis which was three years under treatment. Complete rest of voice for two years, forty galvanocautery applications, guaiacol spray and guaiacol internally were followed by cure. Thomson considered this a case of lupus.

Kilson[18] had a case of a female aged 36, treated

successfully with galvanocautery and internal administrations of arsenic.

J. Safranek[19] presents three cases of primary lupus of the larynx. The first case was a male, 36 years old, slight hoarseness; family history negative. This strong and healthy looking man had an epiglottis thickened in its entirety, mostly, however, in its center; the border covered with small pink nodules breaking down in places, with a deep redness of the laryngeal surface. The aryepiglottic folds were likewise infiltrated and covered with isolated nodules; false cords infiltrated and some subcordal infiltration. There was no temperature and no involvement elsewhere, the lungs were free. The second case was a male, aged 36, spontaneous recovery. The third case was a female, aged 39, with suspected empyema of the accessory sinuses and lupus of the larynx was quite accidentally discovered.

Forchhammer[20] found 5 per cent. of the lupus cases to be laryngeal, but none of those were primary, which he considers to be a rare disease. These statistics were obtained after examination of 1200 lupus patients in the Finsen Light Institute, Copenhagen.

J. Dresch[21] believes that the primary focus in lupus of the mouth, pharynx and larynx exists in the nose, while Rosenberg[12] places the laryngeal cases as being esophageal in origin.

Harms[22] says that although Baumgarten and von Dahrung believe that lupus is of hematogenous origin and does not originate from an external infection, most authors believe that the dissemination in the blood vessels is due to an infection from without. This is shown by the fact that in most of the lupus processes the lungs are not primarily affected, and secondly that the picture of metastatic tuberculosis of the skin differs entirely from that of the mucous membrane. "Primary lupus of the larynx is extraordinarily rare."

Pregnancy has a bad effect on lupus of the mucous membranes especially of the primary sort; Safranek[19] saw a case of primary lupus of the larynx in a pregnant woman in which edema of the larynx supervened and tracheotomy had to be performed. Recovery was prompt after induced abortion.

To differentiate between lupus and syphilis, the Wassermann reaction being negative, and also antisyphilitic treatment with iodides and mercury failing, a hypodermic injection of the old tuberculin may be given, under precautions, however, as laryngeal edema often supervenes upon the tuberculin test. The smallest dose therefore should be given at first. It occurs more frequently in females than in males.

*Treatment.*—Treatment may be medical or surgical. As local applications, lactic acid, caustic potash followed by pyrogallic acid, muriatic acid, after spraying with ethyl chloride, and also calomel have been used.

Pfannenstill[23] has made use of the following treatment: The iodide of sodium is given internally in daily doses of 2 grams following which inhalations of ozone are made. It is claimed that iodine is thus set free and its powerful bactericidal effect is made use of to good advantage.

Ove Strandberg[24] following the method of Pfannenstill, substitutes sprays of hydrogen dioxide acidulated, for the ozone inhaler, and claims that much benefit is obtained.

Rudolph Mandl,[25] believing that the iodine is best applied locally, has prepared a powder which is powerfully hygroscopic. It is a hydro-iodoborate called ulsanin. This is applied directly to the diseased part, a brownish stain results as soon as it becomes moist, and hence must be most carefully applied.

Katschanowski[26] suggests the advisability of local applications of permanganate of potassium.

Koichi Fujinami[27] (Tokio) presents a new method of treating lupus of the larynx with the parallel rays of the Finsen lamp. A funnel is added to the distal end of the apparatus with water flowing about the mouth end. The patient is seated, tongue protruded, with the funnel introduced in the mouth and set with thumb screw. At first the treatment is given once daily and from three to five minutes' duration. The sittings are increased to fifteen or twenty minutes as soon as the patient becomes accustomed to the discomfort to the tongue. As soon as reaction occurs, treatment is interrupted and resumed on disappearance of the reaction. It requires five or six treatments before pain in deglutition, redness and tumefaction occur; from this time improvement begins.

Albanus[28] recommends the use of the high frequency current. The Finsen light could not be used because of the difficulty of applying the rays to the larynx. Radium has not been sufficiently tried to state its value.

The Roentgen rays, while of enormous benefit in lupus of the mouth and pharynx, is technically difficult in the larynx, and can not be carried out efficiently, while external application is necessarily less useful.

The treatment with superheated air is followed by brilliant results. With the proper apparatus and the superheated air directed to the part, the bacilli are killed and the lupoid tissue destroyed. To reach the larynx with this a laryngo fissure should be performed (Safranek[19]).

Operative treatment, however, radical removal of diseased parts, followed by galvano cautery and lactic acid is by all means the best form of treatment, and the earlier this is done the better. The suspension laryngoscope of Killian will undoubtedly lend itself in many ways toward the treatment of these parts.

The total number of cases of primary lupus of the larynx recorded in the literature up to the present time, including the two here presented, is 35, indicating the rarity of this affection, which was first described by Ziemssen in 1876.

It is perhaps noteworthy that the two cases presented by the writer in his former communication were of primary lupus of the larynx in their earliest stages, and were observed for many years, one of them being under his care for eighteen years; while the two here presented were in the later stages of the disease.

With but one exception each writer who has observed primary lupus of the larynx is strongly in favor of the distinctive appellation of lupus as against tuberculosis. All agree that the similarity is very great, for lupus presents the same reactions after subcutaneous injections of tuberculin, vaccinated animals because tuberculous, the tubercle baccilli are produced in pure culture, and injected guinea-pigs become tuberculous. It is very rare for a lupus deposit to become caseous. With this close similarity all other resemblance ceases.

Lupus of the larynx is a chronic disease with but the slightest symptoms, is most frequently an acci-

dental discovery, and the prognosis as to life is relatively good. For these reasons, therefore, we feel that we most cordially endorse the statement that the distinctive appellation of lupus should be maintained, and that primary lupus of the larynx, though rare, does exist.

## ARTERIAL HYPERTENSION:

### ITS CLINICAL SIGNIFICANCE AND LATTER DAY TREATMENT.*

By I. WILLIS BALLARD, M.D.,

OPELIKA, ALA.

Determination of the blood pressure becomes of more and more importance as our knowledge of its significance increases. A relatively recent addition to our diagnostic armamentarium, there exists much confusion as to its real value. In its consideration we are confronted with certain questions, our interpretation of which governs to a very large extent the significance that we attach to this condition.

The answer to these questions depends upon what we conceive the condition arterial hypertension to be. Is it a disease entity of itself? Is it merely a symptom, or is it a condition the result of certain pathology and itself a factor in the production of additional pathology?

Unquestionably, there are patients in whom arterial hypertension is the main etiological factor in their complaints. These are instances of chronic toxemia, defective metabolism, dependent usually upon autointoxication of intestinal origin. Alcohol, syphilis, gout, and lead poisoning probably are next in importance as sources of chronic toxemia.

The fact that the toxins of each of these several sources of origin, circulating in the blood current, are capable of causing vascular hypertension is well proven. These cases constitute a class of patients, usually mature individuals of 25 to 45 years of age, in whom the sphygmomanometer shows the presence of a moderate degree of hypertension, ranging from 120 to 145 mm. of mercury. These patients have developed no degenerative changes of the cardiovascular system and may with proper control be returned to a normal condition. But there probably is no disease so insidious in its onset as is arteriosclerosis, and vascular hypertension in the class of patients under consideration is always to be taken as warning which, unless heeded, will eventually result in the merging of a now curable condition into cardiovascular-renal disease.

A second class of patients in whom arterial hypertension is regularly present are those cases of early arteriosclerosis with a tension of 150 to 175 mm. of mercury in which the degenerative change in the arterial walls is yet in its early stages. Inseparably interrelated with these cases of pure arteriosclerosis are those in which the degenerative changes have advanced further to the development of myocarditis and vascular nephritis. While it is true that the pathologist has on more occasions than one pointed out these different conditions and correlated their signs, yet their clinical separation is at times extremely difficult if not impossible.

Arteriosclerosis may exist and in its early stages be confined to one set of vessels, such as the splanchnics, the cerebral arteries, the coronaries, etc. It may even confine itself to the terminal arteries of an extremity, as witness Raynaud's disease. But, despite these variations in its location, there does not exist an arteriosclerosis in the presence of a good heart which does not invariably show an arterial hypertension, and the degree of hypertension taken in comparison with the pulse pressure gives most valuable evidence in arriving at correct conclusions regarding the degree of arterial involvement and the extent of involvement of additional closely related organs.

When renal changes have begun to develop the so-called arteriosclerotic or vascular nephritis, the most constant and characteristic sign is an additional increase in the hypertension. The range of readings after the development of renal changes may be considered as between 175 mm. of mercury for the minimum up to the highest recorded readings of 300 mm. and over, for in no other disease is such a degree of hypertension found as in vascular nephritis secondary to arteriosclerosis. The pulse pressure ranges from 70 to 90 or even 100 mm., witnessing the large amount of excess work the heart is called upon to perform.

The significance of the third stage findings, or that of myocardial degeneration, may be summed up under that well worn expression, "the begin-

*Read before the Alabama State Medical Association, Montgomery (Ala.) Session, 1914.

ning of the end." A high blood pressure and a wide pulse range indicate a well sustained circulation and a fairly adequate renal function, while a lowering pressure and a narrowing pulse range gives warning of a failing circulation to be followed by progressive renal insufficiency.

We conceive arteriosclerosis, vascular nephritis, and myocarditis, in the relationship above outlined, as constituting a single disease entity in which arterial hypertension exercises a most conspicuous part, not alone in the rôle of effect but also in that of cause. Excessive resistance in the systemic circulation, in a word hypertension, is probably the most important single factor concerned in the production of arteriosclerosis. Furthermore, arterial hypertension is the primary cause of the cardiac hypertrophy developing in the early stages of the disease and this same hypertension, greatly increased as the result of more general arterial involvement and the development of renal change is the primary cause of the final cardiac dilatation.

Excess tension in cardiovascular-renal disease therefore we do not consider compensatory in the sense that it is compensatory in tubular nephritis. A well sustained blood pressure at the time of the development of this triad of pathological changes is a most wise provision on the part of nature to maintain an adequate renal function, in so far as hypertension for this purpose may be necessary; but the all-important factor in this third stage is one of cardiac integrity and the progressive lowering of the blood pressure is an indication of a gradually dilating heart, the result of overloading, such overloading present in the form of excessive arterial tension.

The proof of this is shown by certain cases of generalized arteriosclerosis with high blood pressure, renal, and cardiac changes, in which conservative treatment by methods that reduced the blood pressure without depressing the heart, result not alone in improvement of the patient's subjective symptoms, but even in a moderate rise of the specific gravity of the urine, indicating, at least for the time being, improvement in metabolism and better elimination.

We do not pretend to assert that there is not a form of hypertension that is purely compensatory and that this hypertension is a salutary and beneficent process not to be lightly interfered with or illadvisedly altered. Such is the case in tubular nephritis in which there is interposed in the path of the circulation swollen and congested kidneys with lowered urinary output and the areolar tissues choked with fluid. In these cases the all-important object of treatment is the maintenance of a sufficiently high blood pressure to insure an adequate renal function and to prevent stasis and edema.

In the field of the acute infectious diseases hypertension is rarely seen during the ordinary course of the disease, but in two of these particularly, an estimation of the blood pressure is of peculiar value. In scarlet fever with its specter of acute nephritis constantly present, a gradually increasing blood pressure or more commonly, a sudden change from a hypo- to a hypertension, is the most trustworthy evidence we have of the onset of kidney involvement. In pneumonia we have in the blood pressure record most valuable evidence of the time at which stimulants are vitally indicated. In this connection the suggestion of Gibson serves as an excellent guide "when the pulse in number of beats exceeds the blood pressure in mm. of mercury, stimulants are indicated."

In obstetric practice blood pressure estimations are rapidly assuming an importance comparable with that of uranalysis. As an early sign of the development of the toxemias of pregnancy, hypertension is oftentimes present many weeks prior to the development of other objective symptoms. In a pregnant woman arterial hypertension is to be considered as a warning of defective metabolism and a definite indication for eliminative treatment.

In considering the treatment of arterial hypertension, of first importance is diet, for we believe that autointoxication is a factor to be reckoned with in all instances of this condition. By means of diet, together with proper elimination, we are able practically to control the hypertension of intestinal toxemias and modify that of all forms of toxemia. The skimmed milk diet of Oertel in nephritis and cardiac degeneration probably owes its greatest benefit to the marked reduction in blood pressure which ensues during its administration.

Ordinarily an excellent working rule in the dietetic management of hypertension is to reduce the total quantity of food taken perhaps by half for at least the first few days of treatment. This is of much more importance than merely to limit the protein consumption and increase in proportion the carbohydrate and fat. A mixed diet is preferable provided its quantity be sufficiently limited.

In medication we have in some cases a valuable means of controlling certain symptoms. To this end use is made of spirit of nitre, the nitrites, and upon occasion of nitroglycerin. Sodium iodide in small doses continued over a long period of time is of value in controlling excessive hypertension.

The question of exercise is one dependent almost entirely upon the condition of the myocardium. In very high pressure cases active exercise is contraindicated because of the danger of acute cardiac asystole or of hermorrhage. In cases with a moderate hypertension exercise is very valuable as a means of increasing metabolism and the elimination of waste products.

With the latter day therapeutic apparatus there is offered a most efficient means of combating many of the disease processes dependent upon faulty metabolism. Included among these is arterial hypertension with its associated cardiovascular-renal disease. The high potential static modality with its immense voltage and the high frequency coils and transformers with their high amperage are the two most efficient means with which to obtain therapeutic results.

Autocondensation, according to the method of D'Arsonval, with transformer, resonator, and dielectric in proper circuit, has proven itself a most valuable means of holding in check the pathological advances of this disease and particularly in controlling the excess arterial hypertension. This result is dependent upon a complex action of the current, first upon metabolism producing increased tissue combustion and accelerating the processes of elimination, as shown by increased solids in the urine, and by its effect upon the vasomotor centers and the arterioles, inducing relaxation.

The physiological effects of autocondensation as thus outlined are indicated in the care of all patients showing an arterial hypertension, provided such hypertension is not compensatory. In the presence of hypertension, compensatory in character, as that of tubular nephritis, autocondensation

should not be employed but rather those means which promote increased hyperemia in the peripheral vessels. Such are radiant light and heat. Hyperemia induced by convective hot-air baths increases the lumen of peripheral vessels, relieves congestion and augments the elimination of toxins. These methods of treatment persisted in with care and discretion will enable us to improve very much the results of the past in the care of this class of patients.

## VARIX OF THE INTERNAL SAPHENOUS VEIN RESEMBLING A STRANGULATED FEMORAL HERNIA.

By G. P. COOPERNAIL, M.D.,

BEDFORD, N. Y.

THE following case presents certain points of interest which make it appear worthy of record:

Mrs. W. J., aged sixty-two, married, born in U. S. Occupation, housewife.

*Family History.*—Father died of cancer of the liver at the age of seventy-one. Mother's father died of cancer of the glands of the neck at the age of sixty-one. One sister died of cancer of the uterus at the age of fifty-five. Her mother had a large umbilical hernia. Two of her brothers and one sister had inguinal hernias.

*Past History.*—Never had any serious illness until the present trouble. Menses began at thirteen, always regular, no pain or hemorrhages. Menopause at the age of fifty. Had three children, youngest twenty-two. Never troubled with constipation. About twenty years ago when she was carrying a small wooden tub to the sink she slipped and forced the edge of the tub against her right groin, the bottom of the tub striking the sink. She fell against the edge of the tub with no little force and the injury was very painful. A few hours later she noticed a lump in her groin where the edge of the tub struck her. When she first noticed it, it was the size of a hen's egg. A physician was called in and told her that she had ruptured herself and advised her to wear a truss. She wore a truss for six months but found she was more comfortable without it so she discarded it and never used a truss since that time. This lump has slowly increased in size up to date of present trouble when it was the size of an orange. It would always disappear on pressure and when the patient was lying on her back it would decrease very much in size. It was always a little sensitive and when the woman was working hard and on her feet all day it would ache and at times pain her quite severely. The pain would radiate up into her abdomen and down her leg. The present trouble dates from June 21, 1912. She was in the city and had been on her feet all day shopping. Late in the afternoon she began to have pains in the lump in her groin, so much so she could not walk home. She slept very little during the night on account of the pain. The morning of the 23d she felt a little better so was able to go to her home in the country. Shortly after she arrived home she had a chill, and following this she had an attack of vomiting and the lump became very painful. She then noticed that for the first time she could not reduce it. Also that it had increased very much in size. She had a very bad night, having several attacks of vomiting and a good deal of pain. The morning of the 24th she was no better and during the day she became progressively worse. During the day she had several attacks of vomiting, but there was no very bad odor to the material she vomited. The bowels had not moved since the beginning of the trouble but she had passed a little flatus. I saw her for the first time in consultation the 24th at five P. M. She had had no physician before the morning of the 24th.

*Physical Examination.*—The patient is well nourished; examination of heart, lungs, and kidneys negative. Abdomen slightly distended, tender over the right iliac region, with some rigidity of right rectus. In the right groin is a tumor located over the femoral fossa extending upwards over the edge of Poupart's ligament. It measures 10 cm. long and 8 cm. wide. It is very tender and hard on pressure, slightly movable, no pulsation, slight impulse on coughing. It could not be reduced by quite persistent taxis or by the use of the ice bag. Pulse 110, temperature 101°, respiration, 26. The patient says she feels very sick, and the tumor in the groin gives her much pain.

A diagnosis of strangulated femoral hernia was made, and an operation was advised at once. She was moved to the hospital where she was seen by three of my colleagues and they confirmed the diagnosis of strangulated femoral hernia.

*Operation* the same day at eight P. M. Anesthetic, ethylchloride and ether. Incision made across center of the tumor. When the sac was exposed we found the contents quite firm and as seen through the thin wall of the sac, dark and of the appearance of a gangrenous gut. The sac was first separated below and found to communicate with a blood-vessel. With further dissection down the leg it was found to be a varix of the internal saphenous vein. Incision was made into the tumor and it was found to be filled with a firm but not organized blood clot. This was easily shelled out and as soon as it was removed the blood welled out of both ends of the vein. The vein was so large that when I first discovered that it was a blood-vessel I thought it was the femoral vein:

The hemorrhage was easily controlled by clamping above and below. Both ends were ligated and the sac was removed. The wound was closed without drainage.

The wound healed by primary union. Twenty-two months after operation there had been no recurrence or further trouble in that region.

## Medicolegal Notes.

**Negligence—Evidence.**—In an action against a physician for negligence in treating a wound it appeared that the plaintiff had the index finger of his right hand crushed between two pieces of iron and immediately went to the defendant for treatment. The wound was dirty and ragged. The hand and forearm, within less than a week, became so infected that several operations at a hospital to which the plaintiff afterwards went had to be made to drain off pus and insert drainage tubes; and the usefulness of the plaintiff's hand was largely impaired. After washing the wound, the defendant had stretched the skin over the bone and stitched it in place. The trial court directed the jury to find for the defendant. On appeal this was affirmed. There was no expert testimony as to whether the infection was caused by the defendant's failure to sterilize his instruments or by the removal of the bandage by third persons without authority, but the evidence seemed to show that the infection developed after such removal, and there was no expert testimony as to the effect of the subsequent treatment of the wound at the hospital to which the plaintiff went. It was not error to exclude a question to an expert witness as to what would be indicated if the skin when stretched over the bone and stitched was tight, where the witness fully covered the point in his testimony, and it was not claimed that the infection complained of was produced by the manner in which the skin was stretched.—Moline v. Christie, 180 Ill. App. 334.

**Recognized School of Medical Treatment—Measure of Degree of Care and Skill.**—On the trial of an osteopath for manslaughter it was held to be erroneous to permit an allopathic physician to testify as an expert as to the correctness and professional skill of the treatment administered. The treatment of a physician of one particular school, it was said, is to be tested by the general principles and practices of his school, and not by those of other schools, and a physician or surgeon is bound to exercise such reasonable care and skill as is possessed and exercised by physicians and surgeons generally in good standing of the same system or school of practice or treatment in the locality and community of his practice, having due regard to the advanced state of the school or science of treatment at the time of such treatment. "When a patient selects any one of the many schools of treatment and healing to save him, he thereby accepts and adopts the kind of treatment common to that school or class, and the care, skill, and diligence with which he is treated, when questioned in a court of justice, should be tested by the evidence of those who are trained or skilled in that school or class."—State v. Smith, Idaho Supreme Court, 138 Pac. 1107.

## ELECTRICITY IN THE ABORTIVE TREATMENT OF ACUTE GONORRHEA.

THE use of electricity in the treatment of chronic gonorrhea and its sequelæ is a well known, even if little used, procedure, but Virghi (*Journal d'Urologie*, April, 1914) has gone a step further and employs this remedy in the abortive treatment of acute gonorrhea. Before describing his method the author discusses the indications for abortive treatment. Cases of acute gonorrhea fall into one of two classes: (1) There may be a reinfection from a deep focus; these cases will not respond to abortive treatment since the deep focus cannot be reached and may constantly reinfect the anterior mucosa. (2) The attack may be the first that the patient has ever had, or it may be a fresh attack in a patient who has had gonorrhea previously but had been entirely cured; these are both amenable to the abortive treatment. As to the time limit of successful abortion of the disease, he says the duration of life of the gonococcus on the surface of the mucosa has usually been estimated as not over three to seven days, after which time the organisms which live have insinuated themselves into the subjacent tissues. Virghi thinks, however, that the period is longer than this, for he has treated cases successfully by his method as late as the eleventh day after the appearance of the discharge.

The treatment proposed by Virghi is divided into two stages. In the first, or electrolytic stage, the patient having urinated, the anterior urethra is washed with sterile water by repeated and gentle syringing. Then 5 c.c. of a 2 per cent. cocaine solution is thrown into the urethra, and retained three or four minutes, while the penis is drawn forward in order to distend the folds of the mucosa and thus allow the solution to come in contact with the entire surface. The solution is now expelled by stripping the urethra carefully and then an injection is made of 5 c.c. of protargol, which is retained in the anterior urethra until the completion of treatment. The positive electrode is placed anywhere on the left thigh, and the negative electrode, composed of a flexible metallic staff with insulated surface, carrying a ball, size 13-14 Charrière, attached at the tip, is passed into the urethra, care being taken that none of the protargol escapes. An assistant, charged with regulating the amount of the continuous current, moves the switch, noting the progressive displacement of the needle of the milliampèremeter, and calls out the degree attained. At the same time the operator imparts to the staff gentle and slow movements in and out, touching successively all the walls of the urethra as far as the bulb, in order to conduct the continuous current there through the ball which is plunged in the protargol solution. When the patient, who has been previously warned, experiences a sensation of smarting or tingling in the region of the positive electrode, the intensity of the current is reduced without, however, suspending the movements of the olive. The maneuvers in the interior of the urethra do not cause any disagreeable sensation. Three to four minutes suffice for this portion of the séance. At the end of twenty-four hours this procedure is repeated in every detail. Whether a third treatment should be given will depend upon the result of microscopic examination of the secretion. The presence of the gonococcus constitutes a definite indication for it, providing the reaction of the urethra or the sensitiveness of the patient permit it; if not, the treatment must be deferred to the following day, the anterior urethra being irrigated with boric solution.

The second stage of the treatment consists in the daily lavage of the anterior urethra with boric solution or with sterile water, followed every two or three days by massage upon a straight sound. In addition endoscopic applications of protargol or 4 per cent. silver nitrate solution, according to the resistance of the local infiltration, are made in the region of the fossa navicularis. If the gonococcus reappears in the secretions another series of two electrolyses should be given in order to rid the urethra permanently of this organism.

The author has treated ninety-two cases in about two years, and claims 100 per cent. cures. The duration of treatment varies in accordance with the more or less prompt employment of the method after the first appearance of discharge. In fifty-seven cases where the début was one to three days previously, cure was obtained in eight days on the average; in twenty-four cases where the discharge existed four to six days, all were cured in eleven days; in nine cases of seven to ten days' standing, cures resulted in twenty to twenty-five days; while one case of eleven days' duration required thirty-three days for the cure. There were no complications that Virghi thinks should be attributed to the method, though there were some due to forcible injections made by the patients before consulting him.

The author claims that the abortive electrolytic procedure is the only one which is capable of giving absolutely sure and permanent results in recent cases of acute gonorrhea, it being understood that the operator is master of the technique and the patient obeys his directions. If these claims are verified by other observers, a great step forward will have been made in the treatment of this treacherous disease.

## THE PATHOLOGY AND ETIOLOGY OF DUODENAL ULCERS.

At the recent meeting of the International Society of Surgery in New York the subject of duodenal ulcers was fully discussed and perhaps the question of their causation and treatment was placed on a firmer basis. Nevertheless, our knowledge of the causation of such ulcers is still lacking in many respects and any investigations which will tend further to elucidate the matter, will, of course, be welcomed.

At a meeting of the Edinburgh Medico-Chirurgical Society held on May 6, 1914 (*Lancet*, May 23). Mr. D. P. D. Wilkie read a paper on the pathology and etiology of duodenal ulcer. In this paper he demonstrated certain facts gained chiefly from the postmortem room. During the past three years he had investigated the condition of 400 cadavers and he had met with 41 cases of duodenal ulcer, in only six of which had the ulcer had any direct connection with the death of the patient. In only six cases had a diagnosis been made before death and in all of these operation had been performed. In one or two cases where a chronic ulcer had been found it had caused during life none of the typical symptoms. Such "silent" ulcers might attain considerable size and cause death from hemorrhage or perforation without having previously given any noteworthy symptoms. The "syndrome pylorique" described by Soupault and resembling the Moynihan symptom-complex of duodenal ulcer might be, but was not invariably associated with a duodenal ulcer. This point was emphasized by some of the French surgeons who took part in the discussion at the Surgical Congress in April.

Wilkie concluded from his investigations that (1) Duodenal ulcer is a disease of frequent occurrence and one which often passes unrecognized. (2) Although, as a rule, readily recognized, a chronic ulcer may occasionally exist and give rise to none of the characteristic symptoms, the first evidence of such a "silent" ulcer being sometimes its perforation; (3) "Silent" duodenal ulcers are met with most frequently in the subjects of arteriosclerosis and are found for the most part on the posterior wall. (4) Some toxic or irritative factor, usually within the abdomen and most often associated with the colon or appendix, is found in a large proportion of cases. (5) Probably many acute duodenal ulcers are primarily follicular ulcers from the breaking down of inflamed lymph follicles. (6) Whatever be the primary cause of a gastric or duodenal ulcer, spasm of the muscular coats of the viscus is an important factor in determining its chronicity. (7) The situation of the opposing ulcers on the anterior and posterior walls on the boundary zone of the areas supplied by the anterior and posterior branches of the supraduodenal artery suggests that a common vascular deficiency, rather than a contact infection, accounts for the multiple ulceration with its tendency to chronicity. (8) This vascular deficiency may be due to arteriosclerosis, but probably it is usually due to spasm of the muscular coats of the duodenum induced by a slight local anemia consequent on strain on the supraduodenal vessels, this muscular spasm being favored by the increased vagotonus and the irritable condition of the autonomic nervous system which exists in such cases. (9) The sex incidence of duodenal ulcer is to be explained on anatomical grounds. The relatively high pylorus and short fixed duodenum of the male allow of its vascular supporting ligament, the hepatoduodenal ligament, being exposed to strain, which in the female with her relatively low pylorus and lax duodenum falls on the left border of the gastrohepatic omentum and lesser curvature of the stomach. (10) The fixity of the male duodenum further predisposes to kinking at the first duodenal angle and thus to an unduly long exposure to the acid chyme from the stomach.

It will be gathered from the above conclusions that Wilkie favors Sir Arbuthnot Lane's theory as to kinks and bands being causal agents of duodenal ulcers in that they subject the first part of the duodenum to an unduly long exposure to the acid chyme from the stomach.

## A STATE MEDICAL SERVICE.

The old order is changing everywhere. In England more quickly than in any part of the civilized world. Whether, however, many of the changes are for the ultimate good of the individual, the community, the nation, or the race is an altogether different matter. It is argued by some that the State should assume control of most human activities, as such a course must benefit the people as a whole. Although this is not the place to discuss the question, it may be pointed out that in those countries in which the State has taken upon itself the direction of many activities the result has not been strikingly successful. Unfortunately, so long as politics enter so largely into the guidance of all human affairs there will be corruption, and the fact that the State is at the helm affords no guarantee that concerns under its management will be run either efficiently or honestly.

Recently there has been raised by some medical practitioners in certain countries, notably in Great Britain, the cry that the medical profession should be State controlled, and a beginning in this direction has been made by the establishment of national insurance. In *Popular Science Monthly* for June, 1914, Prof. Paul L. Vogt pleads for a State controlled profession mainly for the reason that the prevention of disease would be more greatly aimed at than its cure. This is true to a large extent and prevention of disease might be greatly aided by a medical service devoted chiefly to this end. But it must not be forgotten that disease will be always with us, and that treatment will ever be the chief part of the physician's work. One objection urged in England against the establishment of a State controlled medical service is that patients would not be able to have free choice of medical attendants. The pros and cons are numerous and the entire matter requires much more discussion ere the medical profession or the community will be convinced that a State controlled medical service is desirable.

### The Bacteriology of the Blood in Typhoid Fever.

An important study of this subject has recently been made by Stanislaus Sasky, who reports his results in the *Zeischrift für klinische Medizin*, Vol. 80, Nos. 1 and 2. His investigation was carried out on eighty cases of typhoid fever. Blood cultures were made in conjunction with the determination of the Widal reaction. The author's conclusions are fully in agreement with those that have been arrived at by other investigators. Thus the typhoid bacteriemia is an almost constant occurrence in the first week of the disease and tends to disappear in the course of the following weeks. In certain mild cases of typhoid fever the causative organisms may be detected in the blood even during the entire febrile period of the disease. There is a relationship between the bacteriemia and the severity of the disease. In the severe and moderately severe cases the bacilli may be isolated from the blood in the second and even in the third weeks of the disease, whereas in the majority of the mild cases the microorganisms are no longer to be found in the blood in the second week of the disease. In comparing the bacteriological findings with the results of the Widal reaction the author notes that even in the course of the second week the blood culture gives a higher percentage of positive results than does the agglutinative reaction. This apparently holds true of the first week, but on account of his scanty clinical material Sasky does not feel justified in drawing a definite conclusion upon this phase of the subject. Following the second week the relationship is reversed. Accordingly the bacteriological findings must be regarded as the most reliable diagnostic criterion of the early stages of typhoid fever, while the febrile curve must be regarded as the most important diagnostic feature of the later stages.

### Treatment of Villous Tumors of the Bladder with the High Frequency Current.

The work of Beer of New York on the "oudinization" of vesical papillomata is well known both at home and abroad. Indeed von Frisch of Vienna terms this procedure "Beer's method." Often termed fulguration, it is said to be in reality a method of desiccation only—an expulsion of all aqueous content without any strict caustic or coagulant action. Judd of the Mayo Clinic has found this method of treatment of the greatest value in heading off recurrence. It is therefore calculated to surprise us when we note in the transactions of the recent Congress of the German Surgical Society (*Berliner klinische Wochenschrift*, May 11, 1914) that Joseph, in a paper on the high tension current in the treatment of villous tumors of the bladder, does not even allude to the work of the Americans, and the same silence is maintained in the discussion of his paper. It is true that Joseph uses diathermy, or, in other words, thermocoagulation to gain his end. His high frequency current serves for this purpose only. His indications and results, however, seem to be closely allied to those reported by Beer, Judd, and others. From the discussion it appears that thermocoagulation has been in use for at least three years in this clinical field, coincident with the introduction of diathermy into practice. It may therefore slightly antedate the method of "oudinization" of Beer. In any case the failure to allude to the latter's independent pioneer work is strange.

## News of the Week.

**Hospital Ship Ashore.**—The hospital ship *Maine*, which was presented to the British nation by Americans and equipped and mantained during the South African War by the Hospital Ship Maine Committee, composed of American women, went ashore on the west coast of Scotland on June 17 and suffered severe injury. A large number of patients were on board but all were removed in safety.

**Opium Conference.**—The International Conference on Opium opened at The Hague on June 15, when it was announced that all the States except Servia, Turkey, and Greece had given their adherence to the decisions of the last convention.

**"Eugenics" Law Upheld.**—The Wisconsin Supreme Court on June 17 sustained the so-called Wisconsin "eugenics" law, which provides that couples intending to marry must in order to obtain a license present certificates from physicians stating that they are physically fit. The Supreme Court thus reverses the decision of the lower court, which had held that the law was unconstitutional.

**New Drug Law.**—On July 1, 1914, the recently adopted act to amend the public health law of New York State in relation to the sale of habit-forming drugs becomes effective, and physicians are advised that it is important to make immediate application to the Secretary of the State Board of Health, Albany, N. Y., for a supply of official order blanks for the purpose of providing themselves with heroine, morphine, codeine, etc., after that date. At the same time it is reported that, because of the failure of the Legislature to make an appropriation for the purpose, no blanks for physicians' and pharmacists' use have been printed.

**Charitable Bequests.**—The will of the late Mr. James Campbell of St. Louis, Mo., disposing of an estate estimated to be worth from $30,000,000 to $60,000,000, provides that all but a few million dollars shall eventually go to St. Louis University for the founding of a large hospital. Subject to a life interest of the testator's widow and daughter and to bequests of $1,000,000 each to the daughter's heirs, Mr. Campbell ordered that the entire estate twenty-one years after the death of his daughter should be turned over to the university to be used "for the erection, equipment, and maintenance of a hospital in St. Louis or St. Louis County for sick and injured persons and for the advancement of the science of medicine and surgery, absolutely and forever." St. Louis University is a Roman Catholic institution and is conducted by the Jesuits. It is doubtful that the will be admitted to probate without a contest on the part of some of the relatives of Mr. Campbell.

The Presbyterian Hospital of Philadelphia receives a bequest of $1,000 by the will of the late Mrs. Annie E. Claghorn of that city.

The Stamford Hospital, Stamford, Conn., receives a bequest of $7,500 by the will of the late Mrs. Alice P. Getman, the money to be used for the endowment of a bed to be known as the Charles H. Getman bed. The will also contains a bequest of $1,000 to the Servants of Relief for incurable cancer patients, New York.

The city of Vinton, Ia., is to be provided with a hospital through the generosity of the late Mrs. Virginia Gay, whose will provides for a bequest of $50,000, of which $20,000 is to be used for the

building and $30,000 for maintenance. The city is to provide a site and the institution is to be known as the Virginia Gay Hospital.

Mr. George W. Nevil of Philadelphia has made a gift of $5,000 to St. Joseph's Hospital for the endowment of a perpetual free bed in memory of the family of Joseph and Amelia Nevil.

**New Memorial Hospital.**—Mr. E. C. Benedict of Greenwich, Conn., has promised the Greenwich Medical Society that he will provide a modern hospital for the town, on condition that the present General Hospital and Greenwich Hospital are abandoned. The former will probably be converted into a hospital for contagious diseases and the latter may become a private hospital. The new hospital is to be known as the Benedict Memorial and will, it is estimated, cost about $125,000.

**Gift to Johns Hopkins.**—It has been arranged by the General Education Board to pay in a lump sum the recent grant of $1,500,000 to the Johns Hopkins Medical School for the establishment of the William H. Welch Endowment for Clinical Education and Research. The fund will be turned over to the school within two weeks.

**Personals.**—Dr. HERBERT S. BIRKETT, professor of otology and laryngology in McGill University, Montreal, has been appointed dean of the medical faculty of the university, succeeding Dr. Francis J. Shepherd, resigned. Dr. Birkett was graduated from McGill in 1881, and is an ex-president and a member of the Council of the American Laryngological Association, and a member of the American Academy of Ophthalmology and Oto-Laryngology, the British Medical Association, the Montreal Medicochirurgical Society, and other special societies.

Dr. EDWARD ANTHONY SPITZKA of Philadelphia, who since 1906 has been professor of anatomy in the Jefferson Medical College, has recently resigned his chair and will establish himself in New York.

**Honorary Degrees.**—At the 214th commencement of Yale University on June 17, the honorary degree of Master of Arts was conferred on Dr. Edward Robinson Baldwin of Saranac Lake; Dr. Fred Towsley Murphy of St. Louis, professor of surgery in Washington University; Dr. John Howland of Baltimore, professor of pediatrics in the Johns Hopkins Medical School; Dr. Charles Franklin Craig of Washington, director of the Army Medical Museum; Dr. Elliott Proctor Joslin of Boston, assistant professor of medicine in Harvard University; Dr. Henry Hun of Albany, professor of diseases of the nervous system in the Albany Medical College; Dr. Oliver Cotton Smith of Hartford, Conn.; and Dr. William Francis Verdi of New Haven, Conn. The degree of doctor of science was conferred on Dr. Richard Pearson Strong of Boston, professor of tropical medicine in Harvard University.

Dr. L. Emmett Holt of New York, professor of pediatrics in the College of Physicians and Surgeons, Columbia University, received the degree of Doctor of Science from Brown University on June 17.

Dr. Milton Joseph Rosenau of Boston, professor of preventive medicine and hygiene in the Harvard Medical School, was given the honorary degree of Master of Arts by Harvard University on June 18.

Dr. Michael J. Lawlor of Waterbury, Conn., received the honorary degree of Master of Arts from Holy Cross College, Worcester, Mass., on June 17.

**The Mohansic Hospital.**—Governor Glynn has vetoed a bill passed at the recent session of the New York State Legislature, which provided for the abandonment of the State Hospital at Mohansic, N. Y., as well as a companion bill appropriating $200,000 with which to begin a new State hospital for the insane at another place. In a memorandum explaining his action the Governor points out that to abandon the Mohansic State Hospital now, after the State has invested nearly half a million dollars in erecting buildings, providing water pipes and drainage, and building a railroad, would be unwise and extravagant. The sale of the site for other purposes at the present time would, it is estimated, entail a public loss of more than $250,000. The hospital has been planned to relieve the congestion in the hospitals for the insane in New York City, and the site selected is situated only forty miles from the city. Construction has been halted because the health authorities refused to permit a large institution to be situated in the watershed, but their objections have been overcome by the provision of an adequate system of sewage disposal, and there seems to be no good reason why the work should not proceed at once.

**Medical College Commencement.**—At the annual commencement exercises of the Jefferson Medical College, Philadelphia, on June 6, the degree of doctor of medicine was conferred on 147 graduates. The valedictory address was delivered by Dr. Henry Harbaugh Apple, president of Franklin and Marshall College, who spoke on "Ideals of Education for the Profession of Medicine."

**Medical Society of New Jersey.**—The 158th annual meeting of the Medical Society of New Jersey will be held at the New Monmouth Hotel, Spring Lake, N. J., on June 29 and 30 and July 1, 1914, under the presidency of Dr. Enoch Hollingshead. The oration in medicine will be delivered by Dr. Lewellys F. Barker of Baltimore, and the oration in surgery by Dr. John B. Deaver of Philadelphia. On the first day the society will hold a joint meeting with the New Jersey State Pediatric Society, and on the next day there will be a symposium on hospitals at the morning session, and the annual banquet in the evening.

**Medical Society of the Missouri Valley.**—Under the auspices of the Polk County Medical Society, the twenty-seventh annual meeting of the Medical Society of the Missouri Valley will be held on September 17 and 18 at Colfax Springs, and on September 19 at Des Moines, Ia., the scientific sessions being held on the first two days, and an interesting series of clinics on the last. Dr. Charles Wood Fassett of St. Joseph, Mo., is the secretary of the society.

**Medical Society Elections.**—MAINE MEDICAL ASSOCIATION: Annual meeting at Portland on June 10 and 11. Officers elected: *President*, Dr. Herman L. Bartlett, Norway; *Vice-presidents*, Dr. Albert L. Stanwood, Rumford; and Dr. Leander A. Dascombe, Showhegan; *Secretary*, Dr. John B. Thompson, Bangor; *Treasurer*, Dr. Edwin W. Gehring, Portland.

MASSACHUSETTS MEDICAL SOCIETY: Annual meeting at Boston on June 9 and 10. Officers elected: *President*, Dr. Charles Francis Withington, Boston; *Vice-president*, Dr. Samuel B. Woodward, Worcester; *Secretary*, Dr. Walter B. Burrage, Boston; *Treasurer*, Dr. Edward M. Buckingham, Boston; *Librarian*, Dr. Edwin H. Brigham, Brookline. Dr. Everett A. Bates, Springfield, was appointed to

deliver the annual oration at the meeting next year.

Alumnae Association of the Woman's Medical College of Pennsylvania: Annual meeting at Philadelphia on June 5. Officers elected: *President*, Dr. Elizabeth L. Peck; *Vice-presidents*, Dr. Marie L. Bauer and Dr. Frances C. Van Gasken; *Recording Secretary*, Dr. Jacobina S. Reddie; *Corresponding Secretary*, Dr. Mary Buchanan; *Treasurer*, Dr. Ellen C. Potter.

**Centenarians Again.**—Mrs. Maria Lossaso of West Paterson, N. J., who was married five years ago, when 105 years old, died of heart disease, at St. Joseph's Hospital, Paterson, on June 8, at the age of 110 years.

In London, on June 9, Rebecca Clark, said to be the oldest Englishwoman, gave a birthday party on her 110th anniversary.

**Obituary Notes.**—Dr. Maus Rosa Vedder, until recently of New York, a graduate of the College of Physicians and Surgeons, New York, in 1861, formerly assistant surgeon in the United States Army, and a member of the New York State and County Medical Societies, died at his home in Caldwell, N. J., on June 13, aged seventy-nine years.

Dr. Leland Madden Baker of Lynn, Mass., a graduate of the Boston University School of Medicine, Boston, in 1894, died at his home, from Bright's disease, on May 26, aged 45 years.

Dr. Carroll E. Proctor of Weld, Me., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1880, a member of the Maine Medical Association and the Franklin County Medical Society, and from 1894 until 1902 superintendent of schools at Weld, died at his home, from lead poisoning, after a long illness, on May 13, aged 55 years.

Dr. Samuel Flagg of Worcester, Mass., a graduate of Dartmouth University, Hanover, N. H., in 1841, and of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1845, a surgeon in the United States Army during the Civil War, died at his home at Lake Quinsigamond, on June 5, aged 93 years.

Dr. William Jasper Wilhite of Modesto, Cal., a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1867, a surgeon in the Confederate Army during the Civil War, died at his home on May 31, aged 77 years.

Dr. Otto Gustaf Ramsey of New Haven, Conn., professor of obstetrics and gynecology in the Medical Department of Yale University, died at his home from pneumonia, on June 12, at the age of 44 years. Dr. Ramsey was graduated from the University of Virginia, Department of Medicine, Charlottesville, in 1890, and later served as associate in gynecology at the Johns Hopkins Medical School. In 1899 he joined the Medical Faculty of Yale. He was consulting physician to the New Haven Hospital, and was also a member of the American Medical Association, the Connecticut State and New Haven County Medical Societies, and the Medico-Chirurgical Faculty of Maryland. During his last illness he received two transfusions of blood from his friend, Dr. B. H. Moore, a service for which the entire senior class of the school had volunteered.

Dr. Sidney H. Gardiner of Brooklyn, N. Y., a graduate of Queen's University Medical Faculty, Kingston, Ont., in 1889, formerly adjunct surgeon to the Long Island College Hospital, and associate physician to the Bushwick Hospital, and a member of the American Medical Association, the Clinical Congress of Surgeons of North America, and the New York State and Kings County Medical Societies, died in a sanatorium, following an operation for appendicitis, on June 11, aged 52 years.

Dr. Ezra New of Dublin, Ga., a graduate of the University of Georgia, College of Medicine, Augusta, in 1887, and a member of the Medical Association of Georgia and the Laurens County Medical Society, died at his home after a brief illness, from angina pectoris, on June 5, aged 54 years.

Dr. Edward J. O'Brien of Chicago, a graduate of the Rush Medical College, Chicago, in 1906, died at West Baden, Ind., where he had gone to recover his health, on June 5, aged 35 years.

Dr. T. E. Enloe of Nashville, Tenn., a graduate of the University of Nashville, Medical Department, in 1874, died at his home from paralysis, on May 26, aged 69 years.

Dr. Henry St. George Lyons Hopkins of Fresno, Cal., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1855, a veteran of the Civil War, having served throughout with the Confederate Army, and for thirty-three years a practitioner in Fresno, died at his home, on May 25, aged 79 years.

Dr. James M. Keller of Hot Springs, Ark., a graduate of the University of Louisville, Ky., Medical Department, in 1852, died at his home on May 27, aged 82 years.

Dr. George W. Newman of Brooklyn, N. Y., a graduate of the New York University Medical College in 1864, surgeon in the Fifth New York Heavy Artillery during the Civil War, died at his home on June 13, aged seventy-two years.

Dr. Eli R. Tullis of Camden, N. J., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1879, and a member of the staff of the West Jersey Homeopathic Hospital, died at his home on June 12, aged seventy-seven years.

Captain George P. Bradley, M.D., Medical Director in the United States Army, a graduate of the College of Physicians and Surgeons, New York, in 1870, and a member of the American Medical Association and the Massachusetts and Worcester District Medical Societies, died at his home on June 14, aged sixty-five years. Dr. Bradley entered the navy as an assistant surgeon in 1870, and was promoted until, in 1887, he became a medical inspector, serving on the *Indiana*. In 1900 he was placed in charge of the Mare Island Naval Hospital and in the same year was made a medical director. From 1903 to 1905 he was in charge of the Naval Hospital in Washington, and from 1905 to 1907 of the Naval Hospital at Portsmouth, N. H.

Dr. Frank R. Newman of Brooklyn, N. Y., a graduate of the Bellevue Hospital Medical College, New York, in 1871, died at his home on June 13.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

"DILATATION MURMURS"—LEUCEMIA—SUSPENSION LARYNGOSCOPY—"DRUGS OF ADDICTION"—HOSPITAL FINANCES—PATENT MEDICINE COMMITTEE—HOUSE FLIES—SMALLPOX.

London, June 12, 1914.

Murmurs in a dilated heart are often the subject of some anxiety or annoyance on account of the difficulty of explaining them. Dr. Samuel West, on the 26th inst., read a paper on them at the Medical Section of the Royal Society of Medicine, of which

he is president. He began by saying murmurs were audible eddies, a definition to which objection was afterward taken. He said a so-called jet produced violent eddies and then enumerated the conditions which led to eddies and murmurs in the vessels, according as blood was passing into or out of a dilatation of a vessel or through a constriction of it. Their force would vary with the force of the circulation. Similar conditions might be met with in the heart with organic disease, but he was only concerned on this occasion with murmurs where there was no organic disease, but only dilatation. These, which he called "dilatation murmurs," might be basic or ventricular and in each case on the right or the left side. *Basic* murmurs were sometimes called hæmic or functional, both undesirable terms; if on the left side and arising in the pulmonary artery they might be due to eddies caused by the blood passing through the normal orifice into a dilated artery above; more likely out of the dilated right ventricle behind; sometimes possibly to a dilated left auricle pressing on the pulmonary artery. At the right base a peculiar systolic murmur over the aorta might for a moment suggest aortic disease when it was found transient on longer observation. *Ventricular* dilatation murmurs were almost always systolic in time, soft and flowing in character, limited to the preordial area, and rarely propagated to the axilla or back. They were commonly referred to regurgitation through the auriculoventricular orifice. If they were they should be propagated as those due to organic disease but were not. He held they were caused by intraventricular eddies.

Dr. A. F. Voelcker said he too had been in the habit of calling these sounds "dilatation murmurs," but though there was much to learn as to their cause, there was no evidence that an eddy could produce a murmur—if it could it would be by vibration of the cardiac wall. Apical systolic murmurs were common in children in any acute illness; he had always thought them best explained by dilatation of a ventricle—but of the right, not of the left. Dr. Alexander Morison said occasionally apical murmurs were rough and propagated round the left side to the back. They could scarcely be other than due to forcible regurgitation through the mitral orifice dependent on acute dilatation, which might pass off or be fatal. The apical murmurs described by the president he regarded as due to actual regurgitation. The aorti systolic murmur referred to he thought due to dilatation of the left ventricle with relative stenosis of the aorta. The importance of apical murmurs in young people was at the present time often made too light of. Dr. Bezley Thorne called these murmurs "postural." They were curable but not to be made light of, as they were not produced by healthy hearts. Dr. Parkes Weber mentioned the murmur about one ear synchronising with the pulse ("pulsating tinnitus"). It worried patients but was not due to aneurysm. It was transient.

At the same meeting Dr. Michell Clarke read an account of the pathological changes in a case of leucemia under the prolonged use of *x*-rays—more or less continuously from 1908 to 1913. At first the spleen only was rayed, later the bones also. For two and a half years the treatment was successful. The enormous spleen, reaching to the iliac crest, gradually became small and hard. Then the liver began to enlarge and at length seemed to fill the abdomen. After 1911 the rays seemed to lose their power of keeping the disease in check. Death took place in July, 1913, from toxemia, hectic, emaciation, and hemorrhage from the gums.

In the Section on Laryngology Professor Gustav Killian gave a demonstration of "Suspension Laryngoscopy." One patient sent for examination had a laryngeal growth. I was not at the meeting, but a friend gave me a report of the proceedings and estimated that the most prevalent opinion was not in favor of the new method. One practitioner asked an old laryngologist what he thought of it. The wary veteran replied with another question. What would most patients think of being asked to lie on the back on the table and hang the head over the edge, with a support to steady it while the light was directed into the open mouth?

The Roentgen Society has been holding an exhibition. A large collection of plates and prints showed how *x*-rays can be utilized in exploring various parts of the body. Photographs of the bismuth meal, of tubercles, of growths in the lungs, and so on, showed their value for diagnosis. Instantaneous radiographs give clearer views than the old photos and can be obtained through the thickest tissues. They only required a 1/100 second exposure. Some new electroscopes were also said to be capable of determining the radioactive material present in ores in extremely minute quantity.

"Drugs of Addiction"—not a very elegant name, but your readers will recognize what is intended. The expression has been chosen for a letter to a newspaper warning the public against the danger of morphine and other sedative drugs. The writer gave a very good account of the injury produced by indulging in their fascinating (shall we not say intoxicating?) effects. He pointed out that various countries had restricted their sale by legislation, but that our parliament had done nothing. As a physician to a large public asylum, he spoke of his own experience of dozens of brilliant careers wrecked and homes ruined through the drug habit. Not engaged in private practice, he was well qualified to appeal to the public and tell them many things familiar enough to the profession. Perhaps in his enthusiasm he was rather rhetorical, and the physician to another asylum forthwith accused him of exaggeration and declared that few cases admitted to his institution were due to the drug habit, adding that the Report of the Commissioners in Lunacy last year gave only twenty-six cases in five years certified as due to drugs out of over 12,000 patients entering all the asylums in England and Wales per annum, and some of these were combined with alcoholism. Thus, we have a discussion between medical officers of our asylums on the menace to the nation of the habit of drug taking.

Guy's Hospital's Anuual Report contains an appeal not only for new subscriptions but for a further capital sum of £60,000. This is to provide for separate children's wards, for more beds in special departments, and for rebuilding, including the tuberculosis out-patient department, already begun. An appendix to the report summarizes the needs of the school as distinct from the hospital. There is a heavy debt to pay off and additional clinical laboratories are required besides an increase of income of about £5,000 to free the authorities from anxiety and remunerate the teaching staff. When our great hospitals are complaining you will not be surprised that the smaller ones are equally suffering. It is generally believed that the Insurance Act has aggravated the difficulties of

hospitals, as was remarked at the League of Mercy's meeting this week, presided over by the Princess Victoria of Schleswig-Holstein. The act increases the demands upon them by patients and their expenditure. At the same time contributions have diminished.

Some Medical Officers of Health are engaging in a campaign against the house fly and trying to enlist the public in an effort to eradicate the pest by circulating information about the part played by flies as carriers of disease. The summer is very backward this year and the warning to householders to be ready to assist in destroying the scourge is pointed out by a reminder of the probable prevalence of infantile diarrhea.

An outbreak of smallpox took place in a Lancashire district at the end of May, some thirteen persons working in the same mill being attacked. Dr. Chadwick, M.O.H., thought the infection might have been brought in a bale of cotton from Mexico.

The chairman of the Select Committee of the House of Commons on Patent Medicines is now drafting the report, and there will be a meeting to consider it within a few days. It is rumored that the document contains a strong statement as to the injury caused by the unrestricted sale of proprietary or so-called "patent" medicines, and furthers a denunciation of the lurid advertisements which certain newspapers do not hesitate to admit into their columns though they must be aware that they are untruthful and a danger to credulous, suffering people.

## OUR BERLIN LETTER.

(From Our Regular Correspondent.)

DEATHS FROM SALVARSAN—PROGRESS IN THE TREATMENT OF SYPHILIS—RELATIVE VALUE OF SALVARSAN AND MERCURY—COMBINED TREATMENT.

BERLIN, May 15, 1914.

THE cases of death which for some time have been attributed to salvarsan have aroused an uncertainty in professional circles as to the use of this remedy. There have appeared notices in the papers in which a Berlin physician, connected with the government, sought to forbid the use of salvarsan. The subject of the real value of salvarsan was brought up for discussion before the Berlin Medical Society on March 4, 11, and 18. The recent progress in the treatment of syphilis was discussed. The first speaker, Lesser, maintained that a definite decision regarding the recent discoveries relating to the spirochetes, the Wassermann reaction, and salvarsan is as yet premature. It may be stated that in the early cases the progress is very considerable. The discovery of the spirochetes enables one to effect the abortive cure of early cases with the excision of the primary lesion and the use of mercury and salvarsan. In well-developed cases the speaker recommends, if there are numerous secondary foci, the use of mercury for eight to ten days and then the use of salvarsan, for in these cases salvarsan alone works too energetically. The greatest success is obtained by means of a rigid calomel treatment lasting for about five to six weeks in addition to two or three injections of salvarsan. The question whether one should persist in the intermittent treatment or whether one should be guided by the result of the Wassermann reaction is to be answered, as a rule, in favor of the former alternative. The combination of iodides, mercury, and salvarsan is also the best treatment in the late cases, particularly in affections of the internal organs. Treatment is necessary until a negative Wassermann reaction is obtained, nevertheless in quite old cases exceptions may be considered. In cases of galloping lues, calomel and salvarsan have produced results such as were not possible before salvarsan was introduced. The speaker concluded that salvarsan is a powerful remedy against lues and promises better results in certain cases than all other known remedies. Up to the end of last year 87 deaths have been attributed to salvarsan. This figure appears small in comparison with the large number of cases in which salvarsan has been employed. In hopeless cases of syphilis, if death occurs after the injection of salvarsan, one cannot always attribute the fatal outcome to this drug. The effect of salvarsan in paresis is negative; in tabes the speaker has seen marked improvement. Upon the latter point one must still suspend judgment. In hereditary lues salvarsan has a very good effect. One of the strongest advocates of the use of salvarsan was the succeeding speaker, Wechselmann. His remarks were of particular importance for he has supervised as many as 45,000 injections of salvarsan and he has used this solely without the coincident use of mercury. The speaker referred to certain patients who had not responded to mercury, but who were cured by salvarsan. The only death that he had observed after salvarsan was produced after the use of mercury by damaging the kidneys had hindered the excretion of salvarsan. Many of the instances of salvarsan deaths are to be explained in this manner. In other instances it must be assumed that there has been some disease of certain organs previous to the injection of salvarsan, as, for instance, encephalitic foci in the brain, or acute yellow atrophy of the liver, both of syphilitic origin. Of bad omen also are the status thymicolymphaticus and Addison's disease.

The next speaker, Blaschko, stated that according to his experience salvarsan is to be preferred in recent cases and mercury in later cases of syphilis, and that the combined therapy is the correct one. Of both remedies the doses are not to be too large. The important point is not the rapidity of the treatment, but the thoroughness with which it is carried out. If it be maintained that salvarsan has added a substantial means to the conquest of lues, nevertheless a decisive judgment on this point must be held in abeyance for many years, for paresis may occur on an average of eleven years after the initial infection. If he had seen no cure in cases of tabes through the use of salvarsan, nevertheless the speaker had observed many instances of marked improvement, such as occurred only seldom following the use of mercury. Citron reported his cases of death, all of which could not be attributed to salvarsan. He has already observed very good results in tabes. His course of treatment consists in the use of calomel or of mercury ointment for seven months with an injection of salvarsan every week. Since 1910 he has seen no adverse results from salvarsan treatment, even though only the bad cases came to him. The contraindications are severe disease of the kidneys and such minor infections as coryza and mild influenza. Fritz Lesser, in 26 cases with a positive finding of the spirochete, has aborted the disease completely; that is, the Wassermann reaction remained negative after two to three years. These results produced by salvarsan were never obtained with the use of mercury.

Oppenheim reported on 135 nerve cases, chiefly of a metasyphilitic nature. Among those cases treated with salvarsan were 19 cases of cerebral lues, of which 8 were treated successfully. Of 15 cases of cerebrospinal lues a pronounced cure occurred in 6; of 50 cases of tabes good results were obtained in 10; of 24 cases of paresis two or three showed a relative improvement. On the whole, it may be stated that salvarsan furnishes a valuable remedy but one whose results are not extraordinary. The discussion was taken up by a large number of speakers who presented the pros and cons of salvarsan therapy. It may be concluded that by means of salvarsan syphilis may be treated much more effectively than it has been in the past and with the exclusion of certain unsuitable cases no special danger is associated with the use of this drug.

2. Some Personal Results in Psychoanalysis, and the Future of Psychotherapy. L. P. Clark.
3. Indications for Operation on the Seminal Vesicles. J. Bentley Squier.
4. Cancer of the Uterus. F. Cobb.

1. Psychoanalysis.—J. J. Putnam believes that the psychoanalytic movement represents a great boon to many sufferers from a series of distressing and disabling maladies. This treatment, like all others, has its well-marked limitations. The persons to whom it appeals, whether as patients or physicians, are mainly limited to those who are able to see that a large share of the troubles of this world have as their basis the doubleness of the mental life and the consequent misconceptions of individuals with regard to the influences by which they are being moved. A portion of these misconceptions is due to the fact that men fail to see that they stand not as separate individuals, with duties that end in the promotion of their own superficial interests, but as members of smaller or larger communities and groups, and eventually of ideal communities. The sense of isolation, doubt, terror, jealousy, depression, and despair which are so prominent as causes of human misery, and especially of the misery of neurotic patients, would undoubtedly be far less if men were carried along by a sense of devotion to some great cause, some great religious sentiment, in which their longing for more exclusive, personal successes should be merged. There is another great element of difficulty, which consists in the existence of schisms of the personality and self-misunderstanding, that have their root in subtle disorders of development which begin in infancy. The fact cannot be too strongly emphasized that there is no necessary hostility between the psychoanalytic mode of treatment and any genuine agency for good that social life or the ingenuity of any physician has to offer.

3. Indications for Operation on the Seminal Vesicles.—J. Bentley Squier states that in selecting cases for surgical drainage of the vesicles, he groups them into three general classifications with regard to pus, pain, and rheumatism. The pus group includes those cases in which there is definite abscess formation within or around the vesicles. Rest in bed, hot rectal irrigations, etc., cause a subsidence of the acute symptoms. This group also includes cases of recurrent epididymitis following acute urethritis and vesiculitis, the operative indication being vesical drainage combined with epididymotomy; and the chronic type of seminal vesiculitis, often rather difficult to diagnosticate, as the symptoms are not as well pronounced as in the acute form. The group in which persistent perineal pain seems a sufficient indication for operation presents interesting features. The indication for operation in those cases in which joint lesions are present is definite, namely, if the focal infection can be proved to be the seminal vesicle, this should be drained. The author is convinced that drainage of the seminal vesicles offers more for the cure of typical cases of gonorrheal rheumatism than any other means as yet suggested.

11. Facilitating the Crile Method of Transfusion. A. Kahn.

1. Insolation.—P. G. Woolley points out that the treatment of an attack of insolation is one that combines refrigeration with elimination, both active enough to produce good effects without embarrassing organs, such as the heart, which are already damaged. To accomplish the former the practice is to give ice cold packs or baths. To compass the latter recourse is commonly had to stimulants. This latter seems not to be best, except as a last resort. Stimulation of an already burdened organ can do little good and much damage. Hydrotherapeutic methods are of more value in insolation than drugs. Ice packs or iced baths have a great value, but should not be continued for more than a few minutes at a time and should be discontinued when the rectal temperature has reached 104° F. To replace the water lost to the body before the attack and to increase elimination, there is no better method than infusion of saline solutions. If it is true that the oxygen content of the body is low and the acid content is high, then such solutions should be alkaline. Such alkaline solutions as those recommended by Fischer are extremely efficacious, whether given by rectum or intravenously, in neutralizing the acids of the body and increasing elimination of water by the kidneys. The following solution for rectal use should be prepared as follows: Sodium chloride, 30 grams; sodium carbonate (crystallized), 20 grams; water, 1,000 c.c. The injection should be given slowly enough to allow retention. The time consumed in injecting a litre should not be less than one hour. For intravenous injection the following solution should be used: Sodium chloride, 14 grams; sodium carbonate (crystallized), 10 grams; water, 1,000 c.c. This also should be given very slowly. The effect of these solutions upon the secretion of urine is remarkable, and as a rule they will make it unnecessary to use digitalis. When the latter drug is used it should be very carefully administered and its effects carefully watched. The use of strychnine is not advised in the active stage of the disease. Such treatment will dispose of the immediate danger and when this has been done treatment is symptomatic. Headache may be treated with the coal tar products or the salicylates, which, however, should be used with extreme caution. Sleeplessness may be controlled with mild sedatives. In apyrexial heat exhaustion external hydrotherapeutic measures are uncalled for and treatment should be eliminative and stimulative. The internal hydrothera-

peutic methods should be very useful in these cases and should be combined with friction, massage, and warm packs, with sufficient internal stimulant medication.

10. **A Magnetized Needle Holder.**—C. M. Stimson states that some time ago it occurred to him that if a magnet were placed in the end of a needle holder it would greatly facilitate the handling of the surgical needle. Not only would it aid in picking the needle from the table, thus rendering it more accessible for adjustment in the jaws of the holder, but it would be of distinct advantage in regaining needles and pieces of needles which had accidentally fallen into inaccessible places in the field of operation. With this object in view, the author had an ordinary Doyen needle holder magnetized and found that the idea was practicable. Magnetization is not affected by the temperature of sterilization. There are several ways in which an instrument can be magnetized. A simple and easy way is to place it upon the magnet of a running dynamo and let it remain for three or four hours. This method is not very satisfactory, as it does not charge the instrument to its full magnetic capacity, yet to anyone interested in the subject it is an easy way of demonstrating the possibilities of the principle. The best method is to have a needle holder especially made of steel suitable for magnetization; it is then placed in an induction coil and charged. A coil for this purpose should be two inches long and wound with approximately 100 turns of No. 16 double, cotton covered copper wire, the core being made large enough to fit snugly the jaws of a needle holder. The charge is made with a direct current of six amperes at 220 volts, the circuit being connected with a six-ampere fuse.

10. An Aid to Prognosis in Pulmonary Tuberculosis. A. Simple Urinary Test. J. Metzger and S. H. Watson.
11. Juvenile Paresis Treated by the Intraspinal Injection of Salvarsanized Serum. C. E. Riggs.

2. **Hemorrhagic Disease of the Newborn.**—V. D. Lespinasse concludes that direct transfusion of blood stops the bleeding, restores the lost blood, and aids in overcoming infection. Direct transfusion of blood has cured where all other methods have failed. Transfusion should be used early, but as long as there is a spark of life evident it is never too late to transfuse.

6. **Aneurysm of Sinus of Valsalva.**—W. A. Smith reports two cases of aneurysm of the aortic sinuses. The frequency of this pathological condition is difficult to determine from the literature. As Osler says, it is a medicolegal aneurysm encountered in coroners' cases, and for this reason perhaps does not get into medical literature. According to most authorities, the lesion occurs in young adults and in males rather than females, though both the cases reported by the author were in young negresses. Its causes have been attributed to increased blood pressure, atheroma, and especially syphilis. The striking signs in the first case were the loud to-and-fro "saw-like" murmur and thrill, the cardiac hypertrophy, especially of the right ventricle, the precordial pulsations, and the so-called closure sound. This last was absent in the second case. The other symptoms were mainly those of failing compensation. In the second case there was also a perforation in the pulmonary artery. In neither case was the diagnosis made before death, and this accords with all the cases which the author has found reported. In both cases death was due to myocardial degeneration and not to rupture. He, therefore, concludes that though the lesion is comparatively uncommon it cannot be excluded in the face of the finding in a young syphilitic of a saw-like bruit and thrill most marked in the pulmonary area and in the face of a negative roentgenogram.

9. **Thyrotoxic Serum.**—M. M. Portis and I. W. Bach state that nucleoproteins, so-called, of human thyroid glands do not act as specific antigens. The antibodies produced are probably due to the small amount of protein contained in the injected material. The action of the serum, so produced, is not specific for the thyroid gland alone, but has an action similar to that of other organs, especially the liver, kidney, and spleen.

5. Congenital Deficiency of the Radius and a Homologous Condition in the Leg. J. Fraser and H. H. Robarts.

1.. **Changes in the Reaction of the Blood.**—F. Gowland Hopkins states that the study of the equilibrium of the blood has increased very greatly during the past few years by the introduction of microanalytical methods of research. One may now add to the quantitative studies of the morphological elements, and of the subtle bodies concerned in immunity phenomena, accurate determinations of the blood gases. One may also estimate a considerable number of ordinary metabolites as they circulate, even when one is limited to such amounts of blood as may be obtained by pricking the finger. A determination of the concentration of the hydrogen and hydroxyl ions yields an absolute measure of the potency of a solution to produce those chemical effects which are correlated with acidity or alkalinity. The fundamental method of determining the hydrogen ion concentration in a fluid is that of measuring the potential set up when a hydrogen electrode is in contact with the fluid which is being studied. In 1905 Haldane and Priestley advanced the view that under normal circumstances the tension of carbonic acid in the blood is the sole factor which regulates the activity of the respiratory center, and so determines the rate of ventilation through the lungs. Subsequent investigations by Haldane and his colleagues, and by Winterstein, Hasselbalch, and others have led to the generally accepted conclusion that carbonic acid exercises its action, not as a specific hormone, but by virtue of its acidity and that other acids have a similar action. The effects of changes in the blood reaction upon the respiratory mechanisms, nervous and chemical alike, are of the clearest kind. Michaelis and Davidoff found a definite diminution of effective alkalinity in diabetic coma. Kennaway, Pembrey, and Poulton have lately pointed out that the alveolar tension of carbonic acid is the best guide to prognosis and treatment in diabetes. A value below 25 millimeters is, according to these authors, of grave significance, and one below 20 millimeters indicates that coma is imminent.

3. **Neosalvarsan in Active Pulmonary Tuberculosis.**—P. Horton-Smith Hartley states that a short time ago a patient was admitted to his wards at the Brompton

Hospital suffering from extensive pulmonary tuberculosis of an active febrile type, both lungs being diseased, but the patient giving in addition a history of syphilis. On this account treatment with salvarsan was prescribed and with good results, the patient's condition being materially improved on his leaving the hospital. The author tried systematically the effect of neosalvarsan in the treatment of cases of acute and active pulmonary tuberculosis, in which other means had failed to bring the temperature to normal and to arrest the further progress of the disease. The neosalvarsan was given by intravenous injection. Sixteen cases were treated. The cases showed the marked effect upon the temperature which may sometimes be produced by the intravenous injection of neosalvarsan and the improvement which simultaneously results in the patient's general condition. The effect as a rule is not immediate, but shows itself after an interval of two or three days. The temperature then falls possibly to normal, where it may remain. In other cases defervescence is not complete, and a second injection is required. With the fall in the temperature an improvement in the patient's general condition occurs which is sometimes very striking, and with this there is a lessening of the cough and a diminution in the amount of the sputum. As regards physical signs these become somewhat drier, but otherwise no very marked alteration is usually observed. The author concludes that the drug is not a specific but it would appear to have the power of influencing very favorably certain cases of active and febrile tuberculous disease of the lungs which have resisted other treatment, and it merits, therefore, a more extended trial. If administered with care and with due precautions it may be given apparently without risk even in very advanced and grave forms of the disease.

**3. Alterations in the Blood in Hay Fever.**—E. E. Roberts reaches the following conclusions: Hay fever is definitely associated with an alteration in the blood picture, which consists chiefly in a decrease of the hemoglobin content, a polycythemia, and an increase in large mononuclears and esinophiles, together with the presence of vacuolated and degenerated leucocytes and a degree of leucopenia. An increased esinophilia coincides with the symptoms of asthma. An altered but modified blood picture persists during the interval between the seasonal attacks.

**New Methods and Results in Physiology of the Brain.**—Trendelenburg gives a résumé of the methods hitherto used in arriving at results in this subject, and the collateral consequences of experimental inquiry which come under the head of artefacts. His conclusions are as follows: in any operative elimination, done within technical requirements and presumably non-irritating, of the arm region; of the cortex the severe initial functional disabilities represent complete abolition of cortical influence upon the member in question. Subsequent functional improvement represents a special adaptation of the brain to offset in part the symptoms of extirpation the nature of which is far from clear. The future should witness combinations of non-irritating extirpation of portions of cortex and methods of adjustment. The former operation may be repeated at pleasure, varying continually experimental conditions. The worker in human physiology and the psychologist should be stimulated by the results. In regard to the human brain Bárány obtained valuable results from refrigeration of the cerebellum; in so much that Rothmann and Sauerbruch will test the method in the epileptic cortex in the hope of limiting cortical irritability. Piper has tested the ape cortex in this manner. The cooling must be done at repeated intervals.

**The Psyche and Aeronautics.**—Loewy and Placzek have studied especially the mental effects of altitude. Controls exist in the sensations of mountain climbers, but the latter show no peculiarities. The tests were simply mathematical, and the rarefaction of the air in pneumatic cabinets also responded negatively in this regard. Recently Koschel has made an extensive compilation of air passengers' and flyers' sensations with special reference to the feelings. These were compared with articles published long ago on the sensations of balloonists and mountain climbers (with special reference to mountain sickness). Generally speaking but little abnormal could be found objectively, and as already stated the intellect may not show impairment in simple mathematical operations. Nevertheless, the disturbance of the emotional sphere may be marked, and represented by depression, apprehension, and the like. These sensations affect the attention notably and correspondingly the entire intellect. The flyer necessarily suffers at a height above 4,500 meters. His will reactions are slowed. His attention is strained to the limits, and the steering gear is the first to show a break in its continuity. Daring and fearlessness abate in rapid ascent at high levels. The cold of upper air plays a part, and the rigid posture and inability for self-covering intensify this element. The blood, driven inward, causes vertigo and other circulatory disturbances.

## Münchener medizinische Wochenschrift.

*May* 26, 1914.

**The Out-of-Bed Treatment of Pneumonia.**—Widmer first alludes to the experience of recent years in permitting women to sit up at a relatively early date after parturition and laparotomy. The former high mortality from postoperative pneumonia, with the patient lying in bed, has been cut in two by the sitting up management. Of the many disastrous presuppositions in medicine, justifiable from every theoretical standpoint, one of the worst may prove to be the lying down management of pneumonia, at least in certain types of the latter. The sort of bacillus involved is not concerned as a factor. There is undoubtedly a strong psychical element in pneumonia, a mental defect, which of course passes eventually into delirium. The impulse to get out of bed, as an isolated phenomenon, may be owing to a mere disorientation due to his unusual position and surroundings. From an analysis of 85 cases of the author, it was apparent that pneumonia delirium is due neither to fever nor exhaustion. The mental state is simply one with gaps in the normal consciousness. While delirium as a rule implies a total loss of consciousness, pneumonia subjects amid all of their disorientation recognize those around them and in other ways show much retention of consciousness.

In other words, a type seen in various intoxications. This is further known by the incomplete amnesia. Allowing the patient to sit up seems at once to widen the contracted consciousness. He may be dressed for a time, and rocked in a rocking chair; and through a number of such experiences the psyche is aroused. In 50 cases on the days following the initial chill, patients were taken from their beds—forcibly if necessary. Those very ill will necessarily ask to be returned to bed. In most cases on the following morning the patient will feel better and be less feverish; he will also state that he slept well. Author never waits for spontaneous remissions; even in the most violent, as well as the most dubious cases, he practises the out-of-bed treatment. From four to six hours daily of the latter is necessary for keeping the patient fresh. As a result the breathing is slowed and there is actually a slight rise of blood pressure. The author's notion of the rationale of his method seems to be that pneumonia is practically a disease of the nervous centers. His silence on other plans of treatment leaves us in doubt as to his attitude toward competitive plans, like the open-air treatment, venesection, cardiac stimulation, etc.

**Pericolitis.**—Herhold gives a general review of this subject. Pericolitic adhesions correspond in German medicine to such designations, in this country and Great Britain as Jackson's membrane, Lane's kink, etc. In Germany Lauenstein described these formations as far back as 1892. At a later period the supposed adhesions about the cecum and ascending colon, from their constancy and certain modifications became separated in the mind from mere inflammatory adhesions. A fetal or congenital origin was suggested by Lane, Mayo, Cheever, and others. Despite the zeal of Lane in upholding this view, most of the Germans and perhaps other colleagues adhere to the purely inflammatory origin. Eastman has recently shown the occurrence of the same condition in the descending colon. The number of inflammatory affections of the colon which can give rise to these adhesions is large and affects early life in numerous ways. Herhold evidently sees no weight of authority for a belief in non-inflammatory adhesions.

---

### Deutsche medizinische Wochenschrift.

*May 28, 1914.*

**Treatment of Pulmonary Edema.**—Groder sums up this subject as follows: no measures should be spared to excite the heart's action. Venesection is indicated in the plethoric or in those with venous congestion, and derivatives may be used later for further unburdening of the circulation. No attention should be paid to quasi indications for antitussic and expectorant remedies, and in general narcotics are not indicated. The prognosis is always serious, and since the sheet anchor is venesection, minute directions are given for its performance. The cardiac stimulants mentioned above comprise atrophantin by intravenous injection, digitalis derivatives, camphor oil, and caffein salts. Derivatives comprise leeches, cups, mustard plasters, etc.

**Abortive Cures and Neurorecidives in the Modern Treatment of Syphilis.**—Werther sums up his article as follows: Salvarsan is an essential addition to our armamentarium. The rapid disappearance of symptoms under its use excels the action of Hg. Patients with sclerosis and papule are rapidly made safe for the community. Salvarsan is of great value when mercury is inert or not tolerated. If we apply the drug early and at the proper moment we can cure one-half of all primary cases; we can cut short the secondary stage. In tertiary syphilis only the symptoms yield. There are bad results at times which are far short of the results of the disease when contracted. Neurorecidives should *a priori* become less in proportion as more is learned of the disease.

**Larva of Malarial Parasite in Nonmalarial Country.**—Grumann and Bontemps first "enumerate" the countries in Europe in which the existence of malaria is conceded and at the same time countries in which it is presumably nonexistent. This refers to ancient domestic malaria, not to victims of tropical malaria who reach Europe. A case is reported with a negative history of exposure of any sort, which developed in a suburb of Altona. No previous case of the affection had been known here. In his military service patient had once been stationed in a place where infection was possible, but there was no history of any acute or febrile illness. His illness at Altona did not in any way suggest malaria. It might have been termed influenza. The discovery of the larvæ form of the plasmodium made the true diagnosis.

**Isolated Rupture of the Mesentery.**—Saalman mentions the extreme infrequency of this accident as a result of blunt violence applied to the intact abdomen. His patient was a milkman, aged 65, admitted to hospital for supposed internal hemorrhage, due to the impact of a heavy object on the lower abdomen. Considerable delay was involved before the hospital was reached. The patient had in the meantime vomited, but had passed neither feces nor flatus. Signs of internal hemorrhage and threatened collapse. Laparotomy was at once performed under local anesthesia. Upon opening the belly there was a free escape of blood, pure and clotted. In searching for the source a Y-formed laceration was found in the mesentery of the small intestine. The patient ultimately recovered. The cause of these tears is not understood in cases of multiple violence, and *a fortiori* when occurring alone. Many plausible mechanical theories have been advanced in explanation. The author, going back to 1845, can find but 26 of these isolated cases, 9 of which were cured by operation. Like all other uncommon accidents, however, this one occurs with greater frequency than is commonly believed. For example, certain cases regarded as lumbago, following blunt violence to the abdomen, may belong here.

---

**Resection of the Pharynx for Carcinoma.**—E. B. Waggett reports a case of a woman aged 47. Operation in February, 1913. The flap was cut with the intention of removing the larynx with the pharynx, consequently no skin was available for a plastic operation. The whole of the hypopharynx was removed with the exception of a strip of the right lateral wall ½ in. broad. The case illustrates the spontaneous adaptability of the parts, the absence of cicatricial stricture, and the functional recovery of the left arytenoideus posticus muscle.—*Proceedings of the Royal Society of Medicine.*

**Resection of Larynx and Pharynx.**—E. B. Waggett reports a case of a man aged 65 years in whom there was an extensive carcinoma of the pharynx, laryngeal vestibule and tongue, commencing in the left pyriform fossa. Palliative measures were dictated by dyspnea and very severe dysphagia. At the patient's request a radical operation was performed in November. A strip of the right pharyngeal wall ½ inch broad, was retained. The case illustrates the spontaneous adaptability of the parts still in process of healing. Facial palsy was produced by a very extensive gland operation with resection of the sternomastoid.—*Proceedings of the Royal Society of Medicine.*

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### HYALINE CASTS.

When Osler proclaimed that in his opinion a small number of hyaline casts in the urine of persons over fifty years of age were in reality nothing more than a few "gray hairs" and carried little or no significance and, further, that life insurance companies were unjustly rejecting many risks on account of hyaline casts, he was near the truth in so far as he could judge from the standpoint of the general practitioner. Cabot (Physical Diagnosis, 1910) also states that a few hyaline casts in the urine of persons over fifty years of age have no known clinical significance and may be considered physiological.

If a few hyaline casts constituted the only impairment in some of their patients, Osler and Cabot would have been justified in reassuring them that the underlying condition was of little importance, provided they followed the good advice which would surely be given, but we may safely assume that Osler and Cabot would have kept them under observation as long as the danger signals persisted. Osler failed to realize, apparently, that the life insurance point of view differed quite materially from that which a general practitioner could entertain. When a person applies for insurance, the examination is necessarily limited to a short space of time and there is little opportunity for keeping him under observation. Nevertheless, a far reaching decision must be given at once, and if the policy is issued, it cannot be recalled if serious trouble ensues later, nor will the mistake be concealed and forgotten under an ivy-covered mound.

Insurance medical men are quite alive to the fact that a very few hyaline casts may be of no importance, but it is not always a simple matter to dispose of these cases by the examination of a few specimens of urine. It seems almost inconsistent for Cabot, after voicing the statement quoted above, to say later, that hyaline and granular casts are found in any type of nephritis, sometimes quite few in number and apparently absent at other times, as well as in many other conditions. Moreover, it is unnecessary to say that disease of the kidneys is much more common in persons he refers to, those over fifty years of age, and that it may require a long observation to determine whether the casts are due to nephritis, nervous tension, ordinary renal congestion, fatigue, etc. Even transitory hyalines have their meaning as they are not normal constituents of the urine, but the process responsible for their presence is insignificant in many instances and one that will not lead up to a more serious disturbance. On the other hand, it would seem, according to Osler, that they appear during the slightest degree of mischief or the incipiency of graver troubles. Hyaline casts probably originate in three ways: 1. From the epithelium itself, shed and altered; 2. From the coagulation of transuded plasma; 3. As a separation of a part of the tubular epithelium. In either case, there is a local disturbance of the normal conditions where they originate, but, fortunately, even when the cells of the kidneys are shed off in numbers as casts, it should be remembered that the kidney epithelium can be regenerated to a moderate extent over small denuded areas. The exact point in the nephritic process at which albuminuria and casts appear in the urine is not known.

It is generally understood then, that while hyaline and other casts are often a manifestation of some process in the kidney that is of small importance, they may prove to be danger signals of serious trouble. When, then, may their presence be ignored? This question can only be answered from a life insurance point of view in an unsatisfactory way, and the answers will vary widely if the opinions of different medical directors are sought.

An application for a large amount was written recently, the insurance to be distributed among twelve or thirteen companies. The case gave an opportunity for learning something about the attitude of different companies in regard to hyaline casts. Some companies accepted the risk without further investigation when no more than two or three casts were found in two slides from one specimen. Another company paid no attention to two or three casts at the most found on one or two slides, as long as there was no blemish on the case in other respects. Another relied upon the amount of solids in the urine when casts were found and no other blemish. The risk was acceptable to all the companies represented, notwithstanding the hyaline casts, with the exception of one. This company was more inquisitive and had six consecutive specimens examined with the following results: hyaline casts in small numbers were found in three specimens, granular casts in one, scattered red blood cells in two, a specific gravity in one so low that the examination was omitted. Indican in large amounts were found in the five specimens which were examined, and may have signified that the casts were primarily due to intestinal disturbance and to nervous tension which the applicant had been subjected to some time before the examination. Further observation was impossible on account of circumstances, and the applicant was postponed, though no direct conclusion could be formed as to the nature of the process causing the presence of these bodies. The point we wish to emphasize is that the more thorough investigation was necessary.

We believe that the presence of a few hyaline casts should be treated in the same way as albuminuria. If they persist the application should be postponed until the inspection of several specimens at some future time has demonstrated the fact that the hyalines are no longer present. As long as they persist in the urine there must be some uncertainty as to whether the process through which they are formed is serious or inconsequential, and this opinion holds even though the condition of the applicant otherwise is satisfactory.

A point to be considered is the special or individual ability of the microscopist to find casts. A decided difference may usually be noticed among several observers, unquestionably competent in other medical matters. An eye with a specially broad scope of vision is demanded so that each field in the microscope can be taken in comprehensively and quickly. Many eyes are not constituted this way and hyaline casts, often so difficult to discern, may be overlooked. The difference is due to physical, not mental, endowments, for those who can not discover casts so readily may be the best of judges as to whether a certain body, when found, is a renal cast, cylindroid, or some other body. As a matter of actual practice, it is not uncommon for some microscopist to find hyaline casts which have escaped the observation of another observer.

# Book Reviews.

KURZE PRAKTISCHE ANLEITUNG ZUR ERKENNUNG ALLER FORMEN DES KOPFSCHMERZES. Von Oberstabsarzt Dr. LOBEDANK, Hagenau i. E. Price 2 marks. Würzburg. Curt Kabitzsch, 1914.

THERE can be no question that headaches constitute the most common complaints of humanity and that their study as a symptom is of extreme interest to every practitioner. In this volume of 71 pages the author presents an introduction to the methods of examination that should be employed in studying the significance of headaches. In synoptic form he discusses the various points in the personal history that bear upon the diagnosis of the underlying cause of headaches and then gives in minute detail the steps in the examination of the patient, indicating the importance of each sign. In this manner the subject is studied with unusual thoroughness. There then follows a number of diagnostic tables comparing the headache due to various conditions, such as brain tumor, brain abscess, meningitis, migraine, hysteria, arteriosclerosis, anemia, rheumatism, disease of the teeth, disease of the ear, various forms of asthenopia, glaucoma, syphillis, dyspepsia, and renal disease. This book serves a most useful purpose as a diagnostic guide to the general practitioner.

KLINISCHE BEITRÄGE, BEITRÄGE ZUR KLINIK DER INFEKTIONSKRANKHEITEN UND ZUR IMMUNITÄTSFORSCHUNG (mit Ausschluss der Tuberkulose). Herausgegeben von Professor Dr. L. BRAUER, ärztlichen Direktor des Allgemeinen Krankenhauses Hamburg-Eppendorf. Redaktion: Für die Originale: Dr. H. SCHOTTMÜLLER, Dr. H. MUCH (Klinischer und bakteriologisher Teil) (Immunitätswissenschaftlicher Teil) beide am Allgemeinen Krankenhaus Hamburg-Eppendorf. Für die Ergebnisse: Professor Dr. H. LUDKE in Würzburg. 11 Band, 2 Heft. Price 6 marks. Würzburg: Curt Kabitzsch, 1914.

THE second number of the second volume of this valuable publication contains the following contributions: "Abortive Scarlet Fever in the First Few Months of Life," by C. Levi; "Meningococcus Serum," by P. Aaser; "The Theory and Practice of Vaccine Treatment," by L. Detre; "The Influence on Infectious Diseases, Particularly Puerperal Infection by Means of Salvarsan or Neosolvarsan," by Dr. Orlovius. This volume also contains the following reviews: "Puerperal Infection from the Medicolegal Viewpoint," by Döllner; "Lymphogranulomatosis, Particularly from Its Etiological Viewpoint," by G. Herxheimer, and the "Serodiagnosis of Syphilis by Means of the Precipitation Methods," by O. Porges.

SPEZIELLE PATHOLOGIE UND THERAPIE INNERER KRANKHEITEN. In 10 Banden. Herausgegeben von FRIEDRICH KRAUS und THEODOR BRUGSCH in Berlin. Lieferung 1-4 (1 Band, 1 Teil, Seite 1,238, mit 5 farbigen und 4 schwarzen Tafeln). Inhalt: Diabetes melitus inkl. Laevulosurie, Heptosurie, Glykuronsäureausscheidung. Nicht diabetische Glykosurien (Pentosurie), von Prof. Dr. AD. MAGNUS-LEVY, dirig. Arzt an der Abteilung für innere Krankheiten des Krankenhauses am Friedichshain in Berlin. Intermediare Stoffwechselstörungen; (a) Aminosäurendiathese; (b) Physiologie und Pathologie der Wasserausscheidung. Diabetes insipidus; (c) Kachexien; von Prof. Dr. UMBER, dirig. Arzt an der Abteilung für innere Krankheiten des Krankenhauses Westend in Berlin, mit 2 Textabbildungen und 1 Tafel. GICHT von Prof. Dr. TH. BRUGSCH, 1 Assistent an der II. medizinischen Universitätsklinik in Berlin. Mit 10 Textabbildungen und 8 Tafeln. Lieferung 5-8 (11 Band, 1 Hälfte, Seite 1,240, mit 3 farbigen Tafeln) Preis jeder Lieferung 2 M. = 2K 40h. Inhalt; Infektion und Immunität; immumodiagnostik und therapie; von Prof. Dr. R. KRAUS, Direktor des staatlichen bakteriologischen und serotherapeutischen Institutes in Buenos Aires. Typhus und paratyphus, von Prof. Dr. G. JÜRGENS, Berlin-Neukölln. Mit 3 Farbigen Tafeln. Berlin: Urban & Schwarzenberg. New York: Rebman Company, 1914.

THE scope of this work, which is to appear in ten volumes, includes a presentation of the subjects of special pathology and therapy in internal medicine. The first two installments comprise parts one to four, or the first section of the first volume, and parts five to eight, or the first section of the second volume. The first installment contains the following articles: Diabetes mellitus, including levulosuria, heptosuria, the excretion of glycuronic acid and the non-diabetic glycosurias (pentosuria). This article is by A. Magnus Levy. The second article, which is written by F. Umber, deals with the disturbances of the intermediate metabolism, and includes the following: The amino-acid diathesis, the physiology and pathology of the excretion of water (diabetes insipidus), and the cachexias. The concluding article in this installment deals with the subject of gout, which is presented by T. Brugsch. The second installment contains the following articles: Infection and immunity; immunodiagnosis and therapy, by R. Krauss; and typhoid and paratyphoid fevers, by G. Jürgens. All of these articles are written with the thoroughness characteristic of German writers, and represent the last word on the subject. They are profusely illustrated with the aid of half-tone cuts and full-page colored plates. There is one colored plate illustrating a case of ochronosis of the ear cartilage in alcaptonuria. The subject of infection and immunity is presented in great detail. For instance, the preparation of diphtheria antitoxin is fully described with the aid of illustrations. Every step in the process, from the injection of the horses to the filling of the syringe containers is given. This work promises to be a monumental one.

CHRONIC COLITIS: Its Causation, Diagnosis, and Treatment. By GEORGE HERSCHELL, M.D., late Senior Physician to the Kensington General Hospital, and ADOLPHE ABRAHAMS, M.D., Medical Registrar to the London Temperance Hospital. Price $2.00 net. New York: Longmans, Green & Co., 1914.

ACCORDING to the authors, this is the first English manual to appear on this subject, and it is certainly a most welcome one. This whole subject, together with that of constipation, which we here learn may be a symptom of colitis, has been in a most chaotic condition, and it is a distinct pleasure to find a work which considers it coolly and dispassionately. The first portion of the book is devoted to causation and diagnosis and contains the details of a large number of laboratory tests. The second part, which amounts to more than half the book, is given over to treatment. The removal of the cause is insisted upon and great attention given to the subject of diet. This includes a number of recipes which should prove useful. The work is very complete and in it the practitioner "may find a convenient work of reference in his diagnosis and treatment of one of the most chronic conditions it is possible for him to encounter."

TROPICAL MEDICINE AND HYGIENE. By C. W. DANIELS, M.D., Cantab; F.R.C.P., London; Lecturer on Tropical Diseases, London School of Tropical Medicine; London Hospital; London Royal Free School of Medicine for Women; Physician, Albert Dock Hospital, Seamen's Hospital Society; formerly Director London School of Tropical Medicine; Director Institute for Medical Research Federated Malay States; Member of Royal Society Malaria Commission, and in the British Guiana and Fiji Colonial Medical Service. With a chapter on snakes. By O. ALCOCK, C.I.E., M.D., F.R.S., Lt.-Col. I. M. S. (retired). In three parts, with colored and other illustrations. Part II. Diseases Due to the Metazoa. Second Edition. Price $3.00 net. New York: William Wood & Company, 1914.

IT was only three years ago that Dr. Daniels' work on tropical medicine and hygiene first made its appearance. That the work filled a much needed want has been proven by the comparative rapidity with which the first edition has run out. The study and treatment of tropical diseases and their prevention bulk larger every year, for white men are invading and inhabiting tropical regions continually and in greater numbers. The aim of the authors in the book before us and in the other volumes of the series has been to provide a concise description of the diseases due to various kinds of parasites, and of the manner in which they spread and the rationale of the preventive measures advocated. The metazoa are dealt with thoroughly and the numerous advances made in our knowledge of these diseases are set forth as far as possible. This volume then provides a ready and authoritative handbook concerning the diseases due to the metazoa and may be recommended as such to medical practitioners and students. The book is copiously and graphically illustrated.

# Society Reports.

## AMERICAN MEDICAL ASSOCIATION.

*Sixty-fifth Annual Meeting, Held in Atlantic City, June 22, 23, 24, 25, and 26, 1914.*

(Special Report to the MEDICAL RECORD.)

HOUSE OF DELEGATES.

*Monday, June 22—First Day.*

THE PRESIDENT, DR. JOHN A. WITHERSPOON OF NASHVILLE, TENN., IN THE CHAIR.

**President's Address.**—Dr. JOHN A. WITHERSPOON of Nashville, Tenn., begged the indulgence of the House, in that owing to ill health, he had been unable to prepare an address. He said, however, that he wished to express his appreciation of the great honor conferred upon him; it had been one of the greatest pleasures of his life to have presided over a group of men so sincere and earnest in their desire to conduct their work along lines good and noble and for the welfare of humanity. He had never met a body of men so eager to do the right thing. The Association was to be congratulated on having such a body of men to perform the functions of the House of Delegates.

**Report of the Secretary.**—Dr. ALEXANDER R. CRAIG of Chicago presented this report. He stated that on May 1, 1914, the Fellowship of the Association was 37,319; since that time 2,850 names had been deducted from the Fellowship roll for various reasons, while there had been added 5,990 names, making the Fellowship on May 1, 1914, 41,029, a net increase for the year of 3,116. At the Minneapolis session, the House of Delegates adopted a recommendation endorsing the formation of a section to be entitled the Gastro-Enterologic and Proctologic Section of the American Medical Association under the conditions that the American Gastro-Enterological Society and the American Proctologic Society be disbanded and hold their meetings jointly as a section of the American Medical Association and it was recommended that the number of papers to be read at any annual meeting be limited to fifteen. This section had not been formed as the conditions had not been met. At a conference of the secretaries of the sections at the Association headquarters in Chicago, November 6, 1913, the advisability of dividing the sections into two groups—general sections and special sections—was discussed. The former were to include Practice of Medicine, Surgery, Pharmacology and Therapeutics, Pathology and Physiology, and Preventive Medicine and Public Health; the second group was to comprise the remaining sections. It was also suggested that the by-laws be so amended that at any annual session of the Scientific Assembly a Fellow should be privileged to present one paper before a general section and a second paper before a special section. It was requested that the House consider these suggestions. In this report were presented the resolutions of the Medical Society of the State of New York urging the House of Delegates to use its influence to have the National Food and Drug Act amended to read as follows:

"That for the purpose of this act an article should be deemed to be adulterated: In case of drugs: If, when a drug was sold under or by a name recognized in the United State Pharmacopœia or National Formulary, it differed from the standard of strength, quality, or purity, as determined by the test laid down in the United States Pharmacopœia or National Formulary official at the time of investigation; or, if the strength or purity fell below the professed standard or quality under which it was sold."

The resolutions of the Medical Society of the State of New York pointing out the dangers of the present laxity in the admission of insane and defective immigrants and the need of federal legislations for the more careful mental examination of immigrants was called to the attention of the House. This report also included resolutions relative to arrangements for the proposed Medical Congress to be held in San Francisco in 1915.

**Report of the Board of Trustees.**—Dr. W. T. COUNCILMAN, Boston, Mass., submitted this report. He stated that the past year had been distinguished by no unusual events in the Association; all the forms of activity by which it served the medical profession and the public had been marked by successful effort. All Fellows and members of the Association might be proud of the demonstration which its yearly reports gave that the ideal of service to man was dominant in the minds of the medical profession of this country. In the pursuance of such ordeals it was natural that animosities should be excited, for the efforts of the Association opposed the interests of those who preyed on humanity.

Of all the activities of the American Medical Association, none had aroused more antagonism than those connected with the work of the Council on Pharmacy and Chemistry. The publicity department of their pharmaceutical manufacturers and the journals which depended on advertising for their existence were ever ready to find fault with, to condemn, and to misrepresent the Council. Nevertheless, it was gratifying to note that there was a gradually increasing appreciation of its aims and objects and what it was accomplishing. The medical profession was slowly but surely appreciating the value of the work and the manufacturers, also, both foreign and domestic, were recognizing that the reports of the Council were authoritative and final, and must be respected.

The work of the committee on a selected list of drugs had resulted in the publication of a book called "Useful Drugs." This had already been adopted as a textbook by a number of the best schools; its adoption had been considered by State licensing boards, and there was every indication that this enterprise would have a most beneficial effect. Among other constructive work by the Council was that conducted through its Committee of Therapeutic Research. Eventually this work would result in bringing back into use well known drugs—non-proprietary preparations that had been swept aside by the commercial propaganda for proprietaries. It was to be regretted that more physicians did not take sufficient interest in the Council's work and its reports.

Not the least of the enterprises of the Association was the work done in their chemical laboratory. An idea of what was done here could be only in a slight degree obtained from the material that was published in *The Journal* from week to week. The unpublished work included examinations made for the Council on Pharmacy and Chemistry, on the results of which often depended the action of the Council; also, a large amount of work was done in connection with their propaganda department in the investigation of "patent medicines," much of which was never published. Still further, considerable chemical work was done at the request of individual physicians.

The Council on Pharmacy and Chemistry was created for the purpose of enlightening the profession concerning the so-called "ethical proprietary medicines," but it was soon found that there was no dividing line between such medicines and the ordinary patent medicines sold direct to the public. There gradually developed a demand from the profession and later from the public for information regarding proprietary medicines. The attempt to meet this demand gradually broadened out until it became necessary to create a new department—the Propaganda Department.

One of the most encouraging features of the work done by the Propaganda Department was the interest it seemed to have awakened on the part of the lay magazines and newspapers in censoring the advertisements of a medical or quasi-medical nature that appeared in their pages. There was a very evident desire on the part of the better class of lay publications to exclude from their pages fraudulent medical advertisements. A number of such publications were constantly referring to the Propaganda Department for information regarding the different preparations or devices whose manufacturers sought advertising space. Not a few newspapers were submitting medical advertising copy to the Propaganda Department.

This state of affairs contrasted strangely with the attitude of the majority of the so-called independent medical journals. It was but rarely that inquiries came from these publications regarding the character of the advertisements of medicinal products they were carrying. More than once the Propaganda Department had had to advise newspapers against carrying advertisements of certain products that were at the same time being advertised in medical journals—and the advice had been taken. It was an unfortunate fact that the effect of the work against frauds in medicine was more evident in lay than in medical journals.

In speaking of the various publications of the Association it was noted that while the *Archives of Internal*

*Medicine* and the *American Journal of Diseases of Children* had been conducted at a slight loss, there was every reason to believe that it would be counterbalanced by an equivalent gain another year. The "American Medical Directory," just off the press, was a great improvement over its predecessors. In addition to the features of the former editions, there was a list of the members of various national and special societies, and the specialty of those who, while not members of special societies, have designated their desire to be classed as specializing in certain lines. By the aid of symbols and abbreviations a great deal of information had been included in a small space.

In presenting the financial report of the Association the speaker stated that the profits of the Association for the year ending December 31, 1913, were very near the vanishing point, owing to the fact that the general Association expenses had been practically doubled during the past five years. In connection with this slight surplus for the fiscal year it was pointed out that the recent social medical legislation in England had reduced the large surplus of the British Medical Association to an equally large deficit. The American Medical Association should have a reserve fund of at least $300,000. At present over 75 per cent. of the expenditure of the Association was for altruistic purposes. This was made possible by the profits of the *Journal*.

### Reports of Standing Committees.

**Report of the Judicial Council.**—Dr. Alexander Lambert presented this report. He stated that the appeal of the Home for Widows and Orphans of Physicians, which had appealed for funds, had been thoroughly considered, and while the home was a most deserving endeavor to aid the unfortunate, the funds of the association were devoted to raising the standards of medical education, enlightening the public on matters of public hygiene and public health, and in disseminating medical knowledge, and as it would require a large outlay of money to enter on such a philanthropy the judicial council felt that it should not be undertaken. A recommendation to this effect was, therefore, presented. The judicial council recommended that the by-laws relating to the judicial council be amended so as to extend the power of this council making their decisions final in all cases which arose between constituent State associations and one of its component county societies; between component county societies of the same constituent State association and the component society to which said member belonged or between members of different component societies of the same constituent State association. They asked further that the judicial council might at its discretion investigate general professional conditions and all matters pertaining to the relations of physicians to one another and to the public, and should make such recommendations to the house of delegates and the constituent associations as it deemed necessary These changes would define more clearly the functions of the judicial council. It had been the object of the house of delegates to make the judicial council amount in reality to a dignified court. At present it had only original jurisdiction in cases in which the American Medical Association or one of its constituent associations was a party. There was no appellate function which it could exercise. This was not intended as an endeavor on the part of the judicial council to gain more power, but this appellate function had been found to be necessary in the control of the fellowship of the association. After setting forth all its reasons the judicial council asked appellate jurisdiction in the cases mentioned above. The council also recommended that to the principles of ethics of this association be added the following:

"The council also recommends that to section 4, chapter III, of the by-laws, there be added:

" 'Fellowship shall be further conditioned on a fellow conducting himself in accordance with this constitution and by-laws and principles of medical ethics of this association.'

"In the opinion of the judicial council the time is ripe for the house of delegates to proclaim that fellowship in the American Medical Association is a right that must be protected. The section here recommended is not an endeavor to make the principles of ethics a code of rules and punishments. It is simply a demand that the rules of decency and honorable action shall be observed by the fellows. The principles of ethics of the American Medical Association are only those broad rules of conduct which are naturally and spontaneously followed by honorable physicians in their dealings with their fellow men. It may be said of these rules, as of all duties, it is no credit to perform them; it is personally discreditable to leave them unperformed. They are analogous to the standards of the army and the navy which require that a man shall conduct himself as an officer and a gentleman."

The judicial council believed that the functions of the different branches of the American Medical Association should be carefully preserved, and to this end a national council should not deal directly with a county society excepting through the constituent State society. After defining the position of the principles of ethics relative to advertising on the part of physicians and calling attention to the popular write-ups of scientific subjects for the daily press, which were practically advertisements, the council recommended that State and county societies should appoint publicity committees to cooperate with the editors of the public press in order to devise a plan by which articles and interviews on medical topics by members of the society, published in the daily papers, should be truthfully and correctly reported. Such a committee acted as a means by which without mentioning names and without exploitation of any individual, the daily press could obtain accurate knowledge of all matters in medicine which it desired to publish. The judicial council, therefore, presented the following resolution:

"*Resolved*, That it is the sense of the house of delegates of the American Medical Association that each county society should constitute a publicity committee whose duties shall be to give to the daily press accurate information on all medical matters of interest to the public; that this shall be freely given without the mentioning of names or from whence the information comes, and that this committee shall further act in an advisory capacity to all physicians of its society in questions relating to publications other than in the medical press. And be it further

"*Resolved*, That the secretary of the American Medical Association be instructed to forward this resolution, with the reasons calling it forth, to the secretary of each constituent State association, with the request that it be transmitted to each component society of that constituent society."

**Report of the Council on Medical Education.**—Dr. Arthur Dean Bevan of Chicago submitted this report, in which he stated that this council had now completed the tenth year of persistent and steady efforts in establishing better educational standards in medical education and the results had more than fulfilled the highest hopes of those who had urged the formation of this council. Instead of 160 medical colleges they now had 100. Instead of only four medical colleges holding fairly high entrance standards there were now 82 colleges which, after October 1, 1914, would require for admission one or more years of collegiate work in addition to a standard four years high school course. Where ten years ago there were only a few medical colleges which possessed adequate clinical facilities now there were many which had control of at least fairly adequate clinical material. Above all, instead of only a few medical colleges which were training their students in an atmosphere pervaded by the hopefulness of medical research, now at least some effective research was being conducted in a large number of colleges. The improvements in the past ten years had been so marked and the standard of preliminary education had been fixed at a point so reasonably high that it now seemed desirable to go more slowly and to allow time for a careful readjustment under the new order. It was desirable at this time to pay a deserved tribute to the medical schools of the South for the remarkable manner in which the problems of medical education had been grappled with. They had still to deal with a very large problem, that of preliminary education, but even this was being firmly and admirably met. The most serious problems of medical education were no longer to be found in the South, but rather in some of the large cities of the East and the North. The licensing boards of 31 States were now using their legal powers to refuse recognition to the low grade medical college, leaving 18 boards which did not have legal authority to do so, or which were not utilizing that power. In four States—New York, Pennsylvania, Texas, and Georgia—single medical examining boards had been secured. The present classification of medical colleges was based on ten years' study of medical education, including four inspections of practically all the medical colleges. Twenty-eight States were now supporting medical edu-

cation and in fifteen of these States the only medical school in the State was the medical department of the State university. There were only ten States having medical colleges in which the State did not contribute directly to the support of medical education. The report emphasized the duty of the State to support medical education in virtue of the fact that medicine was not only a function of the State, but one of the most important functions of the State. There was need of a reorganization of the clinical departments of our medical schools whereby clinical teaching might be placed on a more satisfactory basis. Toward this end a committee of ten prominent clinicians had been appointed who would bring in a report at the next meeting of the council. Investigation showed that at the present time there were enough good hospitals in this country to provide internship for all graduates of medical schools and the sentiment in all the better medical schools favored the adoption by State boards of a requirement that before a candidate was eligible for a license he must serve such an internship. A careful study of graduate instruction had been started by a special committee of the council. The development of graduate medical education was one of the immediate and pressing needs. There was an abundance of clinical material in our large cities which should be developed so that physicians might take graduate courses without going abroad. The development of graduate medical education was the next great step in the provision for a better trained medical profession in this country. The work of the past gave assurance that the future work of this council would become more and more effective in providing the public with well-trained physicians.

**Report of Committee on Red Cross Medical Work.**—Dr. GEORGE M. KOBER of Washington, D. C., submitted this report. He stated that this committee had been created for the purpose of making arrangements for medical relief in times of disaster. In February, 1913, a communication was addressed to the secretaries of 1,150 component societies affiliated with the American Medical Association and pointed out that the object in view could best be attained by the creation of committees on Red Cross medical work in every county medical society. This committee believed that after securing the appointments of such committees the Red Cross would be assured of the services of qualified medical men and that it would not be a difficult matter to effect concerted action between the various activities of the Red Cross in any community. Fifty-seven county societies in twenty-four States had appointed committees up to May 1, 1913. Up to May 1, 1914, 214 county medical societies located in 37 States, had appointed committees on Red Cross medical work. The committee urged prompt action on the part of all county medical societies, as the services of such committees might be required at any time.

**Report of Committee on Scientific Exhibition.**—Dr. FRANK WYNN of Indianapolis, Ind., submitted this report in which he asked for the usual appropriation of $1,000 for the exhibit. He stated that while the exhibit dealt with a wide variety of subjects its distinctive feature was the practical bearing of the exhibits on medicine and surgery. The *x*-ray exhibits and the work on the cancer problem were especially interesting and suggestive. The research exhibits were along many lines, such as the experimental induction of pneumonia, the experimental production of hydronephritis, lateral blood vessels anastomosis in arteriovenous aneurysm, the effect of pituitary extract on the growth and development of dogs. The exhibit was in marked contrast to the museum-like exhibits of former times. The bulky heterogeneous exhibit had given place to the serial exhibit which developed a single topic more fully and from the educational standpoint was more useful.

**Report of Committee on Nomenclature and Classification of Diseases.**—Dr. CRESSY L. WILBUR of Washington, D. C., presented this report. He stated that as reported last year this committee had been in correspondence with the Committee of the Royal College of Physicians of London appointed to prepare the fourth decennial revision of the English nomenclature of diseases, but as this report was not completed they wished to delay their report as there would be great advantages in cooperation to the end that the nomenclature of diseases employed in the English-speaking world might be in close accord, hence it seemed wiser to defer the preparation of the final report for the present. In this connection it was of interest to state that the second edition of the "Physician's Pocket Reference to the International Causes of Death" had been sent by the Bureau of Census to all physicians in the United States. The booklet contained a list of undesirable terms, which were thus brought forcibly to the notice of physicians throughout the country, with the recommendation that their use be discontinued.

**Report of Committee on Anesthesia.**—Dr. JAMES T. GWATHMEY of New York submitted this report. He stated that last year it had been suggested that the work of this committee be conducted along the lines adopted by the Council on Pharmacy and Chemistry, namely, that the committee on anesthesia should undertake the preparation of a comprehensive and critical review of the entire subject of anesthesia, and that the information therein should be made easily accessible to all physicians either by publication in the journal of the association or in pamphlet form. The House of Delegates approved of this course and the committee now had the pleasure of reporting that a good beginning had been made in carrying out this plan. They had sought to lay special emphasis on the fundamental scientific principles of anesthesia. The titles and authors of the various articles of the review were as follows: "Intratracheal Insufflation," Samuel J. Meltzer; "The Theory of Anesthesia," Evarts Graham; "Anoci-Association," George Crile; "The Present Status of the Acapnial Theory of Shock," Yandell Henderson; "Present Day Methods of General Anesthesia," James T. Gwathmey; "Rectal Anesthesia by the Use of Mixtures of Oil and Ether," James T. Gwathmey; "Present-Day Methods of Local Anesthesia," James Mitchell; "Recent Studies of the Physiology of Anesthesia," W. D. Gatch.

**Report of Council on Health and Public Instruction.**—Dr. HENRY B. FAVILL of Chicago presented this report in which he stated that this council was created four years ago as the representative of the association on all legislative, economic, and social questions, and as the medium of communication between the association and the medical profession on the one hand and other professional and philanthropic organizations on the other hand. The plans of the council had now developed to a point where a comprehensive program could be outlined, and the study of the present situation led to the conclusion that a rational program must include the following three lines of action:

1. A thorough investigation of present public health conditions in the United States, with a view to securing more accurate information on all phases of the public health problem than was now available.

2. Education of the public by every possible means in order that the people might understand the enormous advances in scientific medical knowledge during the last generation and the possibility of utilizing such knowledge in the prevention of disease, the reduction of the death rate, and the prolongation of human life.

3. The crystallizing of such educated public sentiment in necessary public health laws, regulations and ordinances, which would render possible a conservation of human life commensurate with our advancing knowledge and which would render such laws effective through the only force available in this country, namely, educated and enlightened public opinion.

The first of these required an investigation of the health activities of the Federal government in all its departments, and of State and municipal health activities, and also of the work of voluntary health organizations. The Press Bureau established two years ago had been maintained throughout the year and the number of newspapers manifesting an active interest in public health matters was constantly increasing. To increase the usefulness and scope of the Press Bulletin the secretary had during the last year organized an unofficial staff of editorial contributors comprising about forty members of the association who contributed short articles suitable for the bulletin. This report also included a summary of the work of the Speaker's Bureau, and that of the Bureau on Literature. In connection with the work of the latter bureau a plan had been presented for a series of twelve public health pamphlets as a nucleus for a standard series to be issued during the coming year. Attention was also called to pamphlets on medicolegal subjects, sex hygiene, and cancer. Another plan of the council was for the development of a Lantern Slide Loan Bureau, by which sets of stereopticon slides prepared by recognized authorities and accompanied by a skeleton lecture could be loaned to officers and members of county so-

cieties, physicians, and others interested in educating the public on public health topics. They had now completed a digest of all Supreme Court decisions on medical practice acts that included all decisions by American courts of last resort on questions affecting the regulation of the practice of medicine by the State. This material would be of immense value to State boards of examiners and their legal advisors; it would be issued during the coming year. In the field of national health legislation nothing had been done during the last year owing to the other problems occupying the present regular session of Congress. The sentiment in favor of proper governmental regulation of health matters was growing both in the public and the legislative mind. It was safe to say that in view of the triumphant demonstration of modern sanitary methods in the Canal Zone, Cuba, and Vera Cruz, and the practical abolition of typhoid fever in the United States Army, that when the subject of a national department of health next came before the American people it would receive greater support than it had at any previous time. When that time came this association would be able to supply accurate knowledge of the situation and a carefully worked out feasible plan for organizing a national department of health. The most direct national legislation during the past year were the socalled Harrison bills for the regulation of the manufacture and traffic in habit-forming drugs. Representatives of this council participated in the conferences and hearings on this bill and helped to frame its provisions. As it passed the House it provided that any person who "produced, imported, manufactured, compounded, dealt in, dispensed, sold, distributed, or gave away opium or coca-leaves or any compound manufactured salt derivative or preparation thereof" should register with the internal revenue collector of his district. A provision in the second section specified that nothing contained in the section should apply to the dispensing or distribution of any of these drugs to a patient by a physician. Several amendments rather burdensome to the physician had been added, but it was believed that these would not be pushed. The association should lend its support to any measure that offered any prospect of controlling the traffic in these dangerous drugs. This report also contained a review of the legislation enacted in the various states during the past year. One of the most effective means of putting the association in a favorable light before the people had been the plan of furnishing speakers for the churches on the Sunday preceding the annual meeting of the association. This year, on account of the few pulpits to be filled in Atlantic City, the privilege had been asked of filling the pulpits of the churches of Philadelphia. This plan had been endorsed by the officers of the Philadelphia County Medical Society and speakers were provided for fifty churches. Attention was called to the work of the various subcommittees of the council on health and public instruction. These included the committee on resuscitation from Mine Gases, committee on the protection of medical research, committee on conservation of vision, committee on public education among women, committee on cancer, committee to confer with the national educational association, committee on expert testimony. Special attention was called to the report of the committee on the conservation of vision and that of the committee on cooperation with the national education association, and public education among women. These committees had shown a tendency to develop definite and limited fields and to the accomplishment of actual constructive work. The committee on conservation of vision had prepared weekly nontechnical articles for the Press Bulletin on such subjects as "The Eyes and the Movies," "Face Powder and the Eyes," "Illumination in Homes, Offices, Schools, Shops, etc." This committee had planned a lecture campaign in almost every State to create a sentiment in favor of the conservation of vision. This lecture campaign had on the whole been successful. The work of the committee on public health education among women had aimed to connect the work of the American Medical Association with the women's clubs of the country and thus draw together existing forces so that cooperation might be secured. They had done excellent work in the better babies movement, the prevention of infant mortality, and subjects of hygiene of special importance to women.

**Report of Subcommittee on Uniform Membership.**—Dr. THOMAS MCDAVITT of St. Paul, Minn., presented this report, in which he stated that a conference of the State secretaries was called at the headquarters of the American Medical Association on February 25, 1914, at which time the reports from the various secretaries showed clearly that practical uniformity in method and results with consequent uniformity in the necessary details was gradually becoming prevalent throughout the organization. All of the executive officers of the different parts of the associations had recognized the importance of sufficient uniformity to reduce correspondence and "red tape" on membership matters to a minimum. The general adoption of the calendar year as the fiscal year of the State societies had alone been of great service in bringing about a better condition in membership regulation. The organization was still far from perfect in its mechanical details. Improvement would come as the executive officers of the various parts of the organization came to recognize more and more the need of simple, automatic, and easily handled methods for the regulation of membership.

**Report of Committee to Consider Mode of Commemoration of the Completion of the Panama Canal.**—Dr. ALBERT L. BRITTIN of Athens, Ill., presented this report, in which the committee recommended that a monument be erected, to be financed by the American Medical Association, possibly with government aid, located on the Canal Zone at a point to be chosen by the Secretary of War. This monument was to be commemorative of the contributions of the American medical profession to preventive medicine and sanitary science. The names of those men whose work was essential to the attainment of the sanitary condition, which made possible the construction of the canal, were to be inscribed on the base. These names were to be selected later by the joint committee. This monument was to be dedicatd by the American Medical Association on the Canal Zone, not more than two weeks before the meeting of the American Medical Association, presumably to be held in San Francisco, in 1915. The joint committee recommended further that the house of delegates request the board of trustees to appropriate $30,000 for the monument, and that a day be set aside during the exposition to be designated as Honor Day in recognition of the services of the men, living or dead, who by their contribution to sanitation and preventive medicine had made feasible the construction of the canal, and that on that day a general session of the American Medical Association be held which should be open to the public.

**Report of Committee to Advise with the British Medical Association Regarding a Joint Meeting with the American Medical Association.**—This report, of which W. W. GRANT of Denver, Col., was chairman, stated that the cordial invitation of the British Medical Association to meet with that Association in Cambridge from July 6 to 10, 1915, would have to be declined as the constitution and by-laws of the association provided that the annual session should be held at some place in the United States. The committee suggested that it be authorized in behalf of the association to invite the British Medical Association to meet with the American Medical Association in annual convention at the earliest date possible.

*Tuesday, June 23—Second Day.*

THE PRESIDENT, DR. VICTOR C. VAUGHAN, IN THE CHAIR.

**Report of Reference Committee on Medical Education.**—Dr. BERT C. ELLIS of Los Angeles, Cal., presented this report, in which it was recommended that the suggestion of the council on medical education that a hospital intern year be recommended for adoption as a requirement by State licensing boards and that medical colleges be urged to approve of this action; that the house of delegates should reiterate its action in recommending that a year in college in physics, chemistry, and biology in addition to the four years' high school work be required for admission to a medical college, and that high school courses in the above subjects be not substituted for college courses in these subjects; that the action of the council in reference to the reorganization of clinical work be approved; that the action of postgraduate schools in giving certificates in special courses be safeguarded; that no medical college conducted in the interest of stockholders be given a rating higher than C; that the changes in the ratings of medical colleges made by the council on medical education be endorsed; that the use of the metric system and the pharmacopeia of 1910 be adopted by medical colleges be endorsed by the house of delegates. The committee expressed itself as much impressed by the

progress in medical education during the past ten years. This report was adopted by the house of delegates.

**Report of Reference Committee on Constitution and By-Laws.**—This committee reported that it had made only a few insignificant changes in the by-laws designed to clarify the meaning and a slight change in arrangement of the sections in one chapter. The recommendations of the judicial council in regard to the matter of appellate jurisdiction were acted upon and the section referring to this matter was changed to conform with the recommendations of that council.

**For and Against the American College of Surgeons.**—Dr. WILLIAM J. NOBLE of Chicago presented two sets of resolutions regarding the new College of Surgeons. The first, from the Medical Society of the State of Illinois, deplored the organization of the American College of Surgeons as opposed to the democratic principles on which the American Medical Association was based and urged the delegates from Illinois to use all honorable means to have this resolution adopted by the house of delegates of the American Medical Association. A second set of resolutions stated that whereas there had been chartered in the State of Illinois an American College of Surgeons, the avowed object of which was to elevate the standard of surgery and to indicate special qualifications on the part of its fellows, and whereas the American Medical Association had never indicated any stated requirements and the public had no other means of knowing what men were properly qualified except they were informed by the American College of Surgeons, it was resolved that the house of delegates endorse and commend the American College of Surgeons as thus far the American Medical Association had failed to adopt resolutions recognizing the organization officially. These resolutions were laid on the table.

**Resolutions from the Section on Surgery.**—A representative of the section on surgery presented resolutions stating that several years ago the section on obstetrics, gynecology, and abdominal surgery, which up to that time had been known as the section on obstetrics and gynecology, requested that its name be changed so as to include "abdominal surgery." The house of delegates had granted this action and as a result they had taken the heart out of the section on surgery. He showed that it was inconsistent that the section on obstetrics and gynecology should appropriate the term "abdominal surgery" and requested that the words "abdominal surgery" be omitted from the name of the section now known as the section on obstetrics, gynecology, and abdominal surgery. These resolutions were referred to the proper reference committee.

**Resolutions on Expert Testimony.**—Resolutions were presented providing for the appointment of a commission to study the subject of expert testimony and for the appointment of a similar commission by each State society, and a committee in each county society. These committees were to report on all cases involving expert medical testimony in their localities.

**To Give the Young Man a Chance.**—Resolutions were also presented calling attention to the fact that only men of wide reputation now obtained the opportunity of presenting papers before the sections, and that one of the objects of the association was the development and encouragement of the younger men in the profession, and providing that hereafter only two-thirds of the program of any section should be filled by invitation, while the remaining one-third be left open for articles which should be submitted three months before the time of meeting so that the officers of the sections might decide on their value. Resolutions were also presented providing for the establishment of a section on hydrography. These resolutions were referred to their appropriate reference committees.

*Held Wednesday, June 24—Fourth Day.*

**Report of Reference Committee on Constitution and By-Laws.**—Dr. W. A. JAYNE of Denver, Col., presented this report, the same presented the previous day but which could not according to the by-laws be adopted until it had laid over for a day. The report was adopted with the changes suggested except that portion relative to the Appellate Jurisdiction of the Judicial Council, which, as it involved the relations of members of constituent state and county societies, it was deemed advisable to submit to the several states societies before taking final action. In reference to the recommendation from the Surgical Section that the name of the Section on Obstetrics, Gynecology, and Abdominal Surgery be changed to the Section on Obstetrics and Gynecology, Dr. Jayne stated that there had been a meeting of the committee with the representatives of both sections. After a great deal of discussion a compromise had finally been agreed upon as a temporary measure. This consisted in changing the name of the Section on Surgery to Section on Surgery, General and Abdominal. The resolution providing that in making the programs for the sections the presidents and secretaries should fill only two-thirds of the program by invitation, leaving one-third to be filled by articles selected from those submitted to the president and secretary of the section in which it was proposed to read them three months before the meeting. This idea seemed to be a good one, but there were a number of difficulties to be considered, so it was deemed best not to take final action at present.

This report was adopted with the exception of the last section which was referred to the Permanent Committee on Sections and Section Work with request to report upon it next year.

**Report of Reference Committee on Reports of Officers.**—Dr. THOMAS B. DAVIS of Pittsburgh, Pa., reported that this committee commended the report of the secretary and praised the Propaganda Department, the various publications of the Association, the new Medical Directory and the Advertisement Bureau. There would be more and better advertisements in the future, and the committee recommended that the work of this bureau be continued. It was also recommended that a reserve fund be established and that to this end all the departments of the Association be careful in regard to unnecessary and extravagant expenditure. The adoption of the resolution providing for the appointment of a publicity committee in every county society was recommended. In view of the fact that the Appellate Court of Illinois had rendered a decision casting doubt on the legality of the incorporation of the American Medical Association, the question had been asked why the text of this decision had never been published in the *Journal*, and had never been explained. The committee recommended that this decision should not be published because it was not right that the space in the *Journal* should be devoted to this purpose, and because the decision of a higher Court, the Supreme Court of the State of Illinois, had overruled the decision of the Appellate Court and consequently the decision in question was not worth printing.

This report was adopted.

**Report of Judicial Council.**—Dr. ALEXANDER LAMBERT reported for the Judicial Council that in the matter under advisement, relative to the holding in trust of patents of medical and surgical appliances, such a plan would insure the medical profession and the public against cheap substitutes and would enable the sale of instruments and appliances at a lower cost to the profession than at present. The Judicial Council recommended that the House adopt this resolution providing for the holding in trust by the association of patents on medical and surgical appliances with the provision that neither the Association nor the patentee should receive any remuneration therefrom.

With reference to the scheme presented by the Medico-Legal Protective Association, they had found that this was a form of insurance against libel suits and not the ordinary malpractice suit. In the near future each physician would be interviewed on this subject, and it seemed to the Council that this was not a matter for consideration by the House of Delegates but one that must be decided by each one for himself.

**Report of Committee on Sections and Section Work.**—Dr. HUGH CABOT of Boston submitted this report. He stated that the application for a Section on Hydrotherapy had been denied as it was thought that this came within the province of the Section on Pharmacy and Therapeutics. The proposition submitted with reference to dividing the section into two groups, general and special, had been considered, but it was thought that action on this subject should be deferred. It was pointed out that there were good reasons why the further multiplications of sections was not advisable at present. Each new section meant an additional financial outlay. The registration showed that the sections on Medicine and Surgery contained 60 per cent. of the registration; none of the other sections included more than 10 per cent. of the registration, and one section had enrolled only 1 per cent. of the registration. It was recommended that a committee of five be appointed to make a thorough study of the proposition to divide the sections into two groups which should make a report at the next meeting.

**Resolutions.**—The following resolutions were presented: 1. Endorsing the Palmer-Owen Child Labor bill and providing that its sponsers be notified of the approval of the Association. 2. Urging the passage of a comprehensive bill for the care and control of leprosy by the Federal Government. 3. Calling for an investigation of nervous and mental diseases in reference to their incidence, causes, relations to heredity, alcoholism, syphilis, and the means of promoting mental hygiene, etc. 4. Calling for the investigation and control of the sale by grocers of lyes and cleansing substances which had frequently been responsible for injuries, especially to children.

**Invited Guests.**—The following invited guests were in attendance at the session: Harold Collinson, England; Eldred M. Corner, England; Louis I. Doublin, New York; Professor Otfrid Foerster, Germany; Otto Folin, Boston; John Fraser, Scotland; Wilfred Harris, England; W. McKimm Marriot, Baltimore; Alexander Primrose, Toronto, Canada; George B. Roth, District of Columbia.

**Honorary Fellowship.**—Dr. George B. Primrose was elected to Honorary Fellowship in the Association.

---

GENERAL SESSION.

*June* 23, 1914.

The President, Dr. John A. Witherspoon of Nashville, Tenn., in the Chair.

**Invocation.**—Reverend Henry Merle Mellen of Atlantic City opened the meeting with an invocation.

**Address.**—Hon. William Riddle, Mayor of Atlantic City, made this address of welcome, in which he said in part that it was more than a duty, it was a pleasure to speak for the people of Atlantic City on this occasion. Atlantic City owed its success to the physicians of the nation; through them it had grown to be perhaps the greatest health resort in the world. Atlantic City was deeply grateful and there was no body of men who gathered here more heartily welcome than the physicians. After extolling the advantages of the city, he expressed the hope that the American Medical Association would honor them by returning year after next.

**Address of Welcome.**—Dr. Enoch Hollingshead of Pemberton, N. J., president of the Medical Society of New Jersey, welcomed the American Medical Association in behalf of the State Society. He said, in part, that it gave him great pleasure to greet the American Medical Association in the name of the Medical Society of the State of New Jersey, the oldest in America, as Allah greeted the rising sun, with reverence; to greet them as friend greeted friend, as brother greeted brother on his own threshold; to greet them as the greatest creators of medical thought in this country if not in the world. No nation could be successful which did not make its medical ideals the highest. He believed that the knowledge and the inspiration which they brought would, like "Mercy," bless alike those who gave and those who received.

**Address of Welcome.**—Justice Wescott, Attorney-General of the State of New Jersey, made this address as the representative of the Governor of New Jersey. He said the whole proceedings of the meeting suggested the physician; they had been directly to the point, without fuss and without feathers, and the incongruity was that a lawyer should be in their midst. It was very difficult for a lawyer to know the appropriate thing to say. He was much in the position of the young man who was very much concerned about his destiny. He finally decided that the greatest object of life was the saving of the soul and thereupon determined to be a preacher. He soon found that most people were much more concerned about saving their bodies than their souls and then decided to be a physician. After a little further observation he perceived that this was an error and that most people were much more concerned about their pocketbooks than about either their bodies or their souls and immediately began to study law. This might have been a rightful commentary on conditions in this country a short time ago, but happily people were undergoing a change of sentiment. Men were destined to care less and less for their pocketbooks and more and more for their souls and bodies. And it was realized that we could not have great souls without strong bodies. The medical profession from the standpoint of the lawyer had seemed to be a profession based on empiricism and almost necessarily so because it dealt with special and individual cases, but it had developed a peculiar type of courage. The martyr went to his doom once in a century through divine comfort and support; the soldier met his fate under an environment of tremendous dramatic significance; the doctor went to his doom, not once in a century, not under circumstances accentuated by glory, but under conditions of mental calm; he confronted danger and walked to the very gates of death silently, unseen, and unsung daily, and this had developed the peculiar type of courage, the highest species of courage known to the human animal. The medical profession had up to the present time been a profession of separateness, so to speak. It had proceeded under conditions that did not admit of cooperation. The characteristic of the age was cooperation and the physician had come to appreciate the power of coordination and cooperation. The time would come to pass when every county in every state would have its medical society concatenated with the State society, and the State societies would form a great national unit. If these all cooperated with and all possessed the high courage already described they would form the most tremendous power that could be contemplated. They would form an irresistible force in legislation and in the improvement of the people, not only physically but morally and religiously, as without the physical foundation there could be no morality, no theology, no religion. Thus far the profession had worked at each block in the foundation of this great structure, but they had not worked at this foundation as a whole. The average physician was a philosopher, an economist and the soundness of our institutions would be better insured in his hands than in those of any other group of men. In the hands of the physicians rested the future of this country, because in the hands of the profession rested the physical life of the country, and upon this depended its patriotism. The human animal was a susceptible creature in every direction. The average man or woman picking up a newspaper and reading a patent medicine advertisement would, by his constructive imagination, appropriate as a part of his own physical life and as his disease the symptoms of disease set forth in the advertisement. He hied himself to the nearest drug store to purchase freedom from his disease by buying the compound advertised. "What was it?" "God only knows." It was called a proprietary medicine. It was not the result of scientific knowledge but of a knowledge of human weakness. While not wishing to burden his audience with statistics, there was an agreement in the assertions that the people were consuming unknown compounds in the dry forms by the ton and in the fluid form by the hogshead. The foundations of society were being poisoned through the destrictive influences of proprietary medicine. What was this body going to do about it? They had the intellect and the courage and what they should do was to hedge about the manufacturer of proprietary preparations as they themselves were hedged about. He repeated that the medical profession carried in its hands the destiny of this country, and its first duty was that it should save the country from poisoning through liberated ignorance.

Dr. Witherspoon said he wished to express his appreciation of what had been said and to express his gratitude to the last speaker who had outlined the trail along which the medical profession had been barking, and had pointed out the aims of the association as though he were its regularly appointed counsel. He stated that he wished to call upon Dr. Reed to make a report.

**Conferring of Medal on Surgeon-General Gorgas.**—Dr. C. A. L. Reed of Cincinnati said that it was his privilege and happiness to present to an illustrious member of the profession a gold medal in the name of the American Medical Association. He said: "A citizen of the Republic, a graduate in Arts and Medicine, a Doctor of Science and of Medicine, an Army Surgeon by special Act of Congress, Chief Sanitary Officer of the Isthmian Canal Zone, Consultant on Sanitary Problems, Honorable Associate of many foreign associations, illustrious writer and scholar, William C. Gorgas, sanitarian, whose genius made possible the construction of the Isthmian Canal, as one of the acts of the present administration, I am proud to have been appointed Chairman of a Special Committee for the purpose of showing to all the appreciation of ability, of greatness and of genius which made possible the building of the Isthmian Canal. Five hundred thousand lives are lost each year in the United States which might be saved by the proper application of preventive medicine. It is to be hoped that you will always be at the head of the sanitary affairs of the

people. It gives me much pleasure to turn over and present this Gold Medal as a token of appreciation that this country and the American Medical Association contains a man who has done so much for the salvation of mankind."

Dr. WILLIAM C. GORGAS expressed his gratitude for the honor conferred upon him and said that he accepted it only as the chief of the three or four hundred young men who had worked with him and in conjunction with whom he shared the honor.

**Address of the President.**—Dr. VICTOR C. VAUGHAN of Ann Arbor delivered the annual address of the president (see page 1151).

---

SECTION ON PRACTICE OF MEDICINE.

DR. CHARLES LYMAN GREENE OF ST. PAUL, MINN., IN THE CHAIR.

*Tuesday, June 23—First Day.*

**Notes on Cases of Sprue Invalidated from the Tropics—Will It Become Endemic Here?**—Dr. H. B. HIATT of High Point, N. C., and Dr. WM. ALLAN of Charlotte, N. C., presented this communication which was read by Dr. Hiatt. In their summary they stated that cases of sprue were constantly sifting back into this country and should be recognized and treated as such. Sprue should not be confused with pellagra. Rest in bed, a monosaccharid and skimmed milk diet, and cold weather seemed to be the important factors in the treatment. Sprue might very possibly be or become endemic in the Southern States.

**The Syndrome of Adrenal Insufficiency.**—Dr. TOM A. WILLIAMS of Washington, D. C., read this paper. The cases reported and the considerations involved were far from completely presented, and he said he was well aware of this; but a consulting neurologist, without the hospital facilities for research on a large scale, was not well fitted to elaborate what was a very complex problem, namely, the pathogenesis of a complete clinical syndrome, and the treatment of hypoadrenalism. Although it would seem that prolonged psychic strain played a part in the induction of this condition, yet, on the one hand, thousands of individuals underwent long psychic strain and retained their adrenal sufficiency, and perhaps functionating excessively in that respect; while, on the other hand, it was hardly creditable that the adrenal inadequacy from which the Boston physician's daughter died was due to any excessive strain. They were reduced then to the hypothesis of the general inadequacy of the chromafin system to explain cases of this kind. It might be indeed that the inherent inadequacy was responsible for the failure of the adrenals in all cases in which there was no inflammatory or toxic process damaging the glands. He commended the problem to the resources of some large clinic. His paper was presented mainly in the hope of again drawing attention to the need of differentiation, even in a group of cases most typically neurasthenic.

**Neurasthenia and Tuberculosis (Concealed).**—Dr. GEO. DOUGLAS HEAD of Minneapolis, Minn., presented evidence which it seemed to him conclusively proved that many individuals exhibiting the symptom syndrome of so-called neurasthenia harbored a tuberculous infection, and this only; that the tuberculous process in most cases was so concealed as to escape detection by the usual clinical examination methods employed, and a specific test must be used to reveal its presence; that in the light of this evidence these cases should be diagnosed as tuberculosis, and not neurasthenia; that they should recognize and adopt a new clinical symptom type for concealed tuberculosis; that this symptom type was the symptom now recognized by clinicians the world over as neurasthenia.

Dr. NATHAN ROSEWATER of Cleveland said that in 1909 he read a paper on disguised starvation in which he attempted to show this to be one of the causes possibly of beginning tuberculosis. The question then arose how to distinguish between so-called neurasthenia and disguised starvation. In the first place the physician failed to know the time of day when the symptoms became worse. In so-called neurasthenia naturally the symptoms would appear or become worse when the patient was tired, and the nervous system taxed; they would not appear in the morning when the patient was not tired. This was supposed to belong to that class of conditions developed only when the body was tired; yet they might be due to a beginning tuberculosis or to a disguised starvation.

Dr. CHAS. STOVER of Amsterdam, N. Y., said that before deciding that the case was one of neurasthenia they should first exclude myasthenia gravis, a not uncommon condition that appeared when patients became exhausted.

Dr. ELIZA M. MOSHER of Brooklyn, N. Y., said she was particularly interested in the paper, and especially what was said regarding enteroptosis. She believed that they would always find behind neurasthenia, melancholia, starvation, etc., a condition of stasis in the intestine due to falling out of place of some part of the intestinal digestive tract. It was her observation that a peculiar shape of the body already described, with long trunk, wide hips and narrow chest almost certainly predisposed to enteroptosis, and said she had yet to see a young girl with such a body make-up but had enteroptosis. Mr. Lane had stated that enteroptosis was an infantile condition beginning in early life, and even before birth. Enteroptosis produced the very symptoms that had just been described.

Dr. A. J. CAFFREY of Milwaukee, Wis., called attention to the large number of cases of neurasthenia that came to the free clinics, and which reacted positively to tuberculin. There seemed to be some connection between neurasthenia and tuberculosis.

Dr. JOHN RITTER of Chicago believed that at least 40 per cent. of the cases of so-called neurasthenia were tuberculous. They all knew that about 50 per cent. of the typhoid fever cases were tuberculous, and that tuberculosis manifested itself in as many ways as did lues.

Dr. WALTER B. SWIFT of Boston recalled the case of a young woman who had, he believed, all the typical signs of a marked neurasthenia; nothing else could be found. Six months after he examined her she died of carcinoma of the stomach.

Dr. ALBERT ROBIN of Wilmington, Del., referred to the careless manner in which patients were examined in the clinics; 20 per cent. of those applying for aid had no physical examination made of their chests except through the clothing, and so the early cases of tuberculosis were not detected. The effects of exercise, when carefully observed and studied, was of as great diagnostic value as were the injections of tuberculin, and exercise was safer.

**The Use of Atophan and Radium Emanations in the Treatment of Gout and the Arthritides.**—Dr. ARTHUR F. CHASE and Dr. MORRIS S. FINE of New York City presented this communication. Whatever might be the cause, gout was undeniably characterized by a concentration of blood uric acid which was from two to five times as great as that observed in normal individuals. Since the principle of treatment in gout was to avoid purine foods, and to maintain the uric acid of the body tissues as low as possible, it would seem that an agent which was essentially a specific eliminant for uric acid, as stophan appeared to be, would form a rational therapy in this condition. It then became desirable to learn the details attending the action of this drug. Under treatment with atophan, five cases of gout showed improvement of more or less permanence, as also did four cases of possible gouty nature. Of eleven cases of arthritis of various types, two showed some improvement. They had thus far treated thirteen cases of gout and arthritis in an emanatorium with radium emanations in one to two hour sittings for one or two months, and in no instance was there any change whatever in the uric acid concentration of the blood.

Dr. CHARLES G. STOCKTON of Buffalo said he had had a part in some studies relative to the action of atophan in relieving the uric acid burden of the blood during the past winter and he had seen some cases in which the drug administered according to the method of Folin had acted unpleasantly. The term "gout" had been used as though it was a parallel to excess of uric acid in the blood. The term gout implied something in addition to excess of uric acid in the blood. He had observed two cases with similar conditions one of which was treated by the alkaline method and one by atophan; the latter had given rather the better results.

Dr. S. SOLIS COHEN of Philadelphia said that for years he had been making use of this drug and of novatophan. His colleague had been making certain studies which bore out the report made as to the influence of atophan on the uric acid content of the blood but the uric acid was not by any means the whole story nor did clinical results run parallel to the reduction and elimination of uric acid under atophan and radium elim-

ination. The most striking effect clinically in gout, arthritis and acute rheumatism was the relief of pain. In one case under observation the administration of the drug was accompanied by relief of pain and reduction of temperature and withdrawal of the drug by recrudescence of pain and temperature, but this did not mean recovery. The change to the usual salicylate treatment resulted in prompt recovery. In cases of chronic gout he had settled on the following method: He administered atophan for one week in every month but not in large doses, using one gram a day in three doses. In cases of gout with bad heredity the normal uric acid index was higher than that of the normal individual, and all one could hope to do was to bring the uric acid down to what would be normal for that individual and to such a condition that no symptoms were manifested. He had used radium emanations and radium water and thought he obtained better results in acute than in chronic cases. The result of the first few radium treatments was to increase the pain in the joint, and unless there was such an exacerbation one could not hope for curative results.

Dr. ARTHUR F. CHACE of New York said that where there was intolerance for the drug it could be given in smaller doses or in combination with soda. He preferred atophan to novatophan. Gout would have to be defined in the future. He did not call the cases gout unless there was at least four milligrams per 100 c.c. of uric acid of blood. He had been interested in the significance of a high uric acid content in nephritis and uremia and he pointed out the advisability of searching for a foci of infection where the uric acid content remained high. He also administered the drug by giving it four days and then allowing a four days' interval. In nearly all cases he had used the purin-free diet. If the drug was given only one week in the month one might permit a moderate amount of purin in the diet. He had tried reducing the uric acid by a diet purin free and alcohol free and had reduced the uric acid from six to three milligrams per 100 c.c. by dietary precautions. In his experience the radium treatment had given the best results in the subacute cases.

**Intrarectal Administration of Sodium Salicylate in Acute Rheumatic Fever with Satisfactory Results.**—Dr. LOUIS G. HEYN of Cincinnati said that this method had for its justification its ability to answer the requirements of any therapeutic agent such as the ease of administration; the ready absorption of the drug; a minimum of untoward effects; the ability to administer large quantities of the preparation as was to be advocated in bactericidal therapy; the removal of the residue of the drug from the bowel by subsequent enema if the dosage ever proved excessive; and the results were more prompt than by any other measure. He reported cases which he believed to be fairly illustrative of the efficiency of the intra-rectal therapy and he said that if the common methods of treatment in acute rheumatic fever had so often been disappointing the intra-rectal method was offered as a very reliable and safe solution to the therapy of this serious affection.

Dr. E. W. MITCHELL of Cincinnati said he wished to corroborate what had been said of the value of the salicylates when given in primary large doses and this had been found impossible when they were given by the mouth. The method just described had been exceedingly satisfactory in hospital practice and they very seldom had an unpleasant reaction. They had given as much as 300 grains in twenty-four hours without producing more than ringing in the ears and if symptoms of salicylism developed they were relieved by washing out the rectum. Absorption of the salicylates seemed to be more prompt by the rectum than by the stomach. Salicylic acid never circulated in the blood as such but was changed to salicylates, the change being effected by the carbon dioxide in the blood. It was not difficult to employ this method in private practice and it was satisfactory to the patient to be free from the nausea caused by administering salicylates by the mouth, and the treatment had to be given only once or twice a day. There were only one or two cases in which the ringing in the ears was so severe as to make it necessary to stop the treatment. They had tested the drug in both its synthetic and its natural form and had found no difference in its effects.

Dr. JOSEPH L. MILLER of Chicago said that Dr. Heyn's paper was interesting as showing that salicylates given by the rectum were actually absorbed, but he questioned whether there was greater action than when they were given by the mouth since when administered by the mouth they were very freely absorbed. They used larger doses when administering it by the rectum and it was absorbed as completely as by the stomach. In patients who could tolerate larger doses than usual by the mouth, it gave more favorable results. Dr. Heyn's method of administering the drug would be very valuable in cases in which it cannot be tolerated by the mouth. Many would scarcely agree that the salicylates were a specific for acute rheumatic fever as they were a comparatively recent remedy. It had been shown that of the patients receiving salicylates 30 per cent. relapsed while those receiving the alkaline and heat treatment only 6 per cent. relapsed. A comparison of 2,000 cases treated by the older methods and 1,600 by salicylates showed that the stay of the former patient averaged 33.4 days in the hospital, while for the latter the time spent in the hospital was 33.2 days. Dr. Miller referred to experiments on rabbits in which hemolytic streptococci were administered and then large doses of salicylates but this did not prevent the animals from getting arthritis.

Dr. J. N. UPSHUR of Richmond, Va., referred to the advantages of bicarbonate of potassium after having unloaded the liver. He used the preliminary alkaline treatment until the perspiration and the urine became neutral, but did not believe in large doses of salicylates as he believed they predisposed to endocarditis, and the patients were more apt to relapse than those treated by the method indicated.

Dr. J. M. RECTOR of Columbus, O., used a smaller dose and by a certain method caused further absorption along the tract. He used a tube to inject the solution, attaching to its end the Pullitzer bulb, which caused the agent to be trapped along the colon. Another feature to be borne in mind in the treatment of these cases was that two or three enemas a day unloaded the colon and assisted especially in the elimination of the contents of the upper alimentary canal.

Dr. JAMES C. TYSON of Philadelphia added his testimony and said he had described this method some years ago. It was not often necessary to administer the drug by the rectum as there were other compounds as aspirin that could be administered by the mouth.

Dr. NATHAN ROSEWATER of Cleveland, Ohio, said that he did not give large doses of salicylates but had found that 15 or 20 grains at bed time did as well as larger doses. During the day he gave an alkali preferably iodide of potassium in order to preserve a decent circulation and that being good he saw no cardiac complications.

Dr. W. W. TOMPKINS of Charleston, W. Va., asked Dr. Heyn whether he had a record of the number of cases of endocarditis in his series of 124 cases. He emphasized the advantages of rest even in those cases in which the affected joint did not prevent the patient from being about.

Dr. LOYIS G. HEYN of Cincinnati said that Dr. Miller's experiments on animals were a strong argument against the bactericidal effect of the salicylates. In regard to the salicylates predisposing to endocarditis, he said he had given them in cases of marked arrhythmia with no untoward effects so far as could be judged.

*Wednesday, June 24—Second Day.*

There was a joint meeting with the Section on Pathology and Physiology with a symposium on nutrition.

**Newer Points of View Regarding the Part Played by Different Food Substances in Nutrition.**—Dr. LAFAYETTE B. MENDEL of New Haven, Conn., read this paper. He said to speak of "newer" points of view regarding the rôle of the different food substances in nutrition implied a contrast of to-day with yesterday in this progressive domain of physiology. One need not turn back far to reach the days of Liebig, to whom, above all others, were due the beginnings of present-day knowledge of the constitution of foods, tissues and excreta. The vague and indefinite generalizations of a generation ago in respect to the functions of the foodstuffs had slowly been transformed into the more tangible theories of the passing decade. Proteins were now understood to be disintegrated in the digestive tract into relatively simple nitrogenous fragments, the amino-acids, not exceeding twenty in number. It was these digestion products, absorbed into the blood stream, that represented the real form in which the protein intake of the body was transported throughout the organism. Protein metabolism had at length become essentially a question of the behavior of amino-acids in the body, their uses and fate. So far as the nitrogenous transformations were concerned, the amino-acids were the center of interest in nutrition,

the pivot about which the modern conceptions turned. Most, if not all, of these amino-acids were essential for the construction of tissue and the regeneration of cellular losses. Prof. Mendel said that he trusted in his hasty review he had given emphasis to the contention that the problem of protein metabolism had largely become one of amino-acid supply.

**Intermediary Protein Metabolism.**—Dr. Otto Folin of Boston read this paper. He said that in its broad outlines the intermediary protein metabolism appeared now comparatively simple and clear. The blood got amino-acids from the digestive tract and all the tissues got them from the blood. From the amino-acids thus received each tissue rebuilt itself, and the amino-acids which were not needed for such synthesis were converted into urea and carbonaceous remainders. The latter were either converted into carbohydrates or were otherwise oxidized for the production of heat and energy. When protein materials from within the body were broken down, as in fasting and in fevers, these were in all probability digested in the tissues down to the stage of amino-acids, and from that stage on underwent the same transformation as did the amino-acids derived from the food.

**The Specific Dynamic Action of Foodstuffs.**—Dr. Graham Lusk of New York presented this communication. He stated that the results obtained were based upon 250 experiments upon dogs in the respiration calorimeter. The cause of specific heat production lay not within the absorptive or excretive mechanisms, but in the interplay between the living cells and the nutrient material, the sugars and amino-acids contained in the blood. Experiments had been devised to determine the effects of these changes, which demonstrated a marked increased heat production after the ingestion of sugar. The heat production of the fourth or fifth hours after the ingestion of glucose regained the level of the basal metabolism. The speaker discussed the cause of this increased heat production, and stated that it was due to the mass action of the sugar molecules reacting with the living cells. When alcohol was given in addition to glucose the heat production was raised above the level to which glucose alone would have raised it, and the alcohol was oxidized in preference to the carbohydrates. The metabolism of three amino-acids yielding sugar were studied. An amino-acid convertible into sugar and urea might be given without appreciable increase in the heat production. The result which followed the administration of amino-acids was like that which occurred after meat ingestion in that the amount of the increase in heat production was proportional to the quantity of material metabolized. He had presented the view that the great increases in heat production were due to stimulation of the protoplasm to higher activity through the mass action of accumulated amino-acids. Experiments made since had led him to believe that the highest heat production was coincident with the highest metabolism of amino-acids, and that the amino-acids themselves did not lie in the tissues to act as stimuli without being involved in highly active metabolism. It was indicated that specific intermediary acids were formed in metabolism which were the real stimuli, and that when ingested protein was reconstructed into body protein the amino-acids involved in this reaction did not cause an increase in the heat production. It might be stated that living cells metabolized carbohydrates and fats in increased quantity when these were present in large amounts in the surrounding fluid, and that they were also stimulated to a higher heat production during metabolism of certain amino-acids to an extent entirely out of proportion to their energy value.

**The Total Energy Requirement in Disease as Determined by Calorimetric Observations.**—Dr. Eugene F. DuBois of New York presented this paper, which was based on a study of 140 cases in the respiration calorimeter of the Russell Sage Institute of Pathology in Bellevue Hospital. In typhoid fever the heat production might rise to from 100 to 160 per cent. of the normal, and at this stage there was little or no specific dynamic action manifested by protein or carbohydrate; that was to say, the taking of food, even in large quantities, did not increase the amount of heat produced. In exophthalmic goiter the total metabolism might rise as high as 192 per cent. of the normal, and in cretinism it might be as low as 75 per cent. In all the various diseases studied the methods of direct and indirect calorimetry agreed closely.

Dr. Victor C. Vaughan of Ann Arbor, Mich., said that he would not dare criticise the papers as the authors were the best authorities there were on this subject and he congratulated the American Medical Association on having such men in its ranks. He asked Dr. Folin to explain one point. It was recognized that in enterodigestion proteins were split into amino-acids. Dr. Folin held that amino-acids were directly absorbed in the walls of the intestines, carried to the individual cells and each utilized what it found suited to its needs. The point that he should explain was in regard to synthesis; there must be some synthesis in the body. The seroalbumins and globulins of the blood were specific proteins each from diverse sources, and synthesis must occur somewhere. They must not lose sight of the fact that enterodigestion was by no means the only digestive process. The blood had a digestive function. The leucocyte cell of the blood possessed a proteolytic ferment, a trypsin and an antitrypsin, and the adjustment of these to one another was one of the great problems of physiological chemistry.

Dr. S. J. Meltzer of New York said he wished to offer the same congratulations as those of the president. It was gratifying to see the gulf between the scientific investigator and the practical clinician narrowing more and more. It was also gratifying to get four men in the United States together at once who could tell not what was being done abroad but what they were doing themselves, and who took a pride in work that had a practical bearing on the practice of medicine. Dr. Mendel's remark that they saw only guesses and gaps had not been made for the last time. Always from a certain point of view there were guesses and gaps. Guesses and theories existed to bring out facts and a theory continued to live as long as it continued to bring out facts. Mendel had contributed one of the best facts ever demonstrated when he found the usefulness of butter to growth and at the same time that lard did not do what butter did, but had not pointed out the difference between the two. One thing the scientific man should remember was that he should do no harm to the patient, and should consider well before subjecting certain patients to too much experimentation.

Dr. F. M. Potenger of Monrovia, Cal., asked if the difference in the absorption of fats applied the same to all animals, whether it was the same for herbivorous, carnivorous animals and for man.

Dr. J. P. Joselin of Boston asked Dr. Lusk if he could give the reason why the metabolism was not by increased generous feeding in typhoid fever.

Dr. A. D. Eustis of New Orleans, La., said that one point that had been mentioned could be utilized by the practitioner and that was the effect of the different aminos which were the putrefactive results of the amino-acids. These were non-toxic to the normal person, but injected into animals acted as toxins and might be toxic in diseased conditions in man. Dr. Eustis discussed the effect of diet in arterial hypertension and stated that under dietetic treatment alone he had seen blood pressure of 200 to 260 come down to 140.

Dr. George D. Head of Minneapolis asked if observations had been made as to the heat production after feeding butter to enteroptic individuals as compared with those of short stocky build.

Dr. A. J. Carlson of Chicago called attention to the fact that in the particular field covered by these papers America had made a distinct addition to science. He had been greatly impressed by the way in which these papers had been received though it was true that if there was anything in the practice of medicine that was of importance it was a knowledge of nutrition.

Dr. L. B. Mendel of New Haven, Conn., expressed the fear that he had been misunderstood in what he had said regarding the "gaps and guesses" in their knowledge of metabolism; he had intended to show how these gaps and guesses were being filled in and to present present-day views. He did not wish his statements to be taken too specifically. In reference to the experiments in fats, butter, cod liver oil, etc., these had been made only on rats and mice, but these had proved so satisfactory for experimental purposes that it had not seemed necessary to try the experiments on a wide variety of animals. Styles had changed in infant feeding in reference to fats and it had been noticed in pellagrins that the theory of corn in relation to this disease was complicated by the fact that many of these patients used lard to a great extent. The new attitude of the clinical fraternity to the laboratory worker was a cause for mutual thanksgiving and rejoicing.

Dr. Otto Folin of Boston said he thought the audience would agree with him that the question asked by

the president was too much of a question for even a laboratory worker, to attempt to answer it would be to answer the question as to how tissue was produced. He had discussed the problem from the standpoint of metabolism of food. This was a matter that had two aspects, a destructive and a constructive one, but the constructive aspect, the synthesis, was synonymous with the formation of life itself and far from the transformation of amino acids into protoplasm.

Dr. GRAHAM LUSK of New York said that in reference to the question as to the increase of metabolism in typhoid fever, he had studied the basal metabolism which was the metabolism taken when there was no food in the intestines and a high temperature. The 26° C. mentioned in the paper excluded the thermal influence entirely. If an animal was in the cold and the heat production was raised, meat could then be given without causing a further increase in the heat production. That was if one established the heat production at a certain level of metabolism, combining two heat producing factors did not cause a further increase in the heat production.

Dr. EUGENE F. DUBOIS of New York said that a comparison of metabolism in enteroptic individuals with that of short stocky ones was interesting. It seemed that with under nourishment there was low metabolism and with the other class there would be a higher metabolism, yet from clinical observation of enteroptic individuals there seemed to be higher energy requirement.

**The Heart in Pneumonia.**—Dr. ROBERT N. WILSON of Philadelphia said that according to the vitality and endurance of the heart and circulatory system might be reckoned the outcome of the given instances of pneumonia. Seldom, if ever, would the mechanical obstruction of the lungs prove a serious factor except in its influence upon an already crippled cardiac mechanism. In speaking of the microscopical changes he said that the heart showed post mortem evidences of the toxemia in every fatal case of fibrinous as well as of broncho-catarrhal pneumonia that reached the microscope. During the past year he had taken great interest in studying microscopical sections of the cardiac musculature from fatal cases of pneumonia and in not a single instance was there a lack of evidence that a toxic influence had been actively at work.

**The Treatment of Heart Involvement in Syphilis.**—Dr. HARLOW BROOKS and Dr. JOHN CARROLL of New York City presented this paper and offered the following conclusions: 1. Cases of heart involvement in early syphilis might be fully cured irrespective of the character of the lesion by vigorous specific treatment alone and independent of circulatory measures. 2. Even well established and late cases usually respond to treatment with care, or marked though perhaps temporary benefit. 3. In most tertiary instances purely circulatory measures produce but slight benefit unless preceded by or combined with specific medication. 4. Interrupted inefficient treatment established an immunity or resistance on the part of the lesions against the specific drugs employed. Hence the importance of vigorous and carefully systematized treatment. 5. The most satisfactory treatment was one which combined the use of salvarsan with mercury and the iodides. Combined treatment might be unnecessary in early cases but it was essential in late ones. 6. Salvarsan, preferably old salvarsan, produced in most instances the quicker results. It was capable, however, of inducing serious symptoms and in untried cases of heart involvement it should be administered in small doses until its action had been ascertained, particularly in those lesions characterized by disturbances of rhythm. 7. Mercury alone might produce apparent cure. Best effects were secured with this drug when its form was from time to time changed. Its use appeared to be indispensable in all well established cases. 8. The iodides were valuable adjuvants in the treatment of tese cases, especially in their late stages, but they were apparently without specific action. 9. Permanent injury to the heart must be assumed to have taken place in late cases, even though prompt response to treatment and apparent cure occurred. 10. Successful treatment resulted primarily on the recognition of the cause of the disease and on its specific treatment.

**The Four More Common Types of Heart Disease—An Analysis of 600 Cases.**—Dr. RICHARD C. CABOT of Boston presented this communication and offered the following conclusions: 1. 93 per cent. of 600 recent hospital cases of failing heart had been found to group themselves without much resistance in four classes, rheumatic (streptococcic), syphilitic, arteriosclerotic, and nephritic. 2. About 5 per cent. could not easily be thus classified. The remaining 2 per cent. were "goiter hearts." 3. In the 278 rheumatic cases females predominated, 170 or 61 per cent. to 108 males or 39 per cent. 4. Sixty per cent. of these rheumatic cases began before the twenty-second year. The typical rheumatic heart case was therefore a young girl. 5. Of the 74 syphilitic cases 70 per cent. were in men; only 30 per cent. in women. The typical syphilitic heart case was a middle aged man (average age 47) with aortic regurgitation and no rheumatic history. 6. The 93 arteriosclerotic cases averaged 59 years of age. The 117 glomerulo-nephritic cases averaged 36 years old. The arteriosclerotics were therefore 23 years older than the nephritics. The sexes were about equally represented in both groups. 7. Diagnosis, prognosis, and treatment were put upon a more rational basis if they gave up the terms "myocarditis," "cardiorenal" disease, "aortic regurgitation," "mitral regurgitation," or qualified them with an adjective like "syphilitic," "rheumatic," or "arteriosclerotic." 8. Practically the stenoses belonged in the rheumatic group.

**The Effect of Low and High Nitrogen Diet on Renal Function Tests in Chronic Nephritis.**—Dr. C. FROTHINGHAM, Jr., and Dr. W. G. SMILIE of Boston presented this communication. Cases of chronic nephritis were placed on diets of about 2,000 calories daily, which contained alternately 20, 75, and 150 gm. of protein. The blood pressure, phenolsulphonephthalein excretion, and non-protein nitrogen retention in the blood were studied. Apparently the diets had no effect on the blood pressure. In cases which showed an inability to excrete added urea, the waste nitrogen in the blood increased on a high protein or an average protein diet. In cases with salt retention but without urea retention, the waste nitrogen did not accumulate in the blood. In the cases in which the waste nitrogen in the blood rose, the phenolsulphonephthalein excretion in the urine sometimes diminished. It would seem that a low protein diet was especially indicated in certain types of nephritis.

**Studies in Liver Function.**—Dr. L. G. ROWNTREE, Dr. ALLEN CHESNEY, and Dr. E. K. MARSHALL, Jr., of Baltimore presented this communication and offered the following conclusions: 1. Definite functional changes were to be demonstrated in many cases of liver disease. 2. Most marked changes were present in cirrhosis and carcinoma of the liver. 3. The study of phthal excretion of feces, of fibrinogen in the blood, and nitrogen partition in the blood and urine was of decided value in determining the presence of fibroid change.

---

## SECTION ON OBSTETRICS, GYNECOLOGY, AND ABDOMINAL SURGERY.

### DR. E. GUSTAV ZINKE OF CINCINNATI IN THE CHAIR.

*Tuesday, June 23—First Day.*

**A Few Important but Unsolved Problems in Obstetrics, Gynecology and Abdominal Surgery.**—Dr. E. GUSTAV ZINKE of Cincinnati presented the chairman's address, with the above title. He said that chronic intestinal stasis, placenta previa and puerperal eclampsia were a few of the obstetrical conditions that were of paramount import. Of these, chronic intestinal stasis was the most important subject before the profession today. He explained that this condition meant a retention of toxic products in the intestinal canal due to an irregular diet, lack of proper exercise and constipation. As a result of the absorption of these toxic products changes were observed in the liver and gall-bladder; there was loss of fat and there were degenerative changes in the heart. Mental apathy and melancholia were also noted. As to the treatment, he advised the ingestion of paraffin before meals, a restricted diet, moderate exercise and the constant wearing of an abdominal support. Sometimes it was necessary to resort to surgical measures. In the matter of puerperal eclampsia, he referred to a recent meeting of the New York State Medical Society at which two reports on the subject were introduced. One report treated the subject from a standpoint of medical care, while the other dealt with the surgical treatment. The mortality under medical care was 13 per cent., while those treated surgically showed a mortality of 28 per cent. Veratrum viride was given after the first convulsion. Free catharsis was induced and hot baths administered. In many cases of placenta previa, abdominal hysterectomy was indicated.

**The Treatment of the Albuminuria of Pregnancy.**—Dr. EDWARD J. ILL of Newark presented this paper. He

said that sudden albuminuria occurring in primipara was a serious illness, and that the seriousness was increased the further the patient was from term. No single method of treatment sufficed for all cases. If the onset were gradual minor remedial measures were often effective. If coma was present, Caesarian section was indicated. He believed veratrum viride was a valuable remedy. He had no experience with pituitrin extract. In a series of 29 cases treated at the Rotunda Hospital, Elizabeth, N. J., the mortality showed 17.2 per cent. for the mother and 37 per cent. for the child.

**The Treatment of the Toxemias of Pregnancy.**—Dr. A. J. RONGY of New York read this paper. He believed that all symptoms incident to pregnancy from simple morning sickness to pernicious vomiting of pregnancy were varying degrees of toxemia. The treatment depended upon the degree of intoxication. He said there was a pre-eclampsic stage which was of great importance from the standpoint of treatment. He used the placental serum treatment with satisfactory results. Individualization was the keynote of the successful treatment of the condition.

Dr. ASA B. DAVIS of New York said that the pregnant state was not a simple one. At any time it was liable to become serious and threatening. Toxemia was preventable by a careful regulation of the patient's habits. Each case demanded individual treatment.

Dr. PHILIP MARVEL of Atlantic City said he wanted to bring out two points not mentioned. One was the hypertension that existed in these cases and the other was the valuable results obtained from the use of pilocarpin. This drug was administered in a dose of 1/50 of a grain. The hypertension was reduced in less than 24 hours.

Dr. M. HOWARD FUSSELL of Philadelphia thought that eternal vigilance on the part of the family physician was necessary to prevent toxemia. It was necessary to examine the urine every two weeks. Blood pressure records were of great value.

Dr. EDWARD J. ILL of Newark closed the discussion of his paper and said that pilocarpin was used many years ago, but was no longer popular as a remedy. He believed early cases of albuminuria were not dangerous.

**The Treatment of Placenta Previa.**—Dr. EDWARD P. DAVIS of Philadelphia presented this paper. He said placenta previa was a variety of ectopic gestation. Septic infection was the greatest factor in the mortality rate of placenta previa. Frequent vaginal examinations and vaginal manipulations were discouraged. The treatment was divided into methods which were reasonably successful when used by general practitioners in private houses and methods which were successfully carried out in hospitals.

**Hysterotomy.**—Dr. JOHN B. DEAVER of Philadelphia read this paper. He said that hysterotomy was the surest method of treatment in placenta previa and in neglected cases of toxemia of pregnancy. It was recommended as a diagnostic procedure. In uterine hemorrhage of uncertain origin it was the best method of determining the lesion. It had given great satisfaction in dealing with intrauterine polypi and submucous fibroid. It was contraindicated in infected uteri and in inexperienced hands.

Dr. RICHARD C. NORRIS of Philadelphia said that Dr. Deaver's method was too radical. In making a diagnosis he relied upon the curet and the examining finger.

Dr. GEORGE M. BOYD of Philadelphia said the best treatment of placenta previa was bipolar version.

Dr. JOHN O. POLACK of Brooklyn was not in favor of performing hysterotomy for diagnostic purposes.

Dr. HENRY M. FISHER of Philadelphia believed that digital examination of the uterine cavity was sufficient to make a diagnosis. He was not in favor of hysterotomy for diagnostic purposes.

Dr. EDWARD P. DAVIS of Philadelphia closed the discussion of his paper. He said that statistics showed that 10 per cent. of the deaths of lying-in patients were caused by placenta previa.

Dr. JOHN B. DEAVER of Philadelphia closed the discussion of his paper. He said that digital explorations of the uterine cavity were not satisfactory from the standpoint of diagnosis. He urged a thorough education of the rank and file of physicians as to the importance of early diagnosis in placenta previa.

*Wednesday, June 24—Second Day.*

**Vesicovaginal and Rectovaginal Fistulas.**—Dr. HENRY O. MARCY of Boston read this paper. He said that the basis of the operation for the cure of vesicovaginal and rectovaginal fistulas was the complete separation of the vagina from its attachments over a rather wide area, and the closing of the fistulous openings separately with a fine continuous, absorbable suture. When this was done, the coaptation and restoration of the parts to their normal condition by the use of aseptically applied, buried tendon-sutures became a simple problem of easy solution.

Dr. J. WESLEY BOVER of Washington said he was interested in the subject, and highly approved of Dr. Marcy's method of treatment.

**The Embryology of the Umbilical Region.**—Dr. THOMAS S. CULLEN of Baltimore read this paper which was illustrated by lantern demonstration. He said that at the St. Louis meeting of the American Medical Association he had discussed the diseases of the umbilicus, and had laid special stress on the pathological lesions due to remnants of the omphalomesenteric duct, and of the allantois. In this paper the gradual closing in of the abdominal walls was shown. The development of and subsequent atrophy of the omphalomesenteric duct, and of the allantois, was illustrated, and the umbilical cord was unraveled, showing its component parts.

SYMPOSIUM ON SURGERY OF THE LARGE INTESTINE.

**The Pathogenesis of the Pericolic Membranes.**—Dr. ARTHUR E. HERTZLER of Kansas City, Mo., presented this paper, which was illustrated with lantern slides. He said that all lesions were grouped under the general heads of congenital folds, new-formed membranes, vascular dilatations, and subperitoneal scleroses. He believed there was a need of distinction between the anomalies of development and the lesions, the result of antenatal pathologic conditions. Vascular changes were due to temporary or permanent activity of potential vessels not normally visible. Subperitoneal scleroses were due to organization of fibrinous exudates.

**Experimental and Clinical Studies of Colon Stasis.**—Dr. JOSEPH RILUS EASTMAN of Indianapolis read this paper. He demonstrated that the cecum and ascending colon of dogs were almost invariably the seat of pericolitis. Colon stasis in dogs was constant. Artificially induced colon stasis in animals resulted in pericolitis. Membranous pericolitis was almost constant in chronic appendicitis. For the relief of this condition of stasis, numerous operations were advised, but operative procedures gave unsatisfactory results.

**The Condition of a Few Patients Two Years after Ileosigmoidostomy.**—Dr. CHARLES L. BONIFIELD of Cincinnati read this paper, which was based upon results obtained in patients operated on two years ago. The first patient was a woman, age 30 years, who had suffered from more or less constant abdominal pains, and who for the past five years was markedly constipated. She was nervous and irritable, and had lost weight. On the third day after operation, the bowels moved normally, the pain disappeared, and several weeks later the patient reported a gain in weight of fifteen pounds. The second patient was a woman, aged 35 years. She suffered from constipation for years, and, at times, was extremely melancholy. On the third day following operation, the bowels moved normally, and some months later she reported a gain in weight of sixty-five pounds.

**Resection of the First Portion of the Large Intestine and the Resulting Effects on Its Function.**—Dr. WILLIAM J. MAYO of Rochester, Minn., wrote this paper, which was read by Dr. Charles Mayo. He said that in the past too much importance had been attributed to purely incidental changes in the position and attachments of the large intestine, and thus gave bands, kinks, and adhesions of a normal character, a fictitious rôle in the supposed production of symptoms. The results of surgical procedures were good. The patients showed exaggerated conditions of cecocolic stasis and in all of them, constipation was marked. A removal of the cecocolon relieved these conditions. Among the number operated upon there was no mortality.

**Some Surgical Phases of the Sigmoid.**—Dr. CHARLES A. L. REED of Cincinnati read this paper. He said it was rare to find a sigmoid which measured over 25 c.m. It was important to know the anatomic relations of the sigmoid. Redundant sigmoid was encountered oftener than other types. The most constant symptoms were constipation and pain. The *x*-ray was one of the best aids to diagnosis. The palliative treatment consisted of massage, bathing, and postural treatment. Curative treatment was obtained by surgery.

Dr. JOSEPH SAILER of Philadelphia said that these

cases were usually first seen by the internist. He thought that the symptoms were caused by autointoxication. He believed that surgical measures were not curative in every case.

Dr. JOHN H. GIBBON of Philadelphia said that the exact cause of intestinal stasis was not known. In his opinion, surgery of the colon had not found its proper place in surgery as yet.

Dr. JOHN B. DEAVER of Philadelphia said it was a question of cause and effect. He believed that lesions in the intestine were pathological in character and were caused by a previous inflammatory condition. He did not always rely on the *x*-ray in the matter of diagnosis.

**Parenteral Protein Digestion.**—Dr. VICTOR VAUGHAN of Ann Arbor read this paper. He said that some bacteria secreted diffusible ferments while other bacteria furnished intracellular ferments. At the present there were no known bacterial ferments which were capable of digesting the living cells. The leucocytes digested the proteids. The ferment furnished by the leucocytes was different than those furnished by bacteria. The protein ferments were non-specific.

**Limitations of the Dialysis Method as a Practical Test for Pregnancy.**—Dr. CHESTER M. ECHOLS of Milwaukee read this paper. He said that the basis of Abderhalden's test was theoretically correct. The test was carried out by adding the serum from the patient to cooked human placenta. A pregnant woman's serum had the power of digesting human placenta. Many observers thought the test was unreliable, and was hard to execute. The test was tried in a number of cases and showed positive results in pregnant women. In non-pregnant women the test showed positive results in 12 per cent. of the cases.

**The Value of Abderhalden's Biological Reactions to the Obstetrician and Gynecologist.**—Dr. HENRY SCHWARZ of St. Louis read this paper. He said that serum diagnosis was of real service. Cancer serum acted with cancer serum only. It was possible to get a negative test and yet cancer was present in the patient. The serum diagnosis was of value in those cases of cancer where it was impossible to secure material for microscopic examination. It was also of value in controlling cases after radical operations. The serum diagnosis of pregnancy was not suitable to routine work.

Dr. HERMAN J. BOLDT of New York said the dialysis test gave negative results in two of his cases who were pregnant. It was not reliable.

---

## SECTION ON SURGERY.

*Tuesday, June 23—First Day.*

### DR. CHARLES H. FRAZIER OF PHILADELPHIA IN THE CHAIR.

**The Cerebrospinal Fuid as a Problem in Intracranial Surgery.**—Dr. CHARLES H. FRAZIER of Philadelphia presented the chairman's address with the above title. He called attention to the important work being performed at the present time by physicists, chemists, bacteriologists, and psychologists in the scientific laboratory. The same scientific principles were applied to brick laying, agriculture, and hygiene contributing toward modern happiness. The pathogenic factors in meningitis were said to be infection and increased intracranial pressure. This increased pressure followed disturbances in circulation, absorption, and secretion. Increased tension was more important. Hydrocephalus was said to be due to one or other of these factors. Several explanations for its mechanics were offered. The author had several times withdrawn 60-100 c.c. cerebrospinal fluid from the ventricles. This invariably speedily reaccumulated. Cerebrospinal fluid was said to nourish nerve tissue. It was increased by carbon dioxide. Its pressure was thought to equal or exceed intravenous pressure. It was believed to escape into the venous channels through the Pacchionian bodies. Increased secretion of cerebrospinal fluid occurred in cerebral syphilis and brain tumors. The choriod was spoken of as a gland with a duct. It had the ductless gland and the gland with a duct. It had an external secretion and no duct. As in the thyroid ligation of its blood supply decreased its secretion of cerebrospinal fluid. Ligation of the common carotid was mentioned as an effectual means of controlling its secretion in hydrocephalus. Its secretion was increased probably by stimulation of the gland by the introduction into the blood stream of such substances as pilocarpin, atropin, liver, spleen, thyroid, brim, and especially choriod extract. This increased cerebrospinal fluid was associated with decreased blood pressure.

**A Contribution to the Surgery of Brain Tumors.**—Dr. HERMAN KÜTTNER of Breslau had his assistant, Felix Sandau, read for him. One hundred cases had been treated at Küttner's clinic during the past six years. There was difficulty in diagnosing between brain tumor and local hydrocephalus. Decompression was performed to relieve increased tension and to preserve vision. Of his cases 75 per cent. lived to regain full working ability, 30 per cent. survived operation for several months, and 30 per cent. did not survive operation or lived but a few weeks. In 75 per cent. of the cases choked disc decreased. In private practice 50 per cent. of the cases showed good permanent results after early treatment. He did not recommend puncture of corpus callosum.

Dr. WILLIAM G. SPILLER of Philadelphia regarded Dr. Küttner's report as pessimistic. He recognized proper indications for as well as grave dangers of central decompression. Hemiphlegia and hernia were seen to follow trephining. Enlargement of the brain in the presence of a tumor was pointed out as a cause for increased intracranial pressure. Serous meningitis unaffected by decompression gave choked disc. He considered puncture of corpus callosum too radical. Associated markings on inner surface of thinned-out skull and diseased brain indicated the atrophied convolutions of hydrocephalus and not serous meningitis. He had found an occlusion of aqueduct of Sylius in one and of the foramen of Monro in another case of hydrocephalus. He concluded by advising careful study of suspected tumor cases without symptoms.

Dr. HARVEY CUSHING of Boston held classification of brain tumors impracticable. He recognized slowly growing tumors and silent-area tumors as tumors giving no symptoms. He declared his mortality to be but 10 per cent. and Küttner's high mortality as discouraging. He said Krause gave a 50 per cent. mortality. Cushing lost 7.1 per cent. of 148 cases, including subtemporal, transphrenoidal, and suboccipital operations.

**Osteoplastic Closure of the Trifacial Canals: An Experimental and Clinical Study, Illustrated by Lantern Slides.**—Dr. ALLEN B. KANAVEL introduced a new method of blocking cranial nerve exits by advocating the use of bone transplants. The present methods of trifacial nerve blocking were successful only in so far as they succeeded in obliterating the bony foramen or were free from complicating infection. His technique included avulsion of nerve, curettage of foramen, and plugging with tibial bone flap the size of a penny introduced at right angles to the direction of the foramen. He recommended further study before utilization as a clinical measure.

Dr. S. J. MIXTER of Boston blocked the sensory nerve by division and plugging foramen about cut end with amalgam. He reported one success clinically for Kanavel's experimental method.

**Treatment of Unlocalized Intracranial Injuries by Drainage through a Subtemporal Approach.**—Dr. VILRAY P. BLAIR of St. Louis declared frontal temporal and sphenoidal lobes were often pulpified in severe head injuries. Twenty per cent. died in first two hours, 50 per cent. in first 24 hours. Encephalitis was the probable cause of death following traumatism to brain. Removal of pressure allowed room for increased blood supply to damaged part. Subtemporal decompression offered a clean and speedy route for examination following injury.

Dr. OTTO H. SCHULTZE of New York favored the subtemporal route. Puncture of skull when in doubt was favored. It differentiated cerebral shock which did not require decompression.

Dr. EVANS of Milwaukee reported a 25 per cent. mortality for 25 cases.

Dr. C. E. RUBLE of Ann Arbor reported holding to the belief that extradural hemorrhage occurred only in infancy until two recent senile cases compelled abandonment of that belief. He explained there could be no decompression without opening dura.

Dr. BLAIR concluded discussion by correcting former impression of a decompression without opening dura.

**Consideration of 275 Cases of Acute Appendicitis, with Special Reference to Complications and Causes.**—Dr. ARCHIBALD MACLAREN of St. Paul laid emphasis upon amount of pus present in appendicitis and not upon virulence of pus as valuable prognostic evidence.

In his first 150 cases he lost 12 large abscess cases, one small abscess, and no unruptured appendix cases. In his second 150 cases he lost seven of the 24 general abscess cases. He emphasized the importance of rectal examination and rectal drainage.

**Has the Last Word Been Spoken Concerning Appendicitis?**—Dr. T. E. MOORE of Minneapolis emphasized the syndrome pain, local tenderness, and muscle rigidity for appendicitis. He called attention to the exceptions. He considered muscle rigidity most important. When this was absent in the presence of the other symptoms he thought of retrocæcal appendicitis. He advised against refinements of diagnosis until after operation. He gave a mortality of 3.4 per cent. for 87 acute cases and no mortality for his last 44 cases under improved hospital conditions. It was not always necessary to remove appendix although he had removed it in 95 per cent. cases. He advised operation between attacks to avoid subsequent attack in women because of the greater dangers of appendicitis and pregnancy. He held Fowler position unimportant declaring pus would always be forced into pelvis by intraabdominal pressure.

Dr. A. J. OCHSNER of Chicago cautioned against making sure of state of bladder before rectal incision for drainage. He warned against use of purgatives in acute cases and advised palliation in which a favorable outcome from operation was doubtful.

Dr. T. N. T. FINNEY of Baltimore declared we should have 100 per cent. recovery from appendicitis. When this was not the case some one had made a mistake. He advised operation when in doubt of the presence of appendicitis as a conservative measure.

Dr. L. DAVIS of Boston emphasized gravity drainage and gave a mortality for his 249 appendix cases of 5.5 per cent.

*Wednesday, June 24—Second Day.*

**Congenital Cystic Kidney.**—Dr. F. B. JUND of Boston discussed the surgical importance of congenital cystic kidney. He described the symptoms of dragging and pain as important indications for incision over a kidney that could be palpated, felt lobulated, and seemed enlarged. He added cachexia to above symptoms. He recommended delivery of kidney to surface of body and puncture of cysts. This process relieved whatever normal kidney tissue remained from pressure atrophy and saved the patient from uremic death. The fluid obtained on paracentesis was generally clear but sometimes greenish in color. The frequent involvement of both kidneys at same time necessitated careful exploration of corresponding kidney as well as the making sure that no healthy kidney tissue remained in the first kidney before nephrectomy was advisable. He described Rovesing's three cases of puncture of kidney cysts and their favorable outcomes. The operation was described as resting but not curing the cystic kidney process. Of the theories of formation of kidney cysts, including (1) developmental, (2) neoplasm, (3) fetal inflammation of kidney, Dr. Lund favored the developmental method.

Dr. D. N. EISENDRATH of Chicago claimed priority of operation for Dr. Witherspoon. When patient was found to be uremic, he advised consideration of a possible congenital cystic kidney, examination for same and if present, careful consideration of progress in corresponding kidney. He emphasized the additional symptom of hematuria, and the bilaterality of cystic kidney.

Dr. G. L. CHUTE of Boston described one clinical case occurring in his practice. He suggested the bilaterality of suppuration complicating cystic kidney.

Dr. J. BEVAN of Chicago advised consideration of nephrectomy. He pointed to the slowly progressing nature of cystic kidney.

Dr. J. OCHSNER of Chicago emphasized the following palliative treatment: (1) The administration of regulated diet including milk, buttermilk, cream, fruit juices, and eggs and (2) the exposure of women to *x*-ray for three to six twenty-minute periods. This sterilized them and protected them against a possible pregnancy complicating a cystic kidney, a condition usually terminating in uremia.

Dr. F. W. MCRAE of Atlanta reported one case of unilateral polycystic kidney.

Dr. F. B. LUND, in conclusion, advisedly recommended nephrectomy.

**Ischemic Myositis of Arm, Forearm and Leg.**—Dr. J. B. MURPHY of Chicago recommended the term Volkman's contraction and not paralysis. The condition followed fracture of arm bones. Muscles may become secondarily adherent to bone. There was no change in arteries. The essential causes were: (1) the cast or bandage. (2) Flexion of arm. The greatest muscle destruction occurred within the first 48 hours. The symptoms were said to be intense pain after dressing of fracture. (3) Edema of part below dressing. (4) Ischemia. Tight dressings had been applied fallaciously to reduce fractured ends or to hold them reduced. The most efficient treatment was prophylactic; namely, cutting the constricting band as soon as edema of the hand was recognized. He suggested two possible operative procedures: 1. Shortening the bones of forearm and 2, lengthening of tendons. He employed the latter method. He lengthened tendons from one to three inches or long enough to bring hand into proper position. He enclosed his tendons in fat or fascia, transplanted if necessary. He maintained the success of this method depended upon the freedom of tendons from contact with hands. He described the drop-foot to be due to pressure over the external popliteal nerve, and advised keeping dressings from over nerve.

Dr. E. LAPLACE of Philadelphia mentioned the importance of the prophylactic treatment, declaring there to be no post-haste in treating fractures of arm. It was more important to deal with the soft tissues in order to get a good functional result. He held that hematin and fibrin remained after an edema of hand or forearm which agglutinated the tendons together.

Dr. D. D. LEWIS of Chicago reported contraction due to retrofascial hematoma in supracondylic fracture of the humerus in 8 per cent. of cases. He outlined the treatment as incision of anticubical fascia and liberation of blood.

Dr. HAROLD COLLINSON of Leeds called attention to pressure contraction following hematoma. Massage and passive motion worked well in one case of his. His tendon work he declared to be disappointing.

Dr. MURPHY, in conclusion, emphasized as a third cause of Volkman's contraction exudative swelling and hemorrhage. The treatment was declared to be liberational blood clot. He warned against passive motion after fracture when such motion caused pain.

**A Simple Method of Tapping a Distended Bladder and Making Permanent Drainage.**—Dr. W. L. RODMAN of Philadelphia emphasized the importance of relieving the toxemia and doing a suprapubic paracentesis in cases of gonorrheal stricture, hypertrophied prostate, and tumors, especially cancer. It is particularly indicated as the first stage of a prostatectomy and materially lessens its mortality. A general anesthetic is undesirable. He reported 50 cases of prostatic hypertrophy in which he did the two-stage operation without a single mortality.

Dr. H. M. CHRISTIAN of Philadelphia regarded suprapubic puncture as an emergency measure and advocated drainage before prostatectomy in infection.

Dr. ALEX. RANDALL repeated the indications for suprapubic puncture already given, but disapproved of the two-stage operation for prostatectomy.

**Testing the Efficiency of the Collateral Circulation; Its Importance in Determining Surgical Intervention and Methods of Applying the Tests.**—Dr. R. MATAS of New Orleans most ably reviewed the surgery of the vascular system. Bleeding from a collateral vessel, preservation of peripheral pulse, bleeding from a distal end of a vessel compressed at cardiac end were tests for the existence of collateral circulation. He cited additional indications as normal or approximately normal color during the compression of the main vascular supply, bleeding from veins, the integrity of the associated arteries being questionable, instrumental indications, and the indication determined by a calorimeter of Prof. G. M. Stewart. He recommended the application of the occlusive band to facilitate the closure of certain aneurysms.

**Aneurysm of the Posterior Tibial Artery, with Report of Two Cases.**—Dr. ALEXIUS MCGLANNAN of Baltimore reported two exceptionally rare cases of aneurysm in the posterior tibial artery. These two cases occurred in his service at Mercy Hospital within four months. In one case he did the obliterative aneurysmorrhaphy of Matas, in the other he did an excision of sac. He declared the Matas operation to be preferable because it was the more feasible and associated with less hemorrhage.

Dr. B. N. Berheim of Baltimore explained the infrequent use of the above tests for collateral circulation by calling them too involved, difficult to interpret, and when interpreted, not conclusive. He recommended the tying of the occlusive band for the larger trunks and the utilization of some other method than ligation or extirpation for gangrene. The pulse test he considered most satisfactory for the general surgeon. He held that aneurismorrhaphy required laboratory experience.

Dr. A. Primrose of Toronto commended Dr. McGlannan on the choice of his operations for his two critical cases. He reported one case in which he used the Matas method.

Dr. J. W. Price of Louisville described the technic for the vessel in anastomosis, emphasizing the importance of endothelial apposition.

Dr. J. S. Horsley of Richmond proposed excision of sac and the substitution of a piece of vein as a vascular bridge between the ends of the arteries. Dr. Matas concluded by declaring there was no seriousness attached to vascular injury so long as the periphery remained normal in color and temperature. He maintained no method was free from accidental failure.

Dr. McGlannan found the pulse absent in his first case. In the second case, the excision was forced upon him.

**Experimental Surgery of the Heart and Lungs.**—Dr. Axel Werelius of Chicago described considerable operations performed upon cats. He found puncture wounds not serious; when repaired the dangers were those of cardiorrhaphy. He described excision of auricular appendages and other experimental cardiac work. His pneumectomy operation he found particularly fatal on the cat. He described section of tracheas and other tracheal operations.

Dr. J. B. Murphy said that he had performed the first blood vessel anastomosis in 1896. He congratulated Werelius on the exceptional importance of his work.

Dr. Wyllys Andrews of Chicago claimed the greatest benefits of experimental heart and lung surgery to be the skill incidental to the opening of the chest and the treatment of blood vessels.

Dr. Willie Meyer of New York mentioned longitudinal splitting of the sternum for a method of thoracotomy. He had operated successfully on seventeen out of twenty-one dogs in which he had removed one lung. The sensitiveness of the vagus and sympathetic nerves had to be encountered. He emphasized the importance of disinfecting bronchial stumps.

**Oration on Surgery: The Relations of the Surgeon to the Conquest of Cancer.**—Dr. Joseph Bloodgood of Baltimore assigned the mortality of cancer to be due chiefly to ignorance, or fear of operation, which led to delayed or bad treatment. He favored a defusion of information among the profession and the public through the lay and medical press. This information should be under the absolute control of responsible medical authority, such as the A. M. A. He described the protection from cancer to be the seeking of advice and receiving a thorough examination. He mentioned the different warnings of cancer according to its respective location, as "indigestion" in the case of the stomach, and hemorrhage in case of the uterus. The most frequent seat of cancer was said to be external skin and mucous membrane, the stomach and colon, and the uterus. He emphasized the importance of early, thorough operation. The difficulty of making an early diagnosis must be met by the physician.

**Exploration of the Knee Joint and Its Teachings.**—Dr. F. M. Corner of London discussed the importance of the crucial ligaments in fractures of the knee-joint. He believed many injured ligaments had been overlooked, accounting for poor functional results after fracture. He repaired his ligaments using silver wire, if necessary. He showed cases of fractured spines of tibiæ, and believed them occasionally overlooked. In one case, it was necessary to remove a fractured spine. Portions of torn ligaments and periosteum sometimes became free bodies within the knee-joint.

Dr. J. B. Murphy of Chicago discussed Corner's contribution, considering it the first of its kind offered before the A. M. A.

**Exophthalmos and Methods of Surgical Treatment.** Dr. C. H. Mayo of Rochester discussed the mechanics of exophthalmos. They depended upon the existence of a microscopic muscle under sympathetic control, and developed more on some individuals than in others. He knew of two cases in which eyeball had been protruded so far that lids closed behind it, requiring surgical relief to replace it.

Dr. Dean Lewis of Chicago discussed Dr. Mayo's paper.

**Mechanism for Injuries of the Shoulder Region; Results of Forty Operations.**—Dr. T. Turner Thomas of Philadelphia believed injuries to shoulder-joint are most frequently caused by hyperabduction of the shoulder-joint. Fractures of the clavicle, surgical neck of humerus, and dislocations of humerus (anterior) and inner end of clavicle, were caused in the same manner. The fragments were directed downward and inward, except the inner end of the clavicle, which was forced upward. Their corresponding fragments were directed upward and inwards and forwards. He considered painful shoulders which could not be demonstrated as cases of fracture or dislocation were cases in which the antero-inferior capsule had been ruptured by a dislocation under hyperabduction, which had spontaneously reduced itself. He emphasized the need for putting the painful shoulder to rest in the abducted position to prevent the cicatricial shortening of the capsule when the arm was left at rest. He recommended early motion, but so much as to relax the capsule. When relaxed, plication of capsule was necessary.

Dr. A. C. Wood of Philadelphia supported the abduction theory of Thomas. Dr. Wood recommended abduction of shoulder upon a triangle to 40 degrees.

**Operation on Thoracic Wall for Relief of Bronchial Asthma.**—Dr. E. Wyllys Andrews of Chicago urged that the credit for devising the operation of chondrectomy for bronchial asthma be given to Dr. Freud. The operation consisted in removing the costal cartilages of second, third, fourth, fifth ribs on each side. This gave immediate relief in suitable cases. Refixation of chest by fibrous tissue or cartilage could be prevented by interposing muscle tissue.

Dr. Chas. Goodman of New York performed operations in a number of cases. He sutured perichondrium so as to prevent reformation of cartilage.

Dr. Andrews concluded by advising the careful selection of cases in which there was a rigid chest.

**Aperiosteal Amputation (Hirsch-Bunge).**—Dr. Henry H. M. Lyle of New York showed some very striking roentgenograms of amputation stumps, showing spikes of bone reproduced from periosteum. He favored denuding bone of periosteum from one cm. above cut end of bone, and scraping out marrow from interior of bone for corresponding distance. Lyle believed many cases of painful stumps in which pneuromata was supposed to exist were actually made painful by these bony spines. When these new bone processes were removed, pain was relieved.

Dr. Cotton of Boston asked about the mechanical resistance of denuded stumps, and was answered by Dr. Lyle.

---

## SECTION ON DISEASES OF CHILDREN.

*Tuesday, June 23—First Day.*

**The Wet Nurse in Hospital Practice.**—Dr. F. S. Churchill of Chicago read this paper. He said that a large proportion of the death rate in infants occurred in institutions where it was 30 to 40 per cent. Babies were brought in with malnutrition and lowered resistance to respiratory diseases in winter and gastrointestinal diseases in summer. Breast milk had of recent years been found more satisfactory than substitute feeding. For the past five years at the Children's Memorial Hospital wet nurses had been kept on hand. The examination of these women included the Wassermann test. Babies were not put on the breast for fear of infection to the nurse. Infants were put on alternate feedings of breast milk and modified cow's milk, and as they improved took more and more cow's milk. The supply of breast milk was limited, but under hygiene could be increased to perhaps sixty ounces per day. This, with small feedings of two to three ounces, could be distributed to many babies. The first examination of results upon babies (1) receiving breast milk and cow's milk and (2) receiving cow's milk alone showed the mortality about the same. It was found that Group II were heavier and older than Group I, and an estimation based upon equal weight and vigor was determined. Group II was subdivided and the average weight of all babies selected was 7.7 pounds. Group I

then showed a mortality of 36 per cent. as against 44 per cent. in Group II. The difference, however, was slight. With a limited supply of breast milk it was not known that the best distribution had been made. With healthy children some breast milk was undoubtedly better, but was this so with the sick? Among desperate cases the mortality was not found to be lowered by the use of breast milk, but among the less sick the use of part breast milk gave a very decided advantage. Since the use of breast milk the infant mortality rate in the hospital had not been lowered, but it had not risen, while that of the city had risen considerably. Breast milk was not a panacea but a very decided help.

**Some Practical Breast-Milk Problems.**—Dr. A. W. MYERS of Milwaukee, Wis., said that in maternal nursing some difficulties occurred in which both child and mother needed help. A great deal was accomplished by regular habits of nursing for the child, and in rest, fresh air and exercise for the mother. In glandular activity the psychic state was a very important point. Still babies did not always thrive on breast milk, and it was unjust to condemn the mothers for not nursing them. Where the baby was distressed after feedings, lost weight, and did not sleep, the mother also lost rest, became worn out, and her supply of milk diminished. The diet of the mother was very important. In Denmark, the foremost dairy country in the world, strict regulations as to the substances fed to cattle were enforced. The minor changes, however, in human milk, caused by diet, received scant attention. These changes could not be chemically proved, for they did not at once follow changes in diet. But where the child was uncomfortable, distressed between nursings, and perhaps had diarrhea during the earlier stages of lactation it was due to the mother's milk. Dr. Myers cited three cases that had come under his observation of children who showed disturbed digestion, restlessness and fretfulness. Inquiry into the diet of the mothers showed them to be in the habit of eating fruit (oranges, apples, etc.) daily and plenty of vegetables. With elimination of these the children took feedings without distress and breast feedings were able to be continued for several months. These cases were typical. Regulation of diet was all that was required. The explanation was perhaps in the passing of aromatic substances into the milk; some babies were more sensitive to this and the diet of the mother must be bland and starchy. As early as the fourth century writers had restricted from the diet of the nursing mother substances strongly fragrant, acid, sweet, or sour. The lessons of Aristotle might be repeated to present-day physicians.

**The Feeding of Skimmed Breast Milk.**—Dr. F. C. NEFF of Kansas City read this paper. He had found the problem of high fat content of milk of frequent occurrence, resulting in digestive disturbance of the infant. When the fat content was reduced digestion was easier. Only a temporary reduction of the fat might be necessary. Dilution might be tried, but this reduced all percentages alike. With the reduction of fat the emptying of the stomach was facilitated. Later the child might have an increased tolerance for fat. In cases of severe digestive disturbance, persisting vomiting, pylorospasm, etc., complete recovery followed the removal of fat. The method was to obtain twenty-four hours' supply of milk. The milk was kept on ice and the supply of the previous twenty-four hours was used for feeding. The milk was placed in a rubber stoppered bottle (eight ounces), with a tube at the bottom for withdrawing the milk without the fat. In this way the reduction of fat could be measured. The skimmed milk thus obtained was an easily digested food.

Dr. ZAHORSKY of St. Louis said these papers afforded very valuable considerations. Most practitioners had difficulty in keeping babies on the breast. It was a problem what to do with severe cases of dyspepsia. He was surprised to hear Dr. Myers condemn fruit, as he had been told that citric acid did not get into the milk. The exclusion of fruit, however, was indicated by clinical observations. The method of skimming was rational, but the same results could be obtained by putting the baby on rice water till recovery from dyspepsia resulted. What was important was to know why the baby originally got dyspepsia on breast milk. So little was known of breast feeding compared to artificial feeding.

Dr. DOUGLAS of Detroit said that for a great many years he had opposed eating of fruits by nursing mothers, but his views were contradicted by his brother physicians. More time was spent at present in studying the nutrition of young animals than in studying young children. Highly flavored foods had been condemned, but sugar containing foods and medicines were also to be strongly condemned. Nurses were very careless in giving children doses containing sugar because the child seemed to like it.

Dr. LOWENBERG of Philadelphia commented favorably upon the study of the problems of breast milk. Papers of this kind were greatly needed. Physicians were too quick to discontinue breast feeding because of dyspepsia. The suggestion of Dr. Neff was important and should be made known to general practitioners.

Dr. MORSE of Boston said he believed that human milk was the best food for the baby under almost all conditions. It contained fat, milk-sugar, and protein, but where intolerance for sugar or fat existed it would disagree as badly as cow's milk. As regards the question of fruit for the mother these cases were the exception and not the rule. Most healthy women could take fruit without disturbing the baby. Often colic in the baby was due to the nervous make-up of the mother.

Dr. MYERS said that substances producing flavors were purely aromatic acids, phenol derivatives, which were apt to be combined with the glucose in the blood and eliminated in the urine in the form of glycuronic acid. With a new outlet in the breast these might be combined with glucose and eliminated in the milk. One per cent. of substances in human milk were unknown toto us. The cases of disturbance from feeding fruit to the mother were, however, exceptional.

**Care of Delicate and Premature Children in the Home.**—Dr. H. M. MCCLANAHAN of Omaha read this paper. He said the two important requirements were conservation of body heat and nourishment. Incubators were unsatisfactory because ill ventilated. The use of a clothes basket lined with oil cloth and cotton batting and heated with hot-water bottles was to be preferred. A top covering of flannel was used. The bottles maintained a temperature of 90 degrees. The body was warm, the face exposed. Absorbent cotton was used for wrapping the body and for napkins. The body was oiled. Great care was to be taken to make sure the baby drew milk from the breast, as some were too weak to do so and died of exhaustion. A medicine dropper must be used or a Breck feeder. Another source of danger was excessive heat. The temperature must be taken twice or thrice daily.

Dr. H. D. CHAPIN of New York emphatically condemned incubators. Fresh air was a vital factor for the infant. Even the use of a Breck feeder was sometimes difficult and a catheter had to be resorted to. Great care must be exercised lest a food clot enter the larynx and cause death.

Dr. ZAHORSKY of St. Louis preferred the use of a radiator to hot-water bottles. A soapbox with one side out could be placed against this and the heat maintained. Most premature babies died of insufficient feeding. Very small and very frequent feedings were sometimes necessary.

Dr. HAMILL of Philadelphia joined the protest against incubators. He had had an experience of leaving a premature baby in a ward of 55 degrees temperature. The body heat was maintained at 90 degrees near a radiator. The baby had done remarkably well.

Dr. FRITZ TALBOT of Boston said that the newborn baby maintained body by use of glycogen deposited in the liver. If the mother's milk came soon the baby did not depend upon the body fat. If it did not come for five to six days the baby lost weight because it used the body fat. It should be fed milk early to maintain the body heat.

Dr. ROGERS of Manchester, N. H. said that too much packing of cotton about the child caused more or less weight and absorbed energy.

Dr. HELMHOLZ of Chicago advocated a 6 per cent. solution of dextrose in Ringers to be kept up at 5-hour intervals until breast milk became available. This should be used hypodermically.

Dr. MCCLANAHAN of Omaha corroborated Dr. Hamill's views about cold air.

**The Physician's Function in Infant Feeding.**—Dr. H. D. CHAPIN of New York read this paper. He said that the standpoint of physicians towards infants had greatly changed within the last few years. Ideas as to feeding had changed. The processes involved must now be in consonance with animal nutrition. A really scientific food prepared unscientifically might obtain good results. A great deal of scientific work had to be

done in order to find out that something was not the truth. Results justified any method that really produced them. Various viewpoints, such as bacteriological, chemical, and caloric had been studied without regard to the whole. Individual feeding was, however, a biological matter. It was a question of the selective action of the body cells and explained why one individual utilized products which another rejected. The power of selection in the organism picked out for the offspring what it needed giving it in form suitable for the young organism. Attempts to improve on nature were unscientific. Physicians were broadening out in their conception of infant feeding. By too much manipulation the biological elements in food might be ignored. If these principles were practiced in future, physicians might use many methods and get good results.

HOUSE OF DELEGATES

*Thursday, June 25—Fourth Day*

**Election of Officers.**—The following officers were elected for the coming year: *President*, Harry L. Rodman, Philadelphia; *1st Vice-President*, E. S. Fairchild, Kansas City, Mo.; *2d Vice-President*, D. Misner R. Townsend, New York; *3d Vice-President*, Alice Hamilton, Chicago; *4th Vice-President*, William E. Darnall, Atlantic City, N. J.; *Secretary*, Alexander R. Craig, Chicago; *Treasurer*, William Allan Pusey, Chicago; *Trustees*, Philip Marvel, Atlantic City; W. T. Sarles, Sparta, Wis.; Philip Mills Jones, San Francisco.

## CONNECTICUT STATE MEDICAL SOCIETY.

*One Hundred and Twenty-second Annual Meeting, Held at New Haven, May 20 and 21, 1914.*

DR. D. CHESTER BROWN OF DANBURY, PRESIDENT.

**Demonstration of Skin Diseases.**—Dr. R. A. McDONNELL of New Haven exhibited a patient with lupus vulgaris, which had started six years before. Dr. McDonnell stated that the only satisfactory treatment for the disease was to destroy the bacilli, for, in spite of the use of the *x*-ray on the scars, the disease would recur again. He had a patient who had died as a result of a carcinomatous growth around a scar. He also showed a case which he felt no one would have taken to be tubercular. It was an old case of fibroid eczema of the palms and soles and was something like a form of syphilis.

**Newer Methods of Diagnosis and Treatment of Glaucoma.**—Dr. ARTHUR N. ALLING of New Haven declared that there was more written about glaucoma than about any other disease in ophthalmology and that it would always be a subject of perennial discussion, and said that the term "glaucoma" was practically synonymous with high ocular pressure; although not absolutely so, because it was possible for a man to have glaucoma and yet, at times, not show tension—as in the case of glaucoma simplex. He mentioned that formerly the only method of diagnosing intraocular tension was to measure the hardness of the eyeball with the finger; and that although many instruments had been devised with the idea of testing the pressure scientifically, most of them had proved rather unsatisfactory. He spoke of an instrument which they now had for that purpose which was more satisfactory. It was his belief that glaucoma resulted from interference with the drainage apparatus, and he stated that the intraocular pressure normally was between twenty and thirty mm. of mercury. If it rose above that, generally speaking, there was a glaucomatous condition. Dr. Alling stated that when glaucoma attacked an eye it was never really recovered from. A patient might live his or her life out, but the eye would never be right. He said the treatment had been, first, palliative, by means of pilocarpin and eserin, which sometimes did fairly well; and secondly, making an iridectomy. There had been other operations devised, for instance the La-Grange and Eliot. He mentioned Col. Eliot as having been the first to make the procedure of trephining into the sclera, in cases of glaucoma, useful; but said that while they were all enthusiastic over the Eliot operation that they should bear in mind the fact that it was not a cure for glaucoma, but only arrested the disease and afforded a certain amount of drainage. Therefore, they should all hope that something else might be offered by which a cure could be effected. Dr. Alling presented a patient on whose eye he had performed an iridectomy, and spoke of that operation as the "sheet-anchor" treatment for glaucoma. He said they should have had a bleb over the seat of the operation, showing that filtration was going on, but in this case there had been no bleb. The tension, however, was down, which proved that it was possible to relieve tension without the edematous swelling over the wound.

**Diagnostic Methods in Gastrointestinal Diseases.**—Dr. L. M. GOMPERTZ of New Haven, exhibited a number of patients showing a variety of gastrointestinal diseases. The first case was that of a patient who had complained of symptoms that led to a diagnosis of gastric ulcer. That was in August, 1909. He had been treated for a short time and felt so much improved that he failed to return for further treatment. On May 11, of the present year he had returned with an aggravation of the previous symptoms and with loss of weight. He had been given a test supper of meat, rice, raisins, and anything else he desired. The following morning when a tube had been passed into the fasting stomach and some of its contents removed, they showed the presence of sarcinæ and food remnants (hydrochloric acid having been present in order to favor the growth of sarcinæ). A diagnosis of cicatricial ulcer was made. Dr. Gompertz said that although many physicians had difficulty in getting the contents of a fasting stomach, it was a very simple matter; stating that if the patient had a dilated stomach he should be made to lean forward, the tube being compressed at the same time, and that anything in the tube would come out. It was his opinion that no matter how little of the contents were secured they would be sufficient for a microscopic examination.

It was stated that the next patient had been seen at times since 1908, and when any excitement occurred she had spells of vomiting, and could not eat anything. Everything came up almost immediately after being swallowed. Quantities of mucus and food were vomited. In attempting to pass a bougie into her stomach an obstruction was encountered just above the cardia, 42 cm. from the mouth. She was given belladonna and bromides, and recovered; but two years later she had another attack and after it had had a spasm. The patient had these spells so frequently, coming on when there was any excitement, that there was a dilatation of the esophagus above the cardia.

The next case showed the transition of a non-malignant growth into a malignant growth. The patient had come to Dr. Gompertz in June, 1907, with symptoms of ulcer of the cardiac end of the stomach, showing increased acidity. He had been treated for a time and gained weight and improved generally. The doctor did not see him for a long time, when he came back with a different history. The second time his appetite was good but he could not get the food down, and his bowels were constipated. A bougie was passed down and an obstruction was met at the cardia. Dr. Gompertz stated that occasionally the obstruction would let up a little so that food could go down through it. It was his opinion that the case was positively a malignant one and would go from bad to worse, without any possibility of help.

Another case was shown, being that of a young woman seen eight years before for the first time. Then, the clinical history, chemical examination, etc., had indicated the case to be one of pure ulcer. After a month's treatment the girl was told she needed an operation. She left and did not return until a year ago, when she said she was ready for the operation. In passing the stomach tube, hydrochloric acid, sarcinæ and food remnants were found. This time the diagnosis was cancer of the pylorus, which proved to be wrong. Just before the operation an *x*-ray was taken, not suspecting the presence of an hour-glass stomach. Dr. Verdi operated and made an end-to-end anastomosis. At the end of two months after the operation, a picture showed the stomach to be smaller, but normal in position. The young woman was seen within the past two weeks, and was eating three meals a day and was getting fat.

A woman patient was shown, whom it had been thought had a gastroptosis. In passing the tube Dr. Gompertz got into a pocket and thought she had an hour-glass stomach; but the next time he passed a bougie he got into the stomach. She was told that an operation would be necessary. When it was performed multiple ulcers were found, instead of an hour-glass stomach. The ulcers were taken out and the stomach put into proper position by an end-to-end anastomosis. Dr. Gompertz said that with the aid of the *x*-ray, the

microscope and chemical examinations a positive diagnosis could often be arrived at; but, on the other hand, this was sometimes impossible, and he suggested that all the different methods of testing be tried in order to make sure of a correct diagnosis.

**Presentation of Cases of Bone-Grafting for Various Conditions in Different Localities.**—Dr. E. H. ARNOLD of New Haven stated that he had done bone-grafting in almost every situation of the body. He told of having grafted in clubfoot cases; in tubercular tarsus by means of inserting pieces of bone; in the tibia for an osteomyelitic defect; in the knee, etc. He exhibited a patient who had had a tubercular knee, which had been treated at first by scrapings on the outside, by brace, and with plaster of Paris; but they did no good, the destruction continuing to go on. Dr. Arnold did a resection of the knee, cutting away as much as he could. The result was that the patient had some motion in the knee, although he was able to go back to his trade after three months. Later, as one of the sinuses still persisted, a bone-graft was put in at the front of the knee by Dr. Arnold in order to do away with the movement. He succeeded in this, but the discharging did not stop. It was his opinion that a tuberculous knee did not make bone, and the best that could be done was to hope for fibrous union, as no brace would secure absolute immobility, and a child could not be kept in plaster always. A case was shown by Dr. Arnold where he had opened the hip and inserted two grafts. One of these had sloughed out, but the other remained in and stimulated bone-making to such an extent that a firm bony union was made, the child now walking without a brace. The doctor mentioned having grafted in cases of sacroiliac and sacrolumbar disease, the results in these having been generally unsatisfactory. A male patient was displayed who, when he first came to Dr. Arnold, had been moribund. He was put on a plaster of Paris bed for four months, with but little improvement. Then he was operated on, a Y bone-graft being inserted in an inverted position. He had grafts in the lower lumbar and upper sacral region, and immobility was secured. Three weeks after the first operation a second one was done on the other side (two heriotomies being done); and within six weeks the man walked out of the hospital and went back to his work after three months.

**The Wassermann Test for Syphilis.**—Dr. C. J. BARTLETT of New Haven explained that when complement was spoken of in connection with the Wassermann test for syphilis it always referred to the fresh guinea-pig's serum. He said that theoretically speaking the organism producing syphilis was the antigen. It had been shown, however, that an extract of normal tissues would act as a syphilitic antigen in the same way as the red corpuscles acted, as an antigen. Also, that if the serum to be tested was not from a syphilitic there would be nothing to unite the antigen for syphilis to the complement and it would remain free. In making the tests he stated that they got their serum in 5 or 10 c.c.; that they let the serum separate over night and then heated it to 132° F. for half an hour. If they did not get a positive reaction they knew the case was not syphilis. Dr. Bartlett did not think the simple negative test was of much value. He had found that the blood serum would give a negative reaction sometimes when the spinal fluid gave a positive one; therefore, he thought it best to always examine the spinal fluid before discharging a patient as cured.

**Experiments in Nutrition.**—Drs. T. H. OSBORNE and L. B. MENDEL of New Haven presented for inspection charts showing the relative growth of rats fed on different foods. They said the rat would grow for a time on starch and then decline after forty or sixty days. The foods they used for their experiments were water-free and were mixed with lard, generally. The rats grew on that food when certain protein substance was mixed in, and failed to grow when that protein was left out. One chart showed the normal growth on a single protein, such as casein, destin, the albumin of the white of an egg, glutinin from meat, etc. On some foods there was practically no growth, but when this occurred all that was necessary to have growth start again was to change the diet from an imperfect to a perfect protein. Some proteins were shown to be enough for maintenance but not for growth. They had found that solid fats sometimes failed to nourish the animals, but that the animals quickly recovered when butter oil was substituted. They explained that most of the proteins used by them in preparing the foods contained all the aminoacids and were complete proteins, but some lacked one or more of these acids and were incomplete proteins; this enabled them to determine whether the protein that was lacking was of real importance for growth and maintenance. The tryptophane group was found to be necessary for maintenance; without it the animal died in a very short time, but the lysin group was essential for growth only and not needed for maintenance. They felt that several interesting questions had been brought up by the effect of these different proteins on the animals, namely, How long could an animal be stunted and still recover the power to grow? Could the deficiency in one protein be supplemented by adding another protein to it? and How well could that be done? During these doctors' interesting work they had discovered that if the amount of casein were doubled, up went the growth; that one-fourth of destin was insufficient for growth, one-half was nearly enough, and three-quarters was just right. They had tried adding to a diet of 9 per cent. casein, on which the rat was growing slowly, cystin, and it immediately improved the growth. They related an unique experiment of an animal that had been kept for 168 days on a food that did not contain lysin (and so was inadequate for growth), yet it had been able to give birth to young and maintain and nourish them, but it did not recover its original weight. The embryo was produced at the expense of the mother's life. It was their belief that when anorexia was said to be due to the sameness of food it was probably an error. They believed it to be due rather to individual social conditions, claiming that one could eat the same thing day after day if it constituted the correct diet, but as soon as a defective diet was used anorexia would be produced. Malnutrition being the cause of the anorexia, and not *vice versa*, as has been generally supposed. They explained that rats were used for their experiments because they had comparatively the same rate of growth as human beings (250 days covering the period of growth, 250 days more covering the period of middle age, and nearly a similar number of days covering the period of old age), and the cost of feeding them was within the capacity of a scientific institution.

**Transplantation and Examination of Tissues and Organs.**—Dr. ROSS G. HARRISON of New Haven stated that at the time the experiments were made the embryos had no nervous system and that the number of successful operations were nearly 100 per cent. He remarked that as there was no muscular contraction it was unnecessary to give an anesthetic to overcome any sudden movements; also they did not suffer any great amount of pain, as it was assumed they had no nervous system. The embryos were operated on under a binocular microscope and the parts brought together and held in position; they had lived for weeks afterward and even grown remarkably. He said that a union of parts of different species was often useful for experimental purposes, and that the cells being each of different color enabled one to follow the development and growth more accurately. Muscle tissue that was entirely undifferential when taken out of the embryo had been found to differentiate without the presence of any other tissue whatever. Dr. Harrison remarked that a method had been devised whereby it was possible to obtain large quantities of plasms with which to carry on experiments concerning the processes of growth.

**Cesarean Section.**—Dr. O. G. RAMSAY of New Haven exhibited a patient of twenty-one years, on whom he was about to do a cesarean operation. The pelvic organs were so small that he could not get the child's head to engage. She had gone into labor the night before, which had dilated the cervix, making it unnecessary for them to bother with drainage. Dr. Ramsay had tried an experiment with the patient, having given her ergot before she took the ether, to see what it would do for the contraction, as many of those cases bled badly because the uterus would not contract properly. He stated that he usually employed the high incision, taking the umbilicus as the median point, since by so doing there was less chance for adhesions to form and of injuring the bladder. The baby could be gotten at just as well as through the lower incision. He mentioned one case of infection they had had among the cesarean sections from letting the uterus lie against the bladder wall. It was his opinion that some day that operation would be very popular, being, to his notion, much easier than other procedures.

**Exophthalmic Goiter.**—Dr. J. M. FLINT of New Haven showed a patient, a woman of thirty-eight years, with subacute hyperthyroidism in exophthalmic goiter. She was to be operated on. Her physical examination had

shown few [illegible] symptoms, there was no mononucleosis, which usually was associated with the more serious cases. A general anesthetic was used. Dr. Flint said he always used pharyngeal anesthesia in head and neck cases and in those in which the patient was inverted and the anesthetist had to work at a disadvantage. Its chief recommendation was that the anesthetist was not in the surgeon's way, the former being able to sit at some distance. The patient had a relatively small goiter, the right lobe being chiefly involved. It was soft and had no palpable thrill. There was no evidence of thymus persistence.

**The Luetin Reactions.**—Dr. J. B. SULLIVAN of New Haven displayed a patient with a pustular type of syphilis. The woman had had an initial lesion of the breast two years before, caused by nursing a neighbor's child. Six months ago the Wassermann test had been positive. She had been given four injections of Salvarsan and mercury, after which four negative Wassermann tests had been secured. Later it had been found that the luetin reaction was strongly positive, which meant she still had syphilis. Another patient was shown with specific prostatitis. His Wassermann was positive. A third patient had a lesion of the soft palate that had been thought at first to be a malignant growth. After the administration of salvarsan and strong mercury he had shown a papular and almost pustular reaction. A babe was shown from the Children's Clinic. It had ulcers around the rectum and bad teeth, but no spirochetes were found from the lesions; however, the mother's Wassermann was triply positive, while the luetin was negative, whereas the baby's luetin was positive. Dr. Sullivan advised using every test possible, it being his belief that at some stages of the disease all tests were not positive.

**Fractures of the Clavicle.**—Dr. W. E. HARTSHORN of New Haven said that they had had quite a problem presented to them in the treating of fractures of the clavicle at the dispensary. He had found it impossible to reduce the deformity with the ordinary plaster dressings. The Sayre dressings had been unsuccessful, after which he had adopted the Collins, following later with the Bellamy method, which, while better than the others, was not adequate. Lastly he had tried the Peckham dressing and had found that it worked splendidly with children. It not only reduced the deformity, but was comfortable to wear and could be put on over the clothing.

**Apparatus for Suction and Aspiration in the Treatment of Empyema.**—Dr. J. M. FLINT of New Haven exhibited an empyema tube which he had devised six years before that had given excellent results. He said it was like an ordinary empyema tube, but had a large rubber dam. They operated on all cases under novocaine. He explained that the stitches were left untied, the apparatus being inserted up to the hilt. The rubber dam was pulled backwards and the wound closed with silkworm gut. The chest wall near the thoracotomy was smeared with ointment, the rubber dam folded against the chest and covered with gauze. Near the center overlapping strips of adhesive were placed, making an absolutely air-tight job. Dr. Flint said that the use of the Politzer bag was impossible in cases where empyema was associated with bronchial fistula, because the leak through the bronchus caused the bag to collapse. He had devised a water vacuum to obviate that difficulty. He stated that the apparatus could be carried around by the patient while attending to business.

**Apparatus for Aspiration and Irrigation of Joints.**—Dr. J. W. CHURCHMAN of New Haven said that the spinal cord and the joints presented unsolved problems as regarded surgical treatment. Formerly, it had been the custom to apply incision and drainage in their treatment the same as to the treatment of infection elsewhere. It was soon realized that that would not do, for if organisms got into the mucous membrane below the surface, it was impossible to dislodge them, particularly if they had penetrated to the base of the mucous membrane. He knew of no antiseptic that would kill the organisms without destroying the membrane itself. Dr. Churchman exhibited an apparatus which he said would—with perfect technique—enable them to aspirate a joint, washing it out and distending it at the same time; thus permitting the material to reach all the recesses of the joint. Any fluid might be used without exposing the joint to subsequent infection. He stated that they aimed to fill not only the space between the bones, but also all of the interstices, and described the apparatus as consisting of a series of tubes which connected, through common openings, with the tube inserted into the joint and with the leading tube connected with the pump. The pump provided both force and suction power. The apparatus could be autoclaved, just as it stood. Dr. Churchman explained that they first cleaned out the joint, drawing off all pus, then they used an irrigating fluid. He had used this method in two cases of arthritis, the results being very satisfactory, in fact the second case was a complete cure.

**Gentian Violet in Surgery; Influence of Gentian on Tissue Cultures.**—Dr. J. W. CHURCHMAN of New Haven explained that there was a marked bactericidal action possessed by gentian violet dye. At the present time it could not be injected into the body, because if doses sufficient to kill germs were given, the animal changed the stain within two hours, rendering it harmless to the organisms. He thought this very fact might prove of great value in the future because if you could make the stain reach the organisms and stay unchanged long enough to kill them, the body then changing the stain and getting rid of it, you would have a very remarkable antiseptic. He said they had some cultures of tissue growing in gentian violet, absolutely unimpaired, showing that it did not impair tissue growth. The difficulty seemed to be to get the substance in contact with the organisms. Could that be done with this or some similar material, it was his opinion that it would be of great use in surgery.

**Stitch Ulcers after Gastroenterostomy.**—Dr. J. M. FLINT of New Haven said that his investigations had led him to believe that stitch ulcers of the jejunum, following gastroenterostomy, were due either to sloughing out of the stitch or to changes in the circulation that the stitch had produced.

**Facial Hemiatrophy.**—Dr. MAX MAILHOUSE of New Haven stated that facial hemiatrophy was a rare disease and usually occurred between the ages of ten and twenty years. He showed a case, a man, in which it had started at the age of eighteen, with some discolored spots. His family history was entirely negative and there was nothing specific in the case. No beard would grow on the right side of the face, but beard grew on the left; his mouth was drawn to the right side, there was marked atrophy of the right side of the tongue and also of the palate; but he had no difficulty in swallowing. The pathology was unknown. It seemed that Starr classified the case under fifth-nerve affections, but Dr. Mailhouse did not think that could be right. There was a question in his mind as to whether there might not be some pituitary disturbance, as there was considerable difference in the size of the patient's right hand when compared with his left. It was much larger.

**Acromegaly.**—Dr. OLIVER T. OSBORNE of New Haven exhibited a patient with acromegaly. Although there were no serious symptoms, he had developed the disease of recent years and showed a perfectly typical hand and face. The jaw came forward. Dr. Osborne explained that usually hypertrophy of the soft tissues went on all the time, but such had not been the case with the present patient. He said that acromegaly meant increased secretion of the pituitary gland, and described the gland as having three parts, the anterior, the middle, and the posterior. Should the anterior lobe be removed the animal would die, but if even a portion of it were left the animal would live. Whereas, if the anterior part of the gland hyper-secreted there would be a condition of bone growth. If that happened when the human animal was young, before the cartilages of the epiphyses had united, the person would become a giant. He stated that those patients lived from ten to twenty years and usually died from circulatory weakness and cardiac failure. There was no treatment that was curative, so far as he knew.

**Clinical Tests.**—Dr. WILDER TILESTON of New Haven stated that among the numerous methods devised for the estimation of various substances in the blood the following were the most important: The methods for estimation of cholesterin in the blood; sugar in diabetes; of uric acid; and lastly, that of estimating the nonprotein nitrogen in the urea. He dealt largely with the last named. Stating, that in health the method had but little effect, the chief interest centering around nephritis and other kidney diseases. They had examined many such cases. One uremic case showed the effect of diet on the total nitrogen. There had been 56 mgm. of non-protein nitrogen at first. After a few days of low protein diet, it had sunk to 24 mgm. No case which showed very high figures lived more than a

few weeks. The doctor felt that this estimation promised to be of value in hypertrophy of the prostate where operation was considered, though he thought it unwise to operate on a case showing as high as 75 mgm. He had also proven lead to have an injurious effect on the kidneys. Acute intestinal obstruction was the only disease not of the kidney that showed a marked increase. In syphilis they had found a marked increase in many cases, indicating that the kidneys were often more affected than had hitherto been supposed. He said that the value of the method from the standpoint of diagnosis and prognosis was very apparent.

**Pericarditis.**—Dr. GEORGE BLUMER of New Haven spoke of some points that had come up in his experience with pericarditis, especially pericarditis with effusion. He said it was often only recognized on the autopsy table and was frequently found unexpectedly in routine examinations. They had had two or three cases in which the effusion was undoubtedly proved, and in which the apex impulse did not disappear. He observed that the presence of pericardial friction sound did not rule out pericarditis with effusion; and that one was apt to mistake extensive effusion with consolidation, for pleurisy with effusion. In fact he had tapped the pericardium once in mistake for the pleura. He felt the *x*-ray was valuable, not only in diagnosis, but as an indication of where to tap the patient. Dr. Blumer exhibited a little boy who had entered the ward with rheumatic endocarditis, and pointed out the right border of the heart, showing that there was no effusion at the base. The boy had recovered after the tapping. The doctor told of one case where they had tapped and the dulness had persisted. On tapping the pleura it was found that there was pleurisy.

**Officers.**—The following officers were elected: *President*, Dr. Oliver C. Smith, Hartford; *Vice-Presidents*, Dr. Stephan J. Maher, New Haven and Dr. John B. Kent, Putnam; *Secretary*, Dr. M. McR. Scarbrough, New Haven; *Treasurer*, Dr. Jos. H. Townsend, New Haven. The next annual meeting will be held at Hartford, on the third Wednesday and Thursday of May, 1915.

## MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting, April* 20, 1914.

THE PRESIDENT, DR. THOMAS S. SOUTHWORTH, IN THE CHAIR.

**Chronic Intestinal Stasis—Presentation of Cases Illustrating the "End Group."**—Dr. HAROLD D. MEEKER presented two cases: one after ileocolostomy, and one after gastroenterostomy and ileocolostomy. The first case was that of a gentleman 31 years old who was seen for the first time in May, 1912. He had had more or less digestive disturbance for ten years; growing slowly but progressively worse. He suffered from eructations and pyrosis, and the worst symptom was pain in the right hypochondriac region, most severe two or three hours after eating. Frequently he lived for several weeks at a time on milk and eggs. He was depressed, had headaches, suffered greatly from constipation, and was steadily losing weight. On two occasions he had discovered blood in his stools. On examination, Dr. Meeker found him a poorly nourished man, weighing 142 pounds, with a heavily coated tongue, a sallow, almost saffron-colored complexion, loose, dry skin, and cold extremities. Over the abdomen there was a general soreness, with a point of maximum tenderness in the right hypochondriac region. Aside from a low urea output and a large indican content, the urine was normal. Clinically, the patient presented the picture of chronic intestinal stasis, with a probable duodenal ulcer. He was referred to Dr. L. G. Cole for radiographic examination, and Dr. Cole reported that from a study of a series of stomach and intestinal plates taken he felt justified in excluding a new growth. There was, however, a very definite lesion, involving the extreme pyloric end of the stomach, on the lesser curvature. He believed this to be caused by adhesions following a gastric or duodenal ulcer, though there was a slight possibility that it was due to adhesions from the gall-bladder. There was a distinct narrowing of the pylorus, causing bismuth to remain in the stomach seven hours after ingestion. There was evidence of stasis all along the intestinal canal, with a dilated terminal ileum and an obstruction near the ileo-cecal valve. There was also a kink in the first portion of the transverse colon, in the region of the gall-bladder. The patient was operated upon at the Red Cross Hospital on January 13, 1913; when the following condition was found: A portion of the great omentum, twisted upon itself, was firmly adherent to the first portion of the duodenum. Upon separation of the adhesions it was found that this structure formed the anterior wall of the gut over an area 1½ inches long and half an inch wide, where the normal wall had been destroyed by ulcerations. The duodenum was sectioned at the upper and lower limits of the ulcerated area, the ends closed, and a posterior no-loop gastrojejunostomy performed. Further inspection revealed a broad band fixing the terminal ileum, which caused a marked kink when the patient was in the upright position. The colon was dilated, and the last portion of the transverse colon was firmly adherent to the ascending colon by an apparent extension of the so-called Jackson's membrane. Clearly this case had passed beyond the "mid group," of cases of stasis, and, feeling confident that a gastrojejunostomy would not effect a cure unless proper intestinal drainage was provided for, Dr. Meeker then performed an ileocolostomy, the short-circuiting operation. This patient was here to speak for himself. He now weighed 170 pounds, ate anything he fancied, suffered from no pain or gas, and had a bowel movement once or twice daily without the use of medicine. The second case was that of a married lady, 31 years old, who was seen for the first time in November, 1913. She had suffered, ever since she could remember, from "stomach trouble," which manifested itself in occasional pain after eating, frequent eructations, and large quantities of gas in the intestine as well as the stomach. Her bowels were obstinately constipated, and she had not had a natural movement for many years. She was nervous, irritable and depressed, and had a sallow complexion, dry skin, and lumpy breasts. There was general abdominal tenderness, especially marked over the points of normal bowel fixation and in the epigastrium just to the right of the median line. The radiographic examination was made by Dr. A. Judson Quimby, who reported that he found some gastric spasm and a slight deformity on the lesser curvature of the stomach, near the pylorus. The first and second portions of the duodenum were dilated, and there was also some dilatation in the third portion. The ileum was constricted about five cm. from the ileo-cecal valve, which was patulous. When the rectum and sigmoid were not distended, the cecum rested in the left anterior cul-de-sac, but could be pushed upward from the position. The appendix crossed the ileum where it was constricted, and moved with the ileum at this point, though the remainder of its shaft and the tip were movable independently of other structures. The cecum and ascending colon were for the most part dilated, but in the ascending colon near the hepatic flexure there was a decrease of calibre, with limited motility. The pelvic signoid was moderately redundant, with slight interference within it, and the rectum was dilated. The radiographic diagnosis was: Probable small ulcer on the lesser curvature of the stomach, near the pylorus; dilated duodenum, due to mechanical interference at the apex of the conus duodenalis and the juncture of the duodenum and jejunum; moderate ileal stasis, due to constriction of the ileum from an adherent appendix; patulous ileocecal valve—the low position of the cecum aiding in the draining of the ileum; non-functionating, adherent appendix; dilated cecum and ascending colon, due to interference near the hepatic flexure caused by a mesenteric band or contracted mesentery reducing the acute angle—obstructive only when patient is erect; redundant pelvic sigmoid; dilated rectum. The patient was operated upon at the Red Cross Hospital on January 22, 1914. The scar of an old ulcer was found near the lesser curvature of the stomach, four c.m. from the pylorus, and adherent to this was a band extending to the great omentum and causing a marked kink in the transverse colon. The band was divided, the scar of the ulcer excised by an incision parallel with the long axis of the stomach, and the incision closed in the opposite direction, in order to overcome the cicatricial contraction of the old ulcer. The obstruction causing the dilatation of the duodenum was immediately relieved when bands which Dr. Meeker believed had best be called evolutionary, causing a greatly exaggerated duodeno-jejunal angle, were divided. The condition of the appendix had been accurately described in the radiological report. The fixation of the terminal ileum, however, was due, not so much to the adherent

appendix, as to a firm, broad, so-called Lane band. The diseased appendix was removed, and an ileocolostomy was performed; the technique followed being in general that of Lane. The convalescence of the patient (who was present) had been uneventful, and to-day she was bright and happy, having a good appetite and walking five or six miles a day.

Dr. SIDNEY H. GARDINER also presented a patient in good health upon whom he had done an ileocolostomy for marked stasis, and related the history of the case.

Dr. WILLIAM SEAMAN BAINBRIDGE said that, as he had stated at the December meeting of the Association, the cases of chronic intestinal stasis could be classified in a broad way under three groups. The first, in which surgery was unnecessary, was the medical group, and in the third, or end, group either short-circuiting or a colectomy was required. Between these two there was a middle group in which it was possible to "patch up" the drainage system, and thus effect a cure. The cases which he had then presented belonged to this mid group; but as at that time some skepticism was expressed as to the results which were obtained in cases of the end group, he had thought it might be of interest to show some actual cures which had been effected by the radical procedures called for in this class, and he had therefore asked Dr. Meeker and Dr. Gardiner to present the patients who had now been seen. Dr. Bainbridge then described two cases of his own in which complete restoration to health had resulted, and also presented the patients. Both were cases of extreme stasis, and in one he had done an ileocolostomy and in the other a colectomy. In the latter instance the operation was performed more than five years ago, and the patient had been in perfect health ever since.

**Radiological Demonstration of the Changes Found in Chronic Intestinal Stasis.**—Dr. ALFRED C. JORDAN, medical radiographer to Guy's Hospital, London, delivered an address on this subject, which was illustrated by many lantern slides. (Will be published later.)

**On Thyroid Deficiency.**—Dr. EUGENE HERTOGHE of Antwerp made an address with this title. (Will be published later.)

Dr. JOHN ROGERS said that myxedema seemed to represent a terminal stage of a process which showed many variations. Some types of myxedema were much more easily remedied than others, and only a few cases were susceptible of the perfect results described by Dr. Hertoghe. He apparently used in treatment the desiccated thyroid gland substance, but much better preparations were now available. These would help many more cases than formerly could be remedied. Occasionally, improvement could be obtained from the hypodermic injection of thyroid. The relations of the thyroid gland to other organs were often shown in the field of the gynecologist, and sometimes, instead of menorrhagia, we found amenorrhea as the result of thyroid deficiency. The problems of the thyroid were therefore very difficult of solution. In certain conditions almost any kind of preparation seemed to be of service, and, again, in others thyroid administration proved hurtful. As far as we knew at present, the active constituent of the gland appeared to be a protein associated with iodine, and it was a fact that in experimentation upon animals which had not been fed with thyroid or iodine the only part of the body (except in one or two very doubtful instances) in which iodine was found was the thyroid gland. Search was still going on for the active constituent, and recent experiments, in which he himself was participating, with a thyroid derivative showed some curious and apparently contradictory results. The calorimeter was employed to indicate the oxygen consumption, and in one of two cases which seemed to be very much alike which were treated with this derivative there was a fifty per cent. increase, while in the other there was a decrease of twenty per cent. Thyroid disease had been found to be accompanied by disturbances in two or three groups of nerves. Thus it sometimes affected the autonomic system, and sometimes the sympathetic. The whole subject of the internal secretions was still involved in much obscurity and the question arose, Are these internal gland mills in which the inorganic elements of the body are metabolized in order to perform their work? If once the problems of the ductless glands were mastered, it looked almost as if we would have found the solution of old age and of life itself.

Dr. C. AM ENDE said that it had been demonstrated by Dr. Rogers that the thyroid gland contains two active constituents, a globulin and a nucleo-albumin, and that it is the latter which produces the symptoms of hyperthyroidism. Both were closely related chemically, and the structure of the globulin atom was so delicate that such an effect as that produced by a few degrees' rise of temperature would cause in it sufficient molecular changes to reduce it to the nucleo-albumin. As this process was necessarily a gradual one, it would serve to explain much. The speaker then referred to the important effect obtainable in the elimination of the depressing toxins of carcinomatous disease by means of a fluid extract of thyroids prepared without heat or drying, given in teaspoonful doses once a day, or at first twice daily. This produced marked relief of pain and a considerable improvement in the general condition resulting in prolongation of life. One of the most striking examples of this good effect which he had met with was the case of a lady referred to him by Dr. J. C. Taylor. A panhysterectomy for adenocarcinoma had been followed by profuse hemorrhages, which were not completely controlled by the application of the Paquelin cautery. When she was transferred to Dr. Am Ende's care she was so weak that she had to be lifted from her couch to the table, for local treatment. On account of the hemorrhagic condition she was at first given very small doses of the thyroid fluid extract, but the amount was increased later, and under this and x-ray treatment she gradually improved until at last she was able to walk a considerable distance. Unfortunately, as the result of exposure to a violent snow storm she contracted a general peritonitis, which in ten days proved fatal. Having cited other cases in which this treatment had proved of service, he said that as to the mode of action of thyroid substance, it was to be noted that it increases the heart's action, but lowers blood-pressure; a seeming anomaly, since increased cardiac action should (and especially in arteriosclerosis) induce or increase hypertension. He offered as an apparently satisfactory hypothesis the conjecture that the process begins in the blood-vessels, through relaxation of the vasoconstrictors, and that the heart's action in refilling the more easily emptying arteries is secondary.

Dr BAINBRIDGE described some experiments made in the transplantation of the thyroid when he was in Berne in 1900, and stated that after a year or so there was scarcely a trace of the transplanted gland in any of the eighteen cases in which the procedure had been tried. Afterwards he had gone to Antwerp, and, in walking about the streets with Professor Hertoghe, he had seen that it was possible to pick out, simply from their appearance, numerous persons whose maximum efficiency was not what it ought to have been, for the reason that they suffered from thyroid deficiency. It was undoubtedly the fact that in the case of a large number of individuals the administration of a little thyroid would be followed by good results, and when that halcyon time had come when the gospel of Hertoghe was universally accepted and appreciated we should see very much less of the evil effects of hypothyroidism than at present.

Dr. HERTOGHE, in closing, said he could by no means agree with Dr. Rogers, who had expressed the views of Leopold-Levy and Rothschild, in Europe, who had brought forward the idea of what they called thyroid instability. They claimed that certain patients suffering from thyroid deficiency would, after the administration of thyroid extract, straightway become affected with hyperthyroidism. It was not difficult to explain, however, how these eminent authorities had fallen into this error of thyroid instability. When thyroid was given to a hypothyroid patient, infiltrated material promptly began to be absorbed. If this took place slowly, all was well; but if too rapidly, the sudden removal of such infiltrated material would produce pain and other symptoms more acute, even, than those present before the treatment was commenced. Thus cardiac pains and palpitation were often increased by a few, but too large doses of thyroid extract, and we had a condition simulating hyperthyroidism. In fact, however, it was simply one due to too rapid absorption. Intense and sudden oxidation of the accumulated waste matter might also assist in producing such a condition. Rise of temperature was nearly always observed under intensive thyroid treatment, and this increase in body heat had been mistakenly considered as due to hyperthyroidism. If, in cases of thyroid deficiency, we were always careful to use moderation in our dosage, we would not meet with any of the disastrous results referred to. It was a good rule not to attempt to get rid of more than from five to seven ounces of infiltration a day.

# INDEX.

A

Abbe, R., a simple subcutaneous cut to cure "trigger finger" or "snap finger," 426.

Abderhalden reaction, 43, 633; clinical studies with, 312; in dementia, 1088; in malignant tumors, 68; in pregnancy, 489, 493, 951; in psychiatry, 493.

Abdomen, emergencies of, triple syndrome in, 213; extensive wound of, 267; strengthening, 260; surgery of, 360.

Abrahams, R., medical management of exophthalmic goiter, 1122.

Abscess, beginning in lower incisor and pointing in submental region, 545; liver, multiple metastatic, surgery of, 125; orbital, from infection through the ethmoid, 29; subpectoral, 18.

Accident insurance, 999; against blood poisoning, 390; relation of, to medical profession, 44.

Accidents, and sports, 354; and the surgeon, 450; professional, from radioactive substances, 816.

Accouchement by hysterectomy, without preliminary opening of the uterus, 623.

Achondroplasia, nature of, 896.

Acidosis, recent investigations on, 1126.

Aconite as a vasodilator, 1052.

Acromion process, fractures of, 525.

Actinomycosis of cheek treated by parenchymatous injections of formalin, 114.

Adenitis, epidemic cervical, with cardiac complications, 537.

Adenocarcinoma cured by curetting, 589.

Adenoids, and tonsils in children, 862; in children, 862; recurrence of, influence of diet on, 869.

Adenoma of colon, 727; of prostate, 471; of prostate, toxicity of, 763.

Adenomyoma of rectovaginal septum, 220, 580.

Adolescents, albuminuria and glycosuria of, 581.

Adrenal insufficiency, 1187.

Aeronautics and its psychical effects, 1177.

Aeroplanes for conveying wounded in warfare, 256.

Age, brain structures according to, 227; old, and cancer, 125; old, nature of, 115.

Agglutination of *M. melitensis* by normal cow's milk, 633.

Agnosticism in medicine, 552.

Air, as vehicle of infection, 353; douche, hot, in treatment of suppurating wounds, 122.

Albumin, in urine, test for, 725; reaction in sputum, 1041; water, malapplications of, as a nursling food, 171.

Albuminuria, and glycosuria of adolescents, 581; slight or transient, prognostic value of, 491.

Alcohol, and racial degeneracy, 102; and tobacco, effect of, on life expectancy, 1093; effect of, on longevity, 910. housing conditions and tuberculosis, 582; injection of, into Gasserian ganglion, treatment of trificial neuralgia, 1116; wood, proposed tax on, 439.

Alcoholism, acute, institutional requirements for, 75; in German women, 1045.

Aliens, defective, and the Healy puzzle picture, 197.

Alopecia, permanent following *x*-ray treatment for tinea tonsurans, 113.

Amberg, E., injuries of inner ear, 1120.

Amblyopia, tobacco, 980.

American Medical Association; election of officers, 1196; president's address, 1151; report of committee on anesthesia, 1183; report of committee on constitution and by-laws, 1186; report of committee on nomenclature and classification of diseases, 1183; report of committee on Red Cross medical work, 1183; report of committee on scientific exhibition, 1183; report of committee to advise with the British Medical Association regarding a joint meeting with the American Medical Association, 1184; report of committee to consider mode of commemoration of the completion of the Panama Canal, 1184; report of council on health and public instruction, 1183; report of council on medical education, 1182, 1184; report of judicial council, 1182; report of subcommittee on uniform membership, 1184; report of the board of trustees, 1181; report of the secretary, 1181; Section in Medicine, 1187; Section in Obstetrics and Gynecology, 1190; Section in Pediatrics, 1194; Section in Surgery, 1192

Amnesia, after slight commatio cerebri, 909; twilight state and subsequent, after slight concussion of brain, 263.

Amputation, intrauterine, 1051; of leg, 774; of leg and foot, 774 and 775.

Amsden, H. H., Vincent's angina, treated with neosalvarsan, 848.

Anaphylaxis, drug, 816; occurring in horse asthma, 1087.

Anarthria and its relation to aphasia, 995.

Anastomosis, arterial, 781.

Anatomy, and its important relation to the development of surgical knowledge, 375.

Anemia, as an operative risk, 225; enlargement of spleen, hemorrhage, with oral sepsis, 114; pernicious, 1050; pernicious, and pregnancy, 816; pernicious, problem of, 712; pernicious, splenectomy for, 1049; pernicious, treatment of, by splenectomy, 768, 1160; septic, 539; severe, with aphasia and hemianopsia, 32; splenomegaly with, in a syphilitic patient, 593.

Anesthesia, ether-oil rectal, some theoretical considerations, 839; general, by ether-oil method, 269; local after-pains in, prevention of, 998: local, in rectal cases, 949.

Anesthetics, administration of, trained nurses in, 1088.

Anesthetist, standard education qualification for the, 389.

Aneurysm, aortic, recurrent fever in, 1050; large, of aorta without symptoms, 688; of sinus of Valsalva, 1176; subclavian, ligation of innominate artery, 1145.

Angina, Vincent's, 1085; Vincent's, treated with neosalvarsan, 848.
Angioma, of brain, 1007; of synovial membrane of elbow, 66.
Angioneurotic edema, 1029.
Ankylosis of the mandible, operative treatment of, 365; open treatment of, 169.
Anoci-association, 169.
Anthropology of Shakespeare and Burns, 582.
Antagonism, pathological, and its relation to diabetes mellitus, 646.
Anthrax, simple treatment of, 205.
"Antifat" cures, electrical, critique of, 263.
Antigen, cholesterinized, 949.
Antiperistalsis, and colonic peristalsis, *x*-ray observations, 416.
Antipyretic, camphor as, in pulmonary tuberculosis, 32.
Antiseptics versus germicides, 269.
Antityphoid vaccination, 401.
Antivivisection romance, another, 484.
Anus, pruritus of, 1062.
Aorta, embolism of, mitral stenosis, cardiac thrombosis and gangrene of both legs, 492; embolus of, successful removal of, 115; large aneurysm of, without symptoms, 688; sclerosis of, impulse of blood column in the subclavian arteries as sign of, 538.
Aphasia, anarthria and its relation to, 995; and hemianopsia, severe anemia with, 32; in relation, to apraxia, 995; relation of, to mental disease, 948; sensorimotor, 948; theories of, 904.
Aphthæ tropicæ, 992.
Apoplexy, caused by cerebral hemorrhage and by vascular occlusion, comparison of onset and character of, 906; cerebral, diagnosis of, 952.
Appendicitis, acute, infancy and childhood, 9; and tonsillitis, 992; operative mortality in, 813; radiology and chronic, 78; treatment of, operative and postoperative, 813.
Appendix, cyst of the, 271; foreign bodies in, 308; pus, treatment of, 44; removal of, 504; retroperitoneal hernia of, into ileoappendicular fossa, 937; stump, stitch for inverting, 594; tenia saginata in, 729.
Apraxia in relation to asphasia, 995.
Arm and scapula, divulsion of, 985; divulsion of, 1085.
Armament, recent types of, gunshot wounds under, 803.
Arsenic, toleration of, 309.
Art, doctor in, 230.
Arteries, anomalous renal, 251; gunshot injuries of, 7; hypertension of, 1165; sclerosis of, see arteriosclerosis.
Arteriosclerosis, 676; as the orthopedist views it, 797; etymology, 718; experimental, 1050; iodotherapy of, 953; of kidney and hematuria, 122.
Artery, pulmonary, embolism of, 1138, pulmonary, stenosis of, 83.
Arthritis, chronic, 447; chronic, uric acid in relation to, 392; deformans etiology of, 765; gonorrheal metastatis, 763; gonorrheal, tuberculous soil in, 92.
Ascites, eosinophile, 354; permanent drainage in, 1128.
Asphyxia neonatorum and its sequelæ, 868.
Asthma, clinical study of, 675; horse, anaphylactic reactions occurring in, 1087.
Ataxia, cerebellar, 1167; Friedreich's, in America, first observed cases of, 431; locomotor, see tabes.
Atrophy, neural, of small muscles of hand, without sensory disturbances, 824.
Auditory canal, hypernephroma of, 992.
Auscultation, clinical observations of, at the acromion process, 201.
Austin, C. K., cholesterinemic index, 1071; eclampsia, with total absence of albumin, but generalized hard edema, 384; isoserum treatment of incoercible vomiting of pregnancy, 705.
Autointoxication and sub-infection, 310.
Automobile, choice of an, 138; danger in winter, 322; smallest essential part of, 552.
Autonomy, territorial, in cerebral circulation and the psychoneuroses, 994.
Aviation, first aid in, 552.
Avicenna's tomb, 1132.

B

Backache, chronic, causes and treatment of, 1041.
Bacillus, adhesion-producing, 489, 533; Bulgarian, in infantile gastroenteritis, 159; coli as cause of septic onychia, 1090; coli, brain abscess due to, 249; coli complicating pregnancy, labor, and the puerperal state, 868; lactic acid, in diphtheria, 1135; tubercle, problem of, 69.
Bacteria, and bacterial proliferations in dairy products, 889; and blood parasites, diagnosis of, 129; isolated from non-ulcerating cancerous growths, 828; infection, due to, spread of, absorption, 577.
Bacteriemia and Bright's disease, 292.
Baker, S. J., the physical condition of retarded school children, 64.
Baldness, premature, 506.
Balfour, D. C., care of surgical patients, 378.
Ballard, I. W.; arterial hypertension, its clinical significance and latter day treatment, 1165; lacerated cervix uteri and reflex irritation, 800.
Bangs, L. B., cicatrix of bladder relieved by fulguration, 1.
Bassler, A., a cause of peritoneal adhesions in new bacillus, the *Bacillus adhæsioformis*, 427; the adhesion-producing bacillus, 533.
Bazin's disease, 250.
Beer, E., adenoma of the prostate, 461.
Benedict, A. L., cancer statistics, 707.
Benzine poisoning, 404.
Benzinomania, 992.
Benzol, in treatment of leucemia, 46; in treatment of polycythemia rubra, 905; inhalations and pulmonary tuberculosis in rabbits, 1051.
Beriberi, 186; rice polishings in prophylaxis of, 993.
Berkeley, W. N., results of three years clinical work with new antiserum for cancer, 741; the use of pineal gland in the treatment of certain classes of defective children, 1.
Berlin, W. C. K., bacteriemia, infection, and Bright's disease, 292.
Bernstein, E. P., brain abscess due to the *Bacillus coli communis*, 249.
Besredka's antigen in tuberculous disease, 1089.
Best, W. H., salvarsan in non-syphilitic diseases, 802.
Bichloride of mercury poisoning, prevention of, 1058.
Bile duct, common, drainage versus immediate suture of, 905; repair of, by means of transplanted fascia, 455.
Bile passages, obstruction, of, terminal results of, 221.
Birdsall, E., *x*-ray treatment of myoma, 892.
Birth fractures, 87.
Bismuth, meals, 28; paste, active ingredients of, 79.
Blackwater fever, 859.
Bladder, calculus of, 268; cicatrix of, relieved by fulguration, 619; fistulæ of, treatment of, at the vaginal vault following surgical operations, 221; herpes zoster of, 445; inoperable carcinoma of, palliative treatment of, 360; non-papillary benign tumors of, 505; villous tumors of, treated with high frequency currents, 1170.
Blake, J. A., a method for plicating voluminous ceca, 1.
Blastomycosis, and coccidioidal disease, 1051; systemic, 1143.
Blepharoplasty, by a pregrafted flap, 1147.
Blindness, hysterical, 170.
Blood, cells, red, see erythrocytes; circulating, tubercle bacilli in, 1082; changes in causation of surgical shock, 633; changes in hay fever, 1177; coagulation and thyroid, 251; direct transfusion of, in treatment of hyperemesis gravidarum, 46; disturbances of chemical relations of, 856; in whooping-cough, 538; passing during transfusion, method for determining, 535; poisoning, accident insurance against, 390; reaction after cancer inoculation, 1127; reactions, changes in, 1176; splenectomy in diseases of, 1146; sugar content of, 631; transfusion in diabetes mellitus, 675; transfusion of direct and indirect, 913; transfusion of, use of hirudin in, 1136; vessels, surgical repair of; its technique, its uses and limitations, 219.
Blood pressure, 857; determination of, and life insurance, 634; determination of, as aid in diagnosis and prognosis in certain diseases, 561; importance of, in life insurance, 678; low, 535.
Boehme, G. F., "tango-foot," 755.
Bone graft inlay, in fresh fractures, 1040; lesions, heredity in, 353; necrosis, sequester formation, 357; sarcoma of, 1142; second metatarsal, infraction of the, 271; tuberculous foci in, 1147.

Eclampsia, puerperal, surgery of, 506; with total absence of albumin, but generalized, hard edema, 384.
Eczema in infancy and childhood, causes and treatment of, 871.
Edema, and varicosities of the lower limb, new operation for, 79; angioneurotic, 1029; eclampsia with total absence of albumin, but generalized, hard, 384.
Education, medical, 214; medical, standardization of, 543; of crippled children, 175; of deaf and dumb, 921; of high-grade defectives, 588.
Einhorn, M., an appliance for the introduction of instruments into the stomach, 430.
Electricity in abortive treatment of gonorrhea, 1168.
Electrocardiogram, congenital pulmonary stenosis with, 83; form of; diagnostic significance of its variations, 594.
Electrotherapeutics, 976; failures of, 319.
Embolus, successful removal of, from abdominal aorta, 115.
Emetine, in dysentery, 259, 315, 400, 402; in hemoptysis, 46.
Employment, nature of, 1125.
Empyema, double and anomalous forms, 1146; surgical treatment of, 957.
Endarteritis, infective pulmonary, patent ductus arteriosus with, 1050.
Endocarditis, lenta, bacteriological cause of, 769; streptococci in relation to, 352.
Endophlebitis obliterans, of central retinal vein with resulting acute glaucoma, 792.
Energy standpoint, nutrition from the, 781.
Enzyme, proteolytic, in serum of normal and diseased subjects, 998.
Eosinophilia in adenoma of prostate, 763.
Epicondylitis or tennis elbow, 673.
Epidemiology of rhinoscleroma, 312.
Epigastric puncture in treatment of pericarditis, 399.
Epilepsy, and migraine, relationship between, 533; and psychoanalysis, 822; and tuberculosis, 1042; crotalin in, 629; metabolism in, 624; research, 1137; sella turcica in, irregular bony formations of the, 227; therapeutic value of crotalin, in treatment of, 105; traumatic, cured by operation, 820; traumatic, of five years' duration cured by surgical treatment, 687.
Epitheliomas, cutaneous, radium treatment of, 949.
Epstein, S., arteriosclerosis as the orthopedist views it, 797.
Erysipelas, abortive treatment of, 1091; calcium chloride in, 1058; cases, statistical analysis of 1007; in nephritis, 32.
Erythema, infectiosum, Breslau epidemic of, 768; nodosum and tuberculosis, 907.
Erythrocytes, resistance of, studies on, 940.
Esophagoplasty, 170.
Esophagotracheal fistula, 86.
Esophagus, syphilitic paralysis of the, 354.
Ether, intratracheal insufflation of, 125; lavage, 261; lavage, in peritoneal infections, 482; oil method, general anesthesia by, 269.
Ethmoid, orbital abscess from infection through, 29.
Ethylhydrocuprein, effect of, on pneumococcus infection of eye, 114.
Eugenics, and gynecology, 584; case against, 109; legislation and, 24.
Eunuchoidism, late, cause of, 1092.
Eustachian tubes and ears, catarrhal conditions of, exact diagnosis, 468.
Examiner, medical, suggestions to, 313, 494, 634, 678, 770, 864, 954, 1046, 1179; state, viewpoint of, 544.
Examiners, Medical, American Association of, 1093, 1139.
Excitement, manic-depressive, mechanism of, 681.
Exophthalmic goiter, and its treatment, 912; medical history of, 903; medical management of, 1122; operative treatment of, 1042; streaked nephritis following, 1138; treatment of, elements frequently overlooked by surgeons in, 220.
Exostoses, multiple; an hereditary affection of the body skeleton, 453.
Experiments on man, respiratory, 765.
Experts, medical, 849.
Eye, and face movements, congenital insufficiency of, 126; and headache, 908; and heart defects, congenital, 20; filariasis of the, 263; pneumococcus infection of external tissues of, 114; salvarsan of, effect of, 489; sporotrichosis of, 766.

F

Face, keloid scars of, 223.
Fascia, transplanted, repair of common duct by means of, 455.
Fats and proteins, management of in infant feeding, 40.
Favus, mouse, in mankind, 32.
Feces, tubercle bacilli in, 483.
Federation of State Medical Examining Boards of United States, 543.
Feeble-minded, in New York, 529; women, study of, 1025.
Feeding, forced, in childhood, 583; rectal, 908.
Feet, mechanical support for, in tabes, 881.
Femur, fracture of neck of, 272; fractured, treated by, transfixation method, 1098; upper end of, osteoperiostitis of, 1012.
Ferments, defensive, 952; gastric, in the urine, 202.
Ferry, N. S., bacterial vaccines in scarlatina, 936; bacteriology of posterior nasopharynx in scarlatina, 934.
Fetus, microcephalic, at nine months, 86.
Fever, entericoid, 30; nervous, in tabes dorsalis, 171; recurrent in aortic aneurysm, 1051.
Fibrillation, auricular, in a child, 83; auricular, of traumatic origin, 1145.
Fibroids, uterine, see uterus.
Filariasis, 1040; of the eye, 263.
Finger, trigger, its cause and mechanism, 1061.
Fingers and hands, acute suppurative spreading infections of, surgery of, 957.
Fishbone in Steno's duct, 28.
Fistulæ, genital, in female, 15.
Flatfoot, 123.
Flatulence, gastric, relief of, 690.
Fleas and plague, 1081.
Flies, 809, 946.
Fluorescent screen, palpation under, 1059.
Folliculitis, depilating, treatment of, 920.
Food, changes in, caused by canning, 781; from standpoint of energy, 740; preservation of, refrigeration in, 667; refrigeration in the preservation of, 666.
Foodstuffs, different kinds of, nutritive significance of, 738, 781, 1188; specific dynamic action of, 1189.
Foot and leg, amputation of, 774 and 775.
Ford, J. S., treatment of pulmonary tuberculosis by induction of artificial pneumothorax, 793.
Formaldehyde, 674; parenchymatous injections of, actinomycosis of cheek treated by, 114.
Fossa, ileoappendicular, retroperitoneal hernia of appendix into, 937.
Fothergill medal, 671.
Fountain, a disease carrier, 671.
Fractures, birth, 87; compound surgery of, of the extremities, 913; cranial, surgery of, 913; fresh, inlay bone graft in, 1040; metal bone plating in, 212; non-reducing operations for, 729; of

acromion process, 528; of neck and upper end of femur, nonoperative treatment of, in adults, 914; of lower end of femur, 1135; of neck of femur, 272; of neck of femur without loss of functional power, 763; of patella, insert bone graft in, 988; of skull, *x*-ray diagnosis, 316; open, 212; open operation for, 272; operative treatment of, 491, 531, 536; treatment of, 211.
Frambesia, 727.
Francis, C. F. d'A., biological treatment for cancer, 848.
Freudenthal, W., management of laryngeal tuberculosis in sanatoria and private practice, 972.
Friedman, G. A., the typhus germ, 945; value of polycythemia for diagnosis of duodenal ulcer, based upon sixteen cases, 876.
Friedmann culture and Society of German Sanatorium Physicians, 717; injections of, 1064.
Friedreich's disease following diphtheria, 539.
Fuel, economy of, 460.
Fulguration, cicatrix of bladder, relieved by, 619.
Furunculosis, staphylococcus sepsis after, 355.

G

Gall-bladder, inflammation of, 861.
Gallstones, and cholecystitis, *x*-rays in diagnosis of, 861; complicating pregnancy and puerperium, 41; demonstration of, by *x*-ray, 903; formation, primary intrahepatic, 214.
Gangosa, 629.
Gangrene, of both legs, mitral stenosis, cardiac thrombosis, and aortic embolism, 492; of genitals, fulminating, 1127; of lung, 862; of lung, operation and recovery, 687.
Garbage, collection, 74; disposal of, 307.
Gas, bacillus infection, 453, 766.
Gases introduced into pleural cavity, therapeutic value of, 907.
Gastric crises, fecal vomiting in, 32.
Gastritis, chronic interstitial, 1049.
Gastroenterostomy, opening, function of, in permeable pylorus, 1146; treated by, pyloric stenosis in infancy, 1095.
Gastroscope inflating, and duodenoscope for inspection of organs through gastric incision, 636.
Gaucher's disease in a boy, 687.
Gelatin as hemostatic, 598.
Genesis of interstitial keratitis, 1045.
Genitals, fulminating gangrene of, 1127.
Germicides versus antiseptics, 269.
Gilmour, A. J., case of scleroderma, 246.
Glaucoma, 446, 1128; acute, endophlebitis obliterans of central retinal vein with resulting, 792.
Glioma of the cauda equina, 446.
Gluzinski's test, in gastric ulcer, 1144.
Glycerin, sulphate, magnesium and infections, treatment of, 401.
Glycosuria, adrenalin, 483; and albuminuria of adolescents, 581; and diabetes, treatment of, 860; in the course of affections of liver, 171; and life insurance, 313; exophthalmic, see exophthalmic goiter; surgical treatment of, 44; exophthalmic, see exophthalmic goiter; use of wire clamp in operations of, 452.
Gold, colloidal, precipitation of, 402.
Goldberger, L. A., scarlatina treated by vaccines and the method of Milne, 931.
Goldmann, death of, 205.
Goldwater, S. S., the distribution of duties among the Department of Health, the Department of Public Charities, and Bellevue and Allied Hospitals, 1001.
Gonorrhea, and suppurative disease of uterine adnexa, 20; antigonococcic serum in, 949; electricity in the abortive treatment of, 1168; thermotherapy of, 404.
Goodman, A. L., tuberculosis of the testicle, 146.
Gorgas, William C., medal of the American Medical Association presented to, 1186.
Gottheil, W. S., autoserum injections in certain obstinate dermatoses, 1.
Gout, atophan and radium emanations in, 1187; effective combination in, 690; and transplantations, 780; inlay bone, 212; in plastic surgery, 779; vascular, 780.
Granulomata, infective tropical, 1051.
Graves' disease, see exophthalmic goiter.
Greeley, H., cause and vaccine treatment of chronic rheumatism, 1076.
Greenwald, M., clinical observations of auscultation at the acromion process, 201.
Growth, benign and malignant, non-operative treatment, as seen at clinics abroad, 615; influence of nutriment on, 1137; studies on, 212.
Guaiacol poisoning by absorption, 1098.
Gwyn, M. K., the Healy puzzle picture and defective aliens, 197.
Gynecology, and eugenics, 584; radiotherapy in, 403.

H

Hagemann, J. A., the upper respiratory mucous membranes as emunctories, 296.
Haig, A., deficiency of chloride of sodium in the etiology of neurasthenia, 1017.
Hairpin, and stone in bladder, 500.
Hand, small muscles of, neural atrophy of, without sensory disturbances, 824.
Hansell, H. F., some further experiences in the extraction of immature cataract by the Homer C. Smith method, 108.
Harris, C. M., some important factors in the conservation of hearing, 461.
Harrower, H. R., Langerhansian hormone and hormone treatment of diabetes, 1112.
Hartwell, J. A., splenectomy, for pernicious anemia, report of a case, 1160.
Harvey, T. W., pituitary preparations in postoperative conditions, 525.
Hay fever, vaccination against, 907.
Hays, H., exact diagnosis by accurate instruments in the treatment of catarrhal conditions of the eustachian tubes and ears, 461.
Headache and the eye, 908.
Health, public, legislation against, 75.
Hearing, factors in the conservation of, 478.
Heart, affections, prognosis of, from life insurance aspect, 264; and eye defects, congenital, 20; and kidney, disease of, 1073; auricular fibrillation of, of traumatic origin, 1145; beat, clinical irregularities of, 959; dilatation murmurs of, 1172; disease, congenital, 874; displacements of, in pulmonary tuberculosis, frequency, mechanism, diagnosis and effects of, 85; disturbances after accidents, 312; cardiac disturbances of nervous origin, 585; effects of immoderate college athletics, 765; examination of, *x*-ray versus percussion in, 960; function, as measure of, cough dilatation time, 124; in man, development of, 1042; interpleural exposure of, 1145; pathology of, in rheumatic infection in children, 42; sounds, blowing, and their significance to insurance practice, 80; stimulant, caffeine as, 276; successful suture of stab wound in right ventricle of, 219; the drop, 959; thrombosis of, mitral stenosis, aortic embolism, and gangrene of both legs, 492; valvular lesions, significance of, in life insurance, 34; wounds of objective signs and technique of surgical intervention, 859; wound of, suture of, 250; wound of, treatment of, 858.
Heat, and infant mortality, 942; on inoperable cancer effect of, 1042.
Heiser, V. G., beriberi, how knowledge as to its prevention can best be applied from the standpoint of State Medicine, 186.
Hematoma auris, operative treatment, 719.
Hematuria, and renal arteriosclerosis, 122.
Hemianopsia and aphasia, severe anemia with, 32.
Hemiatrophy, facial, 700.
Hemiplegias, pneumonic, 712.
Hemoglobinuria, paroxysmal, 309.
Hemolysis due to intravenous injection of distilled water, 675.
Hemoptysis, emetine in treatment of, 46; pulmonary treatment of tuberculosis, in, 30.
Hemorrhage, anemia, enlargement of spleen, with oral sepsis, 114; cerebral, apoplexy caused by, and vascular occlusion, comparison of onset and character of, 906; cerebral, venesection in, 113; following tonsillectomy, 720; intracranial, in new born, 903; subconjunctival, and suggillation of the lids, rapid removal of, 539; uterine, in young girls, 866; uterine, physiology and pathology of, 766.
Hemorrhagic disease of newborn, 1176.
Hemostatic, gelatin as, 598.
Henry, F. P., the diagnosis and treatment of lumboscral pelvic pain, 93.
Hepatitis, acute infective, 251.
Hereditary diseases in life insurance application, 1093.
Heredity in bone lesions, 353.

Hernia, retroperitoneal, of appendix into ileoappendicular fossa, 937; scrotal mesenteric vessels in, thrombosis of, 365; simulated by varix of internal saphenous vein, 1167.
Herpes, zoster, of the bladder, 445; zoster oticus, 352.
Hexamethylenamine, dose of, 674.
Hiccough, persistent, 66.
Hip, ostitis fibrosa of, 266; tuberculous, joint disease, and its treatment with Bismuth paste, 452.
Hirudin, use of, in transfusion of blood, 1136.
Hodgkin's disease, etiology of, 402; disease, metastatic tumor of spinal cord as first symptom of, 359.
Holding, A. F., technique in radiotherapy with especial reference to deep therapy as practised at Freiburg by Krönig and Gauss, 335.
Holmes, B., Lundvall's remedy for dementia præcox, 27.
Hormones, 349; Langerhansian, and hormone treatment of diabetes, 1112.
Hospital, dispute, 74; paying, 74; children's services in, 390.
Hubby, L. M., the treatment of deafness with sonorous vibrations by the Zund-Burguet method, 200.
Hühner, M., practical scientific diagnosis and treatment of sterility in male and female, 840.
Hydrocephalus internus; lumbar drainage by utilization of a meningocele sac as drainage tube, 362.
Hygiene, institute of, 761; of farmhouse and farm, 143; of tobacco factories, 259.
Hyperacidity, gastric, 353; gastric, prescription for, 598.
Hyperchlorhydria, diet in, 124.
Hyperemesis gravidarum, treatment of, direct transfusion of blood in, 46.
Hyperkeratosis gonorrhoica, 633.
Hypernephroma of the auditory canal, 992.
Hyperplasia, primary, secondary and tertiary or migratory epithelial, study of, 361.
Hypertension, arterial, 1165.
Hyperthymatism, symptomatology, 720.
Hyperthyrodism, toxemias of, 764; *x*-ray treatment of, 1041.
Hypnotics, protection from toxic component of, 33.
Hypodermic injections of salicylates in rheumatism, 397.
Hypophysis, and diabetes insipidus, 356; disappearance of, with fatal exit, 1045; disease of, as related to diabetes insipidus, 242; extract, 905; extract in labor, 907; newer researches concerning, 227; preparations in postoperatitve conditions, 525.
Hypotension associated with a definite symptomatology, 756.
Hypothyreosis, new manifestation of 583.
Hysterectomy, accouchement by, without preliminary opening of uterus, 623; for dystocia due to fibroid in lower uterine segment, 591.
Hysteria, modern theories concerning, 906; modern theories of, 950.

I

Icterus, epidemic, 710; familial, 992; in course of puerperal infection, 769; in extrauterine pregnancy, 538; lithogenic, 998.
Ileocecal coil, surgery of, 270.
Ileocolitis with meningeal symptoms, 76.
Iliac fossa in young women, pain in right, 363.
Illiteracy and mortality, 966.
Immigrants, medical inspection of, 860.
Infant, dietetic disorders of, 1042; feeding, proteins and fats in, management of, 40; mortality, report of committee on, 810; pyloric stenosis in, 362; pyloric stenosis in, treated by gastroenterostomy, 860; scorbutus in, 720; welfare work in New York State, 873.
Infantilism, 398, 536, 581; mental, in tic neucrosis, 553.
Infarctions, septic, tuberculosis of spleen, polycythemia, splenectomy, 593.
Infections, acute, recent procedures in, 1147; acute suppurative spreading, of fingers and hands, surgery of, 957; bacteriemia, and Bright's disease, 292; chemotherapy of, 898; enumerative methods of studying, 121; pneumococcus, prophylactic inoculation against, 212; treatment, of sulphate, magnesium, and glycerine, 401.
Inflammation and tumor formation, comparison of, 907.
Influenza, pneumococcus, 79; some manifestations of, in young children, 870.
Infraction of second metatarsal bone, 271.
Injuries, of aviators, 262; of inner ear, 1120; operative, vagus and internal jugular, 21.
Insane, and criminals, asexualization of, 400; persons, extradition of, 369.
Insanity in latent Bright's disease, 260.
Insolation, 1175.
Insomnia, nervous, especially bromide treatment of neurasthenia, 404.
Instruments, obstetrical set of, available for general practitioner, 86.
Insurability of women as shown by industrial insurance, 405.
Insurance, accident, see accident insurance; and contract practice, 167; companies, health work of, 540; group, 817; life, see life insurance; medico-social problems from viewpoint of, 1139; national, in England and hospitals, 573; notes, 350; state, 305.
Intestine, and stomach, disturbances of, associated with intestinal adhesions, 489; infections of, subacute and chronic, 1004; large, operative treatment of malignant disease of the, 572; movements of, under artificial circulation, 914; obstruction of, 728; ruptured, early diagnosis and treatment of, 262; stasis in, 407; stasis in, chronic, anatomy and treatment, 311; stasis in, chronic etiology, and treatment, 311; stasis in, chronic, medically considered, 409; stasis in, chronic, surgically considered, 411; stasis in, chronic, *x*-ray examination in, 410; strangulated and gangrenous obstruction of, 727; successful removal of, with observations on subsequent metabolism, 364; *x*-ray study of, in conjunction with use of duodenal tube, 702.
Intoxication, rapid and fatal, with bacterial products, 492.
Intussusception, in infancy, delay in diagnosis and treatment of, 1098; recurred, 262.
Iodine, a new solution of, 1150; in treatment of arteriosclerosis, 953; in treatment of plague, 1058.
Iodoform oil, use of, in joints, 1134.
Iodotherapy of arteriosclerosis, 953.
Ionic medication, in the treatment of certain venereal diseases, 310.
Ischemic pains, 765.
Isoserum treatment of incoercible vomiting of pregnancy, 705.

Magnesium, in puerperal infection, 88; sulphate, action of and nature of peristalsis, 1049; sulphate in tetanus, 488; treatment of tetanus, 355.
Maize poisoning, 1043.
Malaria, congenital, 684; during first three months of life, 41; prevention of, by farmer, 942; mononucleosis in, diagnostic value of, 859; larva of parasite of, in non-malarial country, 1178; new, mosquito, 993; organisms of, quinine fast, 859; salvarsan in, 859; symposium an, 41; treatment and cure of, 41; typhoid fever complicating, 689.
Malignancy, in animals, 484; suspicion of, 260.
Malnutrition, tardy, of syphilitic origin, treatment of, 690.
Maloney, W. J. M. A., note on mechanical support for the feet in locomotor ataxia, 881.
Malpractice, 202, 526, 895, 1032, 1125; tort or contract, limitation of action, 298.
Mammals, frozen, and mummies, studies of, 951.
Mandible, ankylosis of, operative treatment of, 365.
Manners and voice in medical practice, 893.
Mannheimer, G., injections of Friedmann vaccine, 1064.
Marriages, life insurance a guarantee for, 217; of women in public positions, 809.
Marshak, M. I., case illustrating a "factor of safety" in lung tissue and pulse pressure as a prognostic sign, 59.
Marshall, H. W., stiff and painful shoulders, 280.
Marshall, V. F., a report of ten cases of acute perforating gastric and duodenal ulcer, 461.
Massey, G. B., surgical ionization and other physical forces in the treatment of cancer, 1.
Mastitis, chronic cystic, or abnormal involution of breast, 591.
Mastoid, radiographic study of, 533.
Mathematics and medicine, 805.
Maus, L. M., alcohol and racial degeneracy, 102.
Maxilla, inferior, advanced carcinoma of, 172; superior, resection of, 727.
Mayer, E., primary lupus of the larynx, 1162; Vincent's angina, 1085.
Mays, T. J., has tuberculosis death rate declined recently? 747; the therapeutic value of crotalin in the treatment of epilepsy, 105
Mead, H. F., persistent hiccough, 66.
Mears, J. E., anatomy and its important relation to development of surgical knowledge, 375; evolution of the study of anatomy and its important relation to development of surgical knowledge, 375.
Measles, advantage and disadvantages of quarantining hospital wards, for, 721; prophylaxis of, 860.
Meckel's diverticulum, 1041.
Medical Society of the State of New York: address of welcome, 820; report of committee on arrangements, 819; report of committee on legislation, 819; report of committee on prize essays, 819; report of committee on public health, 819; report of committee on publication, 819; report of council, 819; report of counsel, 819; report of president, 818; report of secretary, 818.

Medicine, agnosticism in, 552; and divinity, 460; and mathematics, 805; and the law, 552; and the monoplane, 391; books of, as evidence, 895; education in, see education; historian of, 322; history of, 442; in the Italian parliament, 138; microscope in, 305; missions of, 122; of 14th century, 671; practice of success in, 1104; practice of, and good will not subject to involuntary sale, 368; profession of and accident insurance, 44; profession of, and community, midwife problem in relation to, 1014; research in, 761: service of, to civilization, 1151; state service of, 1169; tropical, recent advances in, 256; volunteers in, 487.
Medulla and cord, acute threatening diseases of, conducting to pursue, 404.
Meltzer, S. J., magnesium sulphate in tetanus, 488.
Membrane, Jackson's pericolic, 31, 454; Jonnesco's, 1144; pericolic, resulting from experimentally produced coprostasis, 454.
Mendel, L. B., the nutritive significance of different kinds of foodstuffs, 737.
Meningitis, contagiousness of, 245; in children, 950; meningococcus, modern aspects of, 161; pneumococcus, cure of, by ethylhydrocuprein, 172; serum treatment, fatalities of, 1135.
Meningococcus meningitis, 161.
Menisci of knee-joint, extirpation of, 445.
Menstruation, appearance of, during climacteric, 215; penile, 899.
Mercury and salvarsan in syphilis, 998; bichloride of, prevention of poisoning by, 1058.
Mesenteric vein, thrombosis of, in phlebosclerosis of the portal vein, 449.
Mesentery, lymph cyst of, 721; rupture of, 1178.
Mesothorium, and radium treatment of cancer by Roentgen rays,449; need of care in handling, 172.
Metabolism and diabetes, 961; and vitality, 289; in epilepsy, 624; protein, 1189.
Metastatic tumor of spinal cord as first symptom of Hodgkin's disease, 359.
Methyl chloride, narcosis after industrial work with, 952.
Metritis, chronic, microphotograph from, 730.
Metrorrhagias, function, 402; functional, their nature and control, 317.
Metroscope, the, 717.
Meyers, A., present status of typhoid immunization in hospitals and training schools of New York, 699.
Meyers, J., the passing of the stomach tube, 1.
Microscope in medicine, 305.
Midwife, in America and England, 851; problem in relation to the medical profession and the community, 1014.
Migraine, and epilepsy, relationship between, 533; treatment of, 920.
Milk, casein, simple method of making, 500; certified, theory and practice, 672; collecting human for hospital and dispensary use, 500; electrified, 945; pasteurized, question of, 344; stations, 500.
Mind, development of, 33; disease of and alcoholism, 75; disease of and high vascular tension, 1008; disorders of, in general hospitals, treatment of, 681; disorders of, treatment of, in general hospitals, 860; mental disorders of, personality disturbances, 809; treatment of disorder of, in general hospitals, 860.
Missions, medical, 946.
Mitral valve, stenosis of, 1050; stenosis of, cardiac thrombosis, aortic embolism, and gangrene of both legs, 492.
Mononucleosis in malaria, diagnostic value of, 859.
Monoplane and medicine, 391.
Morris, R. T., let us settle the movable kidney question, 833.
Mortality, among negroes, and life insurance, 771; among women and life insurance, 864; and illiteracy, 966; curve of, 450; figures, better, 1039; in women, causes of, 405, 954; infant, and heat, 942, 947; of war, 910; tables, types of, 540.
Mosquito, diseases borne by, 531; malarial, new, 993.
Mouth, infection of, dental aspect of, 545; infection, dental aspect of, 604; typhoid bacilli in, in typhoid patient, 1119.
Mucous membranes as emunctories, upper respiratory, 296.
Mummies and frozen mammals, studies of, 951.
Mumps, observations on, with discussion of complications, 41.
Munger, C. E., angioneurotic edema, 1029.
Munro, H. S., prevention of psychic trauma, 984.
Myatonia congenita, 1045.
Myelitis, transverse, infectious and toxic forms of, 1052.
Myeloma, multiple, 843.
Myocarditis, syphilitic, 1138.
Myoma, *x*-ray treatment of, 892.
Myopathies, importance of early recognition of, by the general practitioner, 319.
Myope, rupture of choroid in a, following parturition, 444.
Myopia, chronic, a disease in the sense of the imperial insurance law, 264.
Myotonic reaction, 356.

## N.

Nammack, C. E., cardiorenal disease, management of, 1073.
Nanism, varieties of, 806.
Narcosis, after industrial work with methyl chloride, 953; death, secondary, 1092.
Nasopharynx, posterior, bacteriology of, in scarlatina, 934.
Navy, surgeon-general of, 68.
Nearthrosis, operative, 171.
Neck, and upper end of femur, fractures of, nonoperative treatment of, in adults, 914; congenital tumors of, 363.
Necrosis, bone, and sequester formation, 357; hepatic and toxicity of chloroform, influence of diet on, 631; metastatic costochondral, 624.
Needle holder, magnetized, 1176.
Neosalvarsan, concentrated solution of, 197; in active pulmonary tuberculosis, 1176; intraspinal injection of, 400; polyneuritis and Korsakow's psychosis after with fatal ending, 583; Vincent's angina, treated with, 848.
Nephrectomy, accidental injury to the vena cava during, 220; during pregnancy, 546.
Nephritis, acute, medicinal treatment of, 1150; chronic, modern treatment of, 308; chronic, treatment of, 673; early and advanced, value of tests for renal function in, 682; vs. erysipelas, 32; experimental, 1089; postanginal, 444; some problems in, 812; "streaked," following Graves' disease, 1138; syphilitic, 1050.
Nephroparatyphus, 1137.
Nerve, injuries, 568; point doctrine, Cornelius, 171; transplantation, 781; intercostal, conserving, in abdominal incisions, necessity of, 505.
Nervous system, cretinism and, 689; diseases of, diagnosis of, 963; diseases of, diagnostic errors in, 31; diseases of, syphilitic therapy of, 908; disorders of, functional, radiography of gastrointestinal tract in, 353; fundamental activity, new theory of, 940; syphilis of, intensive treatment of, by neosalvarsan and mercury, 823; syphilis of, treatment of, by intrathecal injections, 633; treatment of syphilis, of the, 400.
Neuralgia, trifacial, treatment of, by injection of alcohol into Gasserian ganglion, 1116; intercostal, refrigeration with ice in treatment of, 19; trigeminal, treatment of, by deep intraneural injections, 271.
Neurasthenia, etiology of, deficiency of chloride of sodium in, 1017; especially of nervous insomnia, bromide treatment of, 404; relation of, to tuberculosis, 1187.
Neuritis, brachial, 949.
Neurological cases in pediatrics practice, 1031.
Neurosis, anxiety, 45; traumatic, due to alleged or actual injury from medicolegal standpoint, 382; traumatic, progress of, in general, 540.
Neustaedter, M., case of facial hemiatrophy, 700.
Nichols, H. J., the relation of experimental syphilis to eugenics, 188.
Nichols, J. B., metabolism and vitality, 289.
Nitrogen, by direct insufflation of, cure of peritoneal tuberculosis by, 355.
Nitroglycerin, 211.
Noma, 163, 574; and its infective basis, 827.
Nose, and throat examinations in an institute for delinquent boys, 480; catarrh of, prevalence of, 123; accessory sinuses of, in children, 328; deformation of, operations for correction of, 237; diphtheria of nurslings, bacteriology of, 769; ear, and throat, function of, conservation of, 673; obstruction, instrument for detection of slight degrees of, 768; obstructions of, surgical treatment for reduction of vacuum, caused by, 834.
Novocain, action of, by means of potassium sulphate, intensification of, 276.
Nurse, practice law, 252; scarcity of, 902.
Nursing, mental companionship in, 903.
Nurslings, screaming, soothing, by blowing on them, 215.

Nutmeg poisoning, two cases, 952.
Nutrition from the energy standpoint, 781; part played by various foods in, 1188.
Nydegger, J. A., hygiene of the farmhouse and farm, 143.
Nystagmus, congenital, "wry neck" deformity from, 359.

O

Obesity, hyperglycemic, 1091; the "why" of, 765.

Ochs, B. F., dermatoses due to toxemia, 297.
Oil, cure of habitual constipation, by intraabdominal use of, 655; leak, to stop an, 552.
Olmstead, M. P., the value of absorption methods in the Wassermann test, 341.
Onychia septic, Bacillus coli as cause of, 1090.
Operating to the clock, 354.
Operation, performing, three methods of, with illustrative cases, 978; on brain tumor, some causes of disappointment in, 227.
Ophthalmia, metastatic, systematic disease with, association of, 813.
Ophthalmological congress, 1037.
Ophthalmophobia, 1082.
Oppenheimer, S., the surgical anatomy, diagnosis, and treatment of the inflammatory affections of the nasal accessory sinuses in children, 328.
Organic matter, synthesis of, by inorganic colloids, 672.
Organs, abdominal, to percussion, sensitiveness, 817; transplantation of, 780.
Origin, tobacco and malarial, amnesias of, 77.
Orthopedics, hygienic tests applied to, 994.
Os calcis, bone cyst of the, 812; sprain fracture of, 429.
Osteitis, deformans, 636; fibrosa, after typhoid fever, 449; fibrosa of the hip, 266.
Osteoarthritis, chronic, practical management, 829.
Osteogenesis imperfecta, 404.
Osteoperiostitis of upper end of femur, 1012.
Osteosarcoma successfully treated, 318.
Ovariotomy subpartus, 44.
Ovary, disappearance of, recurrent mammary carcinoma, after removal of, 269; sarcoma of, 504.
Oxycephaly, 211.
Oxygen as therapeutic measure, 1052; tracheal insufflation of, in respiratory paralysis, 1045.
Ozena, an infectious and contagious disease, 213; genuine, etiology of, 214; transmission of, by dogs, 345.

P

Pachymeningitis, internal, in young children, 764.
Pain, hunger, and its significance, 170; ischemic, 765; inguinal, in young men, 538; lumbosacral pelvic, diagnosis and treatment of, 93; relief of, 690; shoulder, in pleurisy, 263; postoperative, prevention of, 1135.
Painlessness of the death struggle, 628.
Palate, cleft, Brophy's operation for, 215.
Palefski, I. O., a modified method of lavage by means of a double-cock glasspiece in conjunction with the modified stomach-tube, 57; visualization of upper intestinal tract by means of conjunction with use of duodenal tube, 702.
Pallidin reaction, 992.
Palpation, under the fluorescent screen, 1059.
Palpitation, nervous, treatment of, 276.
Pancreas, and silica metabolism, 1034; serous cyst of, 998; surgery of, 362; toxicosis, 714.
Pancreatic juice, backflow of, into nursling's stomach, 736.
Panel and non-panel, 167.
Papaverin, action of, 404.
Papilloma of the larynx, 268.
Paquelin cautery in cervicitis, use of, special reference to its value in sterility, 221.
Paradidymitis, acuta erotica, 214.
Paralysis, agitans, 1007; agitans following trauma, 817; atypical infantile, 30; cerebral post-diphtheritic, 573; diphtheritic, 67; general, intraspinous treatment of, 862; Landry's causation of, 951; respiratory, tracheal insufflation of oxygen in, 1044; spastic, operative treatment for, 1057; syphilitic, of the esophagus, 354; traumatic nerve, 967.
Paratyphus in Munich children, 1091
Paresis, general, Swift-Ellis treatment in, 948; intraspinal treatment for, 178; intraspinous treatment of, 862; juvenile, 38; treatment of, 211.

Parturition, rupture of choroid in amyope, following, 444.
Patella, fracture of, 1147; fractures of, insert bone graft in, 988.
Pathology, modern tropical, 859.
Pavor nocturnus and its equivalents, nature and treatment of, 444.
Pease, M. C., the provocative Wassermann reaction, 982.
Pediatrics, two neurological cases in, 1031.
Pellagra, 41, 124, 261; etiology of, based upon experimental inoculation of monkeys and rabbits, 42; in children, 686; in Maine, 30.
Pelvis, renal, latent and masked diseases of the, 393.
Pendexter, S. E., a simple efficient external nasal splint, 800.
Percussion versus *x*-ray in examination of heart, 960.
Pericarditis, dicrotic wave in, inspiratory exaggeration, 1051; treatment of, epigastric puncture in, 399.
Pericolic membranes, or Jackson's veil, 454, 1178; resulting from experimentally produced coprostasis, 454.
Perineum, lacerations of, immediate repair of, 364; retractor of, 547.
Periosteum, callus of, or myositis ossificans traumatica, 452; function of, 505.
Peristalsis, colonic, and antiperistalsis, *x*-ray observations on, 416; nature of, and action of magnesium sulphate, 1049.
Peritoneum, adhesions of, cause of, in new bacillus, bacillus adhaesioformis, 427; infections of, ether lavage in, 482; injections into, 170.
Peritonitis, tuberculous, surgical treatment of, 1134.
Personality disturbances of, in mental disorders, 809.
Pertussis, suggestive therapeutics of, 122.
Peterson, E. A., Streptococcic infection of the cervix uteri, 1.
Pharmacology and therapeutics, instruction medical colleges ought to give in, 544.
Pharmacotherapy during 1913, progress in, 449.
Pharynx, and larynx, pneumococcal infection of, 571, and larynx, resection of, 1178; resection of, for carcinoma, 1178.
Phenolsulphonephthalein as an indicator of renal function, 489.
Phenomena of infection, 446.
Philippines, sanitation in, 947.
Physician, and patient, relation of, 966; care and skill required of, degree of, 298; bill of, 966; employment of, by injured man's employer, 298.
Pineal gland, use of in defective children, 513.
Pituitary gland, see hypophysis.
Placenta, artificial separation of, new method of , 863.
Plague and fleas, 1081; campaign in Manila, 259; in Havana, 763; iodine in treatment of, 1058; outbreak, new, 628.
Pleural cavity, gases introduced into, therapeutic value of, 907.
Pleurisy, 216; chronic, tuberculous, diaphragmatic, 490; diagnosis and treatment of, 1044; shoulder pain in, 263.
Pneumonia, an address on, 213; and bronchitis, medicinal treatment of, 41; heart in, 1190; in the Rand mines, report on, 208; out-of-bed treatment of, 1777; recovery in, 261; unresolved, 7, 40.
Pneumotharax, artificial, 631; artificial, advanced pulmonary tuberculosis treated by, 83; artificial, treatment of pulmonary tuberculosis, by induction of, 793.
Poisoning, benzine, 404; carbon monoxide, 123; maize, 1043.
Poliomyelitis, acute anterior, 172; acute anterior, cause of, 403; acute anterior, epidemiology of, 160; and distemper of dogs, epidemic, 490; pathogenesis of, 1052; toxic polyneuritis due to virus of, 584.
Polk, W. M., treatment of retrodisplacements of the uterus, 231.
Pollution, atmospheric smoke, psychological aspect of, 162; of tidal waters, 898.
Polycythemia, benzol in treatment of, 905; in duodenal ulcer, 876; splenectomy, septic infarction and tuberculosis of spleen, 593.
Polyneuritis, and Korsakow's psychosis after neosalvarsan, fatal ending of, 583; toxic, due to virus of poliomyelitis, 584; unusual case of, 37.
Porter, W. H., uric acid overproduction, 1105.
Postoperative conditions, pituitary preparations in, 525.
Potassium sulphate, action of novocain by means of, intensification of, 276.
Potato juice and paraffin wax, therapy of, 857; therapeutic value of, 816.
Potency, rare disturbance of, 816.
Potts' disease, gross deformities in, prevention of, 1100.
Practising without authority, 390.
Practitioner, general, and dentist, 544.
Precancerous and cancer conditions, 436.
Pregnancy, and cancer, serodiagnosis of, 76; and pernicious anemia, 816; and puerperium, gallstones complicating, 44; complicated by typhoid fever, 729; ectopic, 589; ectopic, evolution of the treatment of, 44; extrauterine, icterus in, 538; iso-serum treatment of incoercible vomiting of, 705; nephrectomy during, 546; ovarian, 548; serodiagnosis of, 88, 493, 489, 951.
Prendergast, F. A., Effect of typhoid vaccine on sugar output in diabetes, 18.
Prescribing, art of, 676; practical, 635.
President's address, 543.
Professors, medical, full time, 856.
Prostate obstruction of, high frequent spark for relief of, 293.
Prostatitis, chronic, 887.
Prostitutes, examination of, 307; registration of, abandonment of, 400.
Prostitution, in Europe, study of, 325; sanitary control of, 1066.
Proteins and fats, management of, in infant feeding, 40; metabolism, 1189; metabolism during starvation, 309.
Pruritus ani, 1062.
Psoriasis, etiology of, 1092; in very young infant, 755.
Psychiatry, Abderhalden's dialysis procedure in, 493; Abderhalden reaction in, 630; and certain military problems, 622; cerebrospinal fluid in, 580.
Psychoanalysis, 1175; and epilepsy, 822; objection to, consideration of 338.
Psychoneuroses, and cerebral circulation, territorial autonomy, 994; certain phases of, 401; further study upon, torticollis as, 371; primary education of children and their value in lessening liability to, 588.
Psychosis, Korsakow's and polyneuritis after neosalvarsan, fatal ending of, 583; manic-depressive, in a child, 177.
Puberty, precocious, implies mental precocity, 677; ulcer of stomach in children before, 503.
Public health, 349; administration, 543; work in Porto Rico, 437.
Publicity, 116, 167; in lay press, 497.
Pulmonary artery, embolism of as surgical complication, 44.
Pulsus alternans, 959.
Purpura, visceral lesions of, 583.
Puerperal, eclampsia, surgery of, 506; infections, treatment of, some methods in, 869.
Puerperium, and pregnancy, gallstones complicating, 44; infection by B. coli in the, 767; retroversion of the uterus and dorsal position in the, 448; uterus in the, and in nulliparous women, retrodeviations of the, 867.
Pulmonary tuberculosis, advanced, treated by artificial pneumothorax, 83; cardiac displacements in, frequency, mechanism, diagnosis and effects of, 85; curability, 1021; Gorky's recovery from, 952; guaiacol in, 213; in childhood, 863; in rabbits, benzol inhalations on, 1051; neosalvarsan in, 1177; patient, post-sanatorium, protection for, 43; treatment of hemoptysis in, 30; treatment of, by induction of artificial pneumothorax, 793; treatment of, transthoracic intrapulmonary injections in, 46.
Pulse pressure, in diagnosis and prognosis, 927.
Pyelography, dangers attending, 581; danger of, 941.
Pylorus, further results in stretching the, 226; hypertrophic stenosis of, Rammstedt's operation in, 764; stenosis of, congenital, 44, 456; stenosis of, in infants, 362; stenosis of, in infancy treated by gastroenterostomy, 1095; stretching the, demonstration of method of, 224.
Pyorrhea alveolaris, bacteriology of, 30.

Q

Quackery in the eighteenth century, 322.
Quarantine, New York, 850.
Question, hypothetical, 368, 802.
Quinine, subcutaneous injection of, 920.

R

Rabinowitz, M. A., two neurological cases in pediatric practice, 1031.
Radioactive substances, kind of cancers best suited for treatment with, 951.
Radiotherapy in gynecology, 403.
Radium, 761; and cancer, 213; and mesothorium treatment of cancer by roentgen rays, 449; and roentgentherapy, in cancer, 86; and roentgen rays, practical

identity of, 32; as palliative measure, 858; in cancer, 1089; institute in London, 1913, work at, 1090; in treatment of cancer, 998; in treatment of cancer of female genital organs, 350; Mesothorium and therapy, status and newest aims of, 449; therapy, 627, 713; treatment of cutaneous epitheliomas, 949.
Rahmet, H., the causation of dreams, 386.
Rats, campaign against, 307.
Reactions, substitution, 1007.
Reciprocity, 544.
Record charts for new born, 874.
Rectovaginal septum, adenomyoma of the, 220.
Rectum, cancer of, in an adolescent, 853; carcinoma of, dissemination in, 582; carcinoma of surgery of, 958; feeding by way of, 908; resection of, for cancer with preservation of sphincter, 222; surgery of, local anesthesia in, 949.
Refrigeration in the preservation of food, 666.
Registration, anomalies of, 1131.
Rehfuss, M. E., French aspect of functional liver testing, 928.
Research, 74.
Resection, intestinal, 401; vagus, fatality following, 69.
Respiration stimulant, cocaine as, 42.
Respiratory tract, mucous membranes of as emuctories, 296.
Retinitis, diabetic, 815.
Rhein, M. L., the dental aspect of oral infection, 1.
Rheumatism, acute articular, etiology of, 953; and tuberculosis, 31; chronic, cause and vaccine treatment of, 1076; hypodermic injection of salicylates in, 397; in children, pathology of heart in, 42; intrarectal injections of sodium salicylate in, 1187; intravenous injections of sodium salicylate in treatment of, 359; salicylates, hypodermic injections of, 397; streptococci in relation to, 352; tuberculosis, 171; tuberculous, 256.
Rhinitis, acute, snuff for, 276.
Rhinoscleroma, epidemiology of, 312.
Rib, first, and clavicle, excision of, for malignant disease, 363.
Rickets and the Nobel prize in medicine, 258; experimental, 1044.
Roach, W. W., open-window schools, 442.
Roberts, P. W., practical management of chronic osteoarthritis, 829.
Robinson, B., full-time medical professors, 856; value of accurate diagnosis in disease, 754.
Robinson, M., venous circulation, 152.
Rockwell, A. D., observation based on 45 years of electrotherapeutic work, 976.
Romoe, P., refrigeration with ice in the treatment of intercostal neuralgia, 19.
Rosenstirn, J., sanitary control of prostitution, 1066.
Rueck, G. A., pathology, etiology, and diagnosis of typhoid fever, 433.
Rumination, in man, 32.

S

Safety, factor of, in lung tissue and pulse pressure as prognostic sign, 59; first, 322.
Salicylates in rheumatism, hypodermic injections of, 397.
Salpingitis nodosa, 547.
Salts, lime for therapy of internal affections, 32.
Salvarsan, and brain tumor symptoms dependent upon syphilis, 994; and mercury in syphilis, 998, 1174; curative action of, and pathology of syphilis, 677; deaths, 538, 1174; in malaria, 859; in non-syphilitic diseases, 802; on the eye, effect of, 489; treated animals, of the serum, subdural cerebral injections of, 400; value of, 446.
Santos-Fernandez, J., four cases of corneoscleral dermoid tumors, 55.
Saratoga Springs and its mineral waters, 680.
Sarcoma, as result of uriol lamp treatment, 355; of clavicle, 267; of long bones, early diagnosis and treatment, 1142; of ovary, 504; of testicle, prognosis of, 445.
Satenstein, D. L., autoserum injections in certain obstinate dermatoses, 1.
Scapula and arm, divulsion of, 985.
Scarlet fever, abortive, in the newborn, 665; as reaction of sensitization, 664; bacterial vaccines in, 936; posterior nasopharynx in, bacteriology of, 934; theory of, 262; treated by vaccines and method of Milne, 931.
Scars, treatment of, 781.
Schlapp, M. G., an economic and social study of feeble-minded women, 1025.
Schmidt, A., some remarks concerning chronic diarrhea and constipation, 277.
Schools, open-window, 442.
Schroeder, H. H., syphilis in relation to life insurance, 691.
Schultze, E. C., scarlatina treated by vaccines and the method of Milne, 931.
Schwartz, L. H., *Bacillus lactis bulgaricus* in infantile gastroenteritis, 159.
Sciatica, treatment of, 212.
Scleroderma, case of, 246.
Sclerosis, disseminated, 1037; multiple, 822.
Scorbutus, infantile, 720.
Scott, R. J. E., the adhesion-producing bacillus, 489.
Secretions, internal, upon female characteristics and functions, 23.
Seff, I., retroperitoneal hernia of the appendix into the ileoappendicular fossa, 937.
Seibert, A., hypodermic injections of salicylates, in rheumatism, 397.
Self-accusation and pathological conditions, 539.
Selfishness, altruistic, as exhibited in life insurance work, 80.
Sella turcica, in some epileptics, 123, 227.
Seminal vesicles, operations on, 1175.
Sense, common, in public health administration, 897.
Sepsis, dental, and its relation to general health, 437; oral, 531; oral, enlargement of spleen, hemorrhage, anemia, with, 114; Staphylococcus, after furunculosis, 355.
Septum, rectovaginal, adenomyoma of, 580.
Sequester, formation, and bone necrosis, 357.
Serpent, trail of the, 565.
Serum, and vaccines, practical application of, 1006; antigonococcic, in gonorrhea, 949; antimeningitis, fatalities from, 1135; Friedmann, and society of German sanatorium physicians, 717; horse, in treatment of wounds, 690; of salvarsan-treated animals, subdural cerebral injections of, 400; salvarsanized, in syphilitic diseases of central nervous system, 673; salvarsanized, intrathecal injection of, 1137; thyrotoxic, 1176.
Services, medical, value of, for jury, 895.
Sexsmith, G. W., case illustrating a "factor of safety" in lung tissue and pulse pressure as a prognostic sign, 59.
Sheehan, J. E., the case against the eugenists, 109.
Shock, 995; after operation, prevention of, 902; surgical, changes in blood in causation of, 633; surgical, prevention of, 1135.
Shoulders, stiff and painful, 280.
Sick, destitute, care of, 895.
Silica metabolism and the pancreas, 1034.
Silicic acid in cancer and tuberculosis, 951.
Sinus, frontal, suppuration in, 1147.
Sittenfield, recent advances in study of patogenesis of cancer, 751.
Skin, suture, catgut as a, 364; varnish, a substitute for rubber gloves, 524.
Skull, fracture of, *x*-ray diagnosis, 316; reconstruction of, 349.
Smallpox, in Samar, 993; on the "Ohio," 401; prevention, 1131.
Smith, O. C., needle protruding through wall of stomach, 1064.
Smoke pollution, atmospheric, psychological aspect of, 162.

Starvation, protein metabolism during, 309.
Stasis, chronic intestinal, effects of, on female generative organs, 311; ileal, 630.
State Board Examination Questions and Answers: Kentucky, 640, 733, 825; Louisiana, 366, 457, 549; New Hampshire, 917, 1009; Pennsylvania, 1101; Texas, 89, 180, 272.
Stedman, H. R., extradition of insane persons, 369.
Steno's duct, fishbone in 28.
Stephenson, J. W., treatment of syphilis of the nervous system by neosalvarsan, intravenously, and mercury by inunction, 786.
Sterility, in male and female, 840; in women, 866.
Stern, S., present status of nonoperative treatment of benign and malignant growths, as seen at clinics abroad, 1.
Stewart, D. H., vegetable hormone in cases of ileus and gastric dilatation, 199; the metroscope, 717.
Stomach, acidity of, test for, without stomach tube, 444; and duodenum, shellac, concrements in the, 677; and duodenum, ulcer of, 776, 1135; and intestines, disturbances of, 489; appliance for introduction of instruments into the, 430; cancer and ulcer, 1051; cancer of, 1049; cancer of, serial roentgenography in, 401; carcinoma of, 223; hair cast of the, 123; mobility of, treatment of disturbances of, 1092; motor insufficiency of, 224; noncancerous tumors of, 28; nurslings, backflow of pancreatic juice into, 736; past-operative acute dilatation of, 363; stasis in, 1088; subtotal excision of, 1144; surgical conditions of, determination of, 965; symptoms, test-meal examination of, 963; tube, passing of, 519; tuberculosis of, 122; ulcer of, 1081; ulcer of, Gluzinski's test in, 1144; ulcer of, in children before puberty, 503; ulcer of, pylorectomy for, 1144; vertigo, treatment of, 414; wall of, needle protruding through, 1064.
Strauch, A., disorders in children by imitation and induction, 95; August, epidemic icterus, 710.
Streptococci in relation to endocaritis, 352; in relation to rheumatism, 352.
Streptococcus, transmutation, 897; infection from, hyperacute, 997; viridans, myacardial lesions from, 31.
Strychnine-tuberculin treatment of hospital tuberculous cases, 1043.
Subinfection and autointoxication, 310.
Sugar, disappearance of, in diabetics after certain pelvic operations, 814; overproduction of, diabetes not simple due to primary, 403; effect of, on the gastric secretions of children, 872.
Suggestion and treatment of pertussis, 122.
Suggillation of lids and subconjunctival hemorrhages, rapid removal of, 539.
Suicide, attempted, with digalea, 909; in children and adolescents, 392.
Suppuration, persistent *x*-rays on, influence of, 1043.
Suprarenal extract, action in dementia præcox, indifference to, 538; and glycosuria, 483.
Suprarenals, practical significance of, 1136.
Surgeon, accident toll of, 450; as autocrat of operating room, 861; general, United States Navy, 21; report of, 21.
Surgery, abdominal, drainage tube in, 907; and diabetes, 263, 489; of pancreas, 362; practical points in, 656; of spastic contractures, present status of, 912; of war, 1135; plastic, grafts in, 779.
Surgical shock, changes in blood in causation of, 633.
Sutter, C. C., development of complement fixation tests, 783.
Suture, direct, of brachial artery for traumatism, restoration of circulation, subsequent development of ischemic paralysis, 219.
Swift, G. M., carditis, 333.
Syndrome, triple, in abdominal emergencies, 213.
Syphilis, acquired, observations concerning the liver in, 86; alleged epidemic of, in Europe, following discovery of the Antilles, 117; and yaws, unity of, 629; autoserosalvarsan treatment of, 211; brain, treatment with salvarsan with complete resort, 688; cerebrospinal, diagnosis and treatment, 950; combined treatment of, 952; congenital, early diagnosis of, 1005; cured apparently by accident, 570; diagnosis of, Ross Jelly method in, 490; experimental, the relation of, to eugenics, 188; familial, and keratitis parenchymatosa, 953; hereditary, 499; hereditary, mortality of, 260; in Europe following discovery of the Antilles, alleged epidemic of, 117; in relation to life insurance, 691; incurability of, 516; mercury and salvarsan in, 998; modern diagnostic measures in, 127, 1052; modern treatment of, 1052; of nervous system, intensive treatment of, by neosalvarsan and mercury, 823; of nervous system, treatment of, by intrathecal injections, 633; of pelvis of kidneys, 122; origin of, 667; parenchymatous, intracranial medication in, 1137; pathology of, and curative action of salvarsan, 677; primary, diagnosis and treatment, 812; progress in treatment of, 1174; prolonged latency of, 584; salvarsan, and brain tumor symptoms dependent upon, 994; salvarsan and mercury, uses and abuses, 16; therapy progress in, 768; treatment of, 768; treatment, of nervous system, 399; treatment of nervous system, by intravenous injections of salvarsan, 672; treatment of, of nervous system by neosalvarsan, intravenously, and mercury by inunction, 786.

T

Tabes, and paresis, treatment of, 211; dorsalis, diagnosis of, 632; nervous fever in, 171; gastric crises of, operative treatment of, 203; in Brazil, 79; mechanical support for the feet in, 881; operative treatment of the gastric crises of, 203.
Tachycardia, paroxysmal, 627; paradoxical, associated with arterial hypertension, 321.
Talipes, calcaneus, and allied distortions, operative treatment of paralytic, 47.
"Tango-foot," 755.
Tannenbaum, S. A., a consideration of objections to psychanalysis, 338.
Tartar, mass of, developing five teeth, 545.
Temporomandibular articulation, arthroplasty for ankylosis of, 1146.
Ten Broeck, L. I., extirpation of *Bacillus diphtheriæ* by means of a thallaphytic fungus, *Achlya muscaris*, a clinical and experimental study, 49.
*Tenia saginata* in appendix, 729.

Tension, high vascular, muscular, and mental, 1040.
Testicle, sarcoma of prognosis of, 445; undescended, conservative treatment of, 365.
Tests, complement fixation, development of, 784.
Tetanus, acute, with recovery, 403; magnesium sulphate in, 488; magnesium treatment of, 355.
Tetany, gastric, 447.
Thacher, J. S., unresolved pneumonia, 7.
Therapeutics, lesson in, medicine and the monoplane, 391; radium, 713; radium-mesothorium, status and newest aims of, 449; suggestive, in children, 992; vaccine, debate on, 443.
Therapia sterilisans in trypanosome diseases, 449.
Thermotherapy of gonorrhea, 404.
Thompson, W. G., failures in typhoid vaccination, 902; occupational diseases, 185.
Thorax, operations in, 1145.
Throat and nose examination in an institute for delinquent boys, 480; ear and nose, function of, conservation of, 673; streptococcus sore, epidemic of, 1052.
Thrombophlebitis, puerperal, 869.
Thymus, a contribution on the, 648; diagnosis of enlarged, 721; irradiation of, in case of Graves' disease, 992; ovary and blood pictures, 215.
Thyroid, gland and blood coagulation, 251; gland, syndromes and growths of, requiring operation, 44; in disease, pathological changes of, 582; relation to diphtheria antitoxin, 125; theories concerning, 951; treatment of hemorrhagic metropathies, 538.
Tic neurosis, mental infantilism in, 553.
Tinea tonsurans, *x*-ray treatment for, permanent alopecia following, 113.
Tobacco, amblyopia, 980; and alcohol, effect of, on life expectancy, 1093; and mental efficiency, 580; factories, hygiene of, 259.
Toeplitz, M., five hundred examinations of the nose and throat in an institution for delinquent boys, 461.
Tongue, cancer of, in early life, 986; cancer of, 1146; tuberculosis of, 727.
Tonsils, operations on, in public school children in New York City, results of, 130; and adenoids in children, 862.
Tonsillectomy, hemorrhage following, 720.
Tonsillitis and appendicitis, 992.
Torticollis, etiology of mental, some observations upon, 232; mental, as psychoneurosis, further study upon, 371.
Tour, European study, 61.
Toxemia, chronic intestinal, of severe type, 155; dermatoses due to, 297; in genesis of hyperthyroidism and their treatment, 764; mobilization, duodenum, traumatic rupture, 456; periodic, explosive, 210.
Toxicity of adenoma of the prostate, 763.
Tubercle bacilli, and tuberculosis, distinction between an infection by, 43; the circulating blood, 1082; in the feces, 483; problem of, 69; su[illegible]rged in water, 580.
Tuberculin, cures in sanatorium, 952; preparations in private practice, how to use, 1049; treatment of spina ventosa, 714.
Tuberculosis, 126; and cancer, solicic acid in, 951; and epilepsy, 1043; and erythema nodosum, 907; and housing conditions, alcohol, 582; and rheumatism, 31; and tubercle bacilli, distinction between an infection by, 43; antipyretic in pulmonary, champhor as, 32; apical, acromial breathing in, diagnosis of, 76; as infective disease, 403; Besredka's antigen in, 1089; calcium therapy of, 924; college of, 945; death rate recent decline of, 747; diagnosis and treatment of. 43; following typhoid fever, 393, 637; in bones, 1147; in children, diagnosis of, 1040; infection, 1092; in immune lung, extension of, 461; in New York City, prevention of, 756; in the tropics, 859; laryngeal, 862; laryngeal, in sanatoria and private practice, 972; laryngeal, prophylaxis in, 883; milien of, child in the, 131; morbid anatomy of, 581; hip, joint disease and its treatment with bismuth paste, 452; of spleen, septic infarction, polycythemia, splenectomy, 593; of stomach, 122; of testicle, 147; of tongue, 727; peritoneal, cure of, by direct insufflation of nitrogen, 355; present problems in, 904; prevention of, in New York City, 757; primary lingual, 534; problem, some phases of the, 44; pulmonary, see pulmonary tuberculosis; renal, lumbar exploration in, 258; role of climate in the therapy of, 666; seasonal and meteorological influence on, 763; oil of in gonorrheal arthritis, 92; surgical, physical therapy of, 125; symposium on, 43; therapy of, role of climate in, 667; treated by special method and plan of control, 135; typhoid fever, following, 393; value of rest, physical and mental in, 43.
Tumors, biology of, 675, 718; congenital of neck, 363; corneoscleral, demoid, 55; formation and inflammation, comparison of, 907; malignant, Abderhalden's test for, 68; non-cancerous, of stomach, 28; nonpapillary benign, of bladder, 505; of brain, treatment of, 756; of spinal cord, 176; spinal cord, local diagnosis of, 448.
Transmutations, streptococcus, 897.
Transplantations and grafts, 780.
Transportation, improved, facilitating the spread of disease, 1039.
Trauma, paralysis agitans following, 817; psychic, prevention of, 984.
Trichinosis, 491; pathology of, 939.
Trypanosome diseases, therapia sterilisans in, 449; report on, 1086.
Typhoid fever, bacilli of, in mouth of typhoid patient, 1119; bacteriology of the blood in, 1170; complicating malaria, 689; immunization, present status of, in hospitals and training schools of New York, 699; immunizing of lake and river seamen against, 1034; oseitis fibrosa after, 449; pathology, etiology, and diagnosis of, 433; simulation of, by marked Hodgkin's disease, 126; spine, 157; spontaneous rupture of spleen in, 39; stools, disinfection of, 169; tuberculosis following, 393, 637; vaccination, 130; vaccination in army during 1913, 905; vaccination, failures in, 902; vaccine, sugar output in diabetes, 18; with hemorrhage and relapse, pregnancy complicated by, 729.
Typhus, exanthematic, 79; germ, 945; new type of, in East Asia, 79.

U

Ulcer, duodenal, diagnosis of, 172; duodenal, polycythemia in, 876; duodenal, recurrences of, 307; gastric and duodenal, 401, 776, 1081, 1135; gastric and duodenal, acute perforating, 476; gastric and duodenal, diagnosis of, 776; gastric and duodenal, early recognition and medical treatment of, 498; gastric and duodenal, etiology and surgical treatment of, 521; gastric and duodenal, etiology, pathology, and operative technique of, 777; gastric, and gastric carcinoma, relationship between, 1051; gastric, and hyperchlorhydria, diet in, 124; gastric, in children before puberty, 503; gastric, suggested by diaphragmatic pleurisy, 490.
Ureters, presenting three, 589; strictures of the, 215.
Urethra, traumatic rupture of, 123.
Uric acid, in relation to chronic arthritis, 392; overproduction, 1105.
Urine, albumin in, test for, 725; and feces, normal amount of diastetic ferment in, 1052; ferment preparation, 309; gastric ferments in the, 202.
Urology, French congress of, 258.
Urticaria, lotion for use in, 690.
Uterus, adnexa, gonorrhea and suppurative disease of the, 20; and dorsal position in the puerperium, retroversion of the, 448; cancer of, 1134; carcinoma of, 730; carcinoma of cancer ascitic fluid in, 583; cervex of, streptococcic infection of, 571; displacements, operations for, effect of subsequent labors of, 867; fibroids of, early operation in cases of, 666: fibroids of, radiotherapy of, 132; fibromyoma, sarcomatous changes in, 730; hemorrhage from, in young girls, 866; hemorrhage from, irregular, 149; hemorrhage from, thyroid treatment of, 538; hemorrhage from, physiology and pathology of long standing inversion of, conservative operative treatment of, 505; cervix of lacerated and reflex irritation, 800; preliminary opening of, accouchment by hysterectomy, without, 623; procidentia of, in elderly women, radical cure of, 492; prolapse of, interposition operation for, 730; puerperal, inversion, and total prolapse of the, 356; retrodeviations of the, in the puerperium and in nulliparous women, 867; retrodisplacements of, treatment of, 231, 266; retroversion of, 220; rupture of, following cesarean section, 491.

V

Vaccination, against hay fever, 907; against typhoid fever, resolution endorsing, 130; and variola, 1044; antityphoid, 401; antityphoid, in children, 872; antityphoid in army during 1913, 905; efficiently performed, 579; contraindications to, 574; cowpox, 949; typhoid, failures in, 902; typhoid-paratyphoid, with mixed vaccines, 78.

Vaccine, a new antigonococcic, 258; anaphylaxis, 766; experimental, 583; gonorrheal, intravenous injections of, 633; therapy, some causes of failure of, 767; therapy, debate on, 443; therapy, status of, in acute suppurative infections, 958; treatment and cause of chronic rheumatism, 1076; typhoid, sugar output in diabetes, 18; and method of Milne, scarlatina treated by, 931; and serums, practical application of, 1006; bacterial, in scarlatina, 936; bacterial, standardizing, in hemocytometer chamber, 815; graduated by their opacity, 77; sensitized, 401.

Vagina, artificial, by intestinal transplantation, 220; congenital absence of, 591.

Vagotomy, 309.

Vagus, and internal jugular, operative injuries, 21; hypertonicity and hypotonicity of, 210; resection, fatality following, 60.

Validity, 435.

Varicosities and edema of the lower limb, new operation for, 79.

Variola and vaccination, 1044; cause of, 493.

Vasodilator, aconite as a, 1052.

Vaughan, V. C., the service of medicine to civilization, 1151.

Vein, anomalous renal, 251; internal jugular, and vagus, operative injuries, 21; varix of internal saphenous, 1167.

Veins, varicose, instrument and method for removing, 363.

Vena cava, accidental injury to, during nephrectomy, 220.

Venereal diseases, certain, ionic medication, in treatment of, 310.

Verruga in human subject directly traceable to phlebotomus verrucarum, 758.

Vertigo, gastric, treatment of, 404.

Vesalianum, mistaken for fracture of fifth metatarsal, 948.

Vesiculitis, internist and seminal, 662.

Vincent, W. G., [illegible] appendicitis in infancy [illegible] childhood, 9.

Visualization of upper intestinal tract by means of the *x*-ray in conjunction with duodenal tube, 224.

Vitality and metabolism, 289; from viewpoint of diet, 33.

Vitamines, clinical significance of the, 572.

Voice and manners in medical practice, 893.

Vomiting, fecal, in gastric crisis, 32; incoercible, of pregnancy, isoserum treatment of, 705.

Von Pirquet reaction, 1043.

Van Baggen, N. J. P., progress of education of deaf and dumb and difficulties of aural instruction, 921.

W

Wagner, C., the New York Laryngological Society, 1.

Wagner, J., report of cases of amebic dysentery treated with emetine, 190.

Walker, F. E., practical points in surgery, 656.

Wallace, R., neurosis, traumatic, due to alleged or actual injury from medicolegal standpoint, 382.

Warts, plantar, 862.

Wassermann reaction, and life insurance, 494; clinical value of, 527; methods of increasing the accuracy of, 536; provocative, 982; reaction value of, absorption methods in, 341.

Water, sterilization of, 578.

Webster, D., endophlebitis obliterans of central retinal vein with resulting acute glaucoma, 792.

Weiss, R., quantitative colorimetric analysis in aid of clinical diagnosis, 432.

Wells and waters, healing, 627.

Whitman, R., further observations on the operative treatment of paralytic talipes, calcaneus, and allied distortions, 47.

Whooping-cough, 675; blood in, 538; strange aspects of, 630.

Wiener, A., a preliminary report upon the specific action of ethyl hydrocuprein on pneumococcus infection of the external tissues of the eye, 114.

Wilcox, Dr., retirement of, resolution on, 731.

Wilcox, S. F., divulsion of the arm, 1085.

Wilensky, A. O., sprain fracture of the os calcis, 429.

Williams, E. H., the drug habit menace in the South, 247; the liquor question in medicine, 612.

Wire clamp, use of, in operations of goiter, 452.

Wise, Fred, lichen planus of glans penis, its treatment with Roentgen rays, 388.

Woldert, A., determination of the blood pressure as an aid to diagnosis and prognosis in certain diseases, 561.

Worcester, J. N., a method for plicating voluminous ceca, 1.

Wounds, gunshot, treatment of, 28; gunshot, under recent types of armament, 803; hose serum in treatment of, 690; stab, successful suture of, in right ventricle of heart, 219; suppurating, hot air douche in treatment of, 122.

Wright's solution, a substitute for antiseptic solutions, 1124.

X

*X*-rays, 761; and radium in cancer, 86; and radium in treatment of cancer, 998; changes in animal tissues caused by, 208; diagnosis by, in case of fractures, 914; diagnosis of pulmonary tuberculosis by, 767; diagnosis of surgical lesions of stomach and duodenum, 1144; evidence in early and latent cancer of stomach, 1051; examination in chronic intestinal stasis, 410; examination, serial, in gastric cancer, 401; in diagnosis of fracture of skull, 316; in diagnosis of gallstones, 903; in diagnosis of gallstones and cholecystitis, 861; on persistent suppuration, influence of, 1043; photographs and expert testimony, 343; therapy, technique, 133; therapy, technique in, deep therapy as practised at Freiburg by Krönig & Gauss, 335; treatment of hyperthyroidism, 1041; treatment of myoma, 892; treatment for tinea tonsurans, permanent alopecia following, 113; therapy of uterine fibroids, 132; use of, in examination of the digestive tract, 225; versus percussion in examination of heart, 960; visualization of upper intestinal tract by means of, in conjunction with duodenal tube, 224.

Y

Yaws and syphilis, unity of, 629.
